Industrialists in England and on the Continent Exhibit a Growing Interest in Methods Installed in the United States—The Purchase of More Efficient Machines and Equipment Has Not Brought the Expected Prosperity, and It Is Now Found That Management Is as Important as Processes

By WALLACE CLARK,[1] NEW YORK, N. Y.

THE scope of management engineering is no longer confined to the installation of so-called mechanisms of management or the technique of carrying on the routine of a business. It now covers all the psychological, physical, and economic conditions which affect a certain enterprise. It applies method to every phase of industry and nothing is left to the old haphazard way of getting into an unexpected situation and then moving heaven and earth to get out of it. The executive in these days is expected to foresee practically every change in conditions both inside his company and those outside which will affect it. Where possible he is expected to prevent an undesirable event from happening, or when he cannot do that, he must already have planned a course of action which will make the best of the changed conditions. It is obvious that the man who first sees his way out of a difficulty has a decided advantage over his competitor.

The management engineer has for a long time provided the executive with the technique for the routine management of production and distribution, and more recently he has provided budgets for the financial direction of the business. He cooperates with the statisticians in applying forecasts of general business conditions to a specific industry. He works with the economists in their attempt to secure a greater general prosperity and with the workers in their desire for greater security, better living conditions, and the chance to use and develop their creative energies.

The Application of Method

The application of method to his daily duties does not deprive either the worker or the executive of initiative. On the contrary, it frees more of his time for those parts of the work which require the use of his creative faculties rather than his memory.

If a workman has to do a certain task for the first time, there is no good reason why he should be allowed to flounder around and discover his own method when the same problem has been met and solved a thousand times by other men. It is obvious that the existing knowledge should be made available to him in the form of a method, and that he should use his mind in improving that method. If the situation is complicated, he must use his judgment in deciding which of the several methods will accomplish the best results under those particular circumstances. The application of method means the selection of the best from the many current ways of doing a thing, improving that, if possible, and then teaching it to all who have to do that thing. In this way the individual starts from the best-known method and employs his creative ability in developing a better way. He does not waste his time in discovering things which were discovered long ago.

The same is true of the executive, for the application of method to his work frees his mind for the use of keen analysis and good judgment in determining a course of action and of will power and resourcefulness in following that course.

One of the greatest services the management engineer can render is to make existing knowledge and method available, so that constructive minds will not need to go over ground which has already been covered; to simplify the routine so that it will require a minimum of time, and in other ways to free the creative energies of executives and workers.

The pioneering work of applying science to management has been done and the mechanisms or technique of management have been developed. Much will be done in future to improve this technique and extend its application to new fields, but the task of the management engineer now is to place this science of management at the disposal of every part of industry and then to concen-

[1] Wallace Clark & Company, Consulting Management Engineers. Mem. A.S.M.E. Mr. Clark was graduated from the University of Cincinnati in 1902, and then entered the employ of the Lodge & Shipley Machine Tool Co. In 1910 he was engaged by the Remington Typewriter Co. in New York City. When H. L. Gantt was retained by that company to install his methods of management, Mr. Clark was selected as an understudy and later as an executive to carry out the new system.

In 1917 he resigned from the Remington Company to join Gantt's staff and went to Washington, where he had charge of the latter's work of planning the utilization of ships controlled by the U. S. Shipping Board. In 1919 he started his own consulting practice, which he has since maintained.

During the next six years he investigated the operation of the U. S. Patent Office for Herbert Hoover, then Secretary of Commerce, and was a member of the commission which drew up the plan for the organization of the proposed Federal Department of Public Works. In 1926, as the engineer member of the Kemmerer Finance Commission which stabilized the currency of Poland, he recommended methods for the reorganization of the Polish salt and tobacco monopolies. In 1927, at the request of the Minister of Finance and a group of manufacturers in Poland, he reorganized some of that country's leading industries and since then has extended his services to Germany, France, Switzerland, Czechoslovakia, Rumania, England, and Denmark. He is the author of a number of books, among them being "The Gantt Chart," which has been translated into seven languages.

Contributed by the Management Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of The American Society of Mechanical Engineers.

trate his energies on developing the individuals and stimulating their creative brains.

Making These Methods Available Abroad

Should an American engineer make the methods developed here available to industry in foreign countries?

That is a question which is sometimes asked and more often suggested indirectly. Should America keep her prosperity to herself and not share it with the rest of the world? Should we too develop the intense and selfish nationalism which brought on the World War and is still a grave danger in Europe?

To the engineer or the scientist the answer seems obvious, for to him right methods of work and good conditions for workers have no nationality. Politics is outside his domain. If improved processes and methods, through some later political upheaval, are turned to the uses of war, it is because civilized brains and intelligent forecasting are not concentrated on removing the underlying causes or conditions which lead to the political upheavals or catastrophes. If the economics of nations were planned according to engineering principles, there would be friendly cooperation in place of fear and hatred.

America, as a matter of fact, has gone far in making her methods available to foreign countries. We began years ago to ship our machine tools and other labor-saving devices to Europe, and they have had a marked effect on increasing the productivity and wealth of those countries. We have exchanged our inventions for those originating abroad.

It seems to be generally agreed in Europe that our methods of management have been largely responsible for our recent period of prosperity, and our books and papers on management have been eagerly translated and published. Countless delegations and individuals have been sent to study our plants, and American executives have freely opened their doors and have given the visitors all the information they could take away with them.

Industrialists and engineers have apparently learned that no country can live entirely to itself, and that our prosperity is closely tied up with that of the rest of the world.

Maintaining Our Standard of Living

The present business depression has lasted so long that some in Europe are asking whether we can maintain our high standard of living, and even more frequently in the American press some one says that the standard of living of our workmen must be reduced.

To the engineer who has taken part in the growth of management, any loss of what men have gained through the development of industry is unthinkable.

If the workman is to go back to an outgrown stage in his progress, there will be no need for the inventor to bring forward his ideas for improvements aimed to make life easier and more satisfying. The scientist will have no incentive to carry on his experiments for the benefit of mankind, and the engineer will be out of a job.

It is not the American way to be satisfied with things as they are. It is not intelligent, with the advance we have made, to continue to suffer these periodic depressions. The task before America is to regain our prosperity and then to stabilize it.

We have an abundance of raw materials and foodstuffs, plenty of machines standing idle, and millions of men and women wanting work. There are many more millions who need the good food, better clothing, housing, and other things produced by those machines.

The money to buy the products of our machines must be placed in the hands of those who need to buy them. Some way must be found to direct a flow of money to consumers which will more nearly balance our ability to produce goods. When this problem is solved, we shall be able not only to maintain our standard of living, but to continually raise it.

Progress in Europe

The leaders in European industry generally recognize that a higher standard of living for their own people can be attained only through a better development of their own resources, increased productivity of labor, and better methods of management to eliminate waste and to coordinate the various parts of each business. Much progress has already been made in the application of American methods, as will be shown in the summaries from different countries. Some of the characteristics of European industry are these:

There is less mass production there than in America because of tariff walls, different habits of peoples, and lower purchasing power.

Turnover of investment is slower, due to less effective management.

There are not enough practical men among the executives, due to class distinctions.

The introduction of results of research into practice is slower.

More labor is wasted, because wages are low.

There is more respect for knowledge and authority than in America.

Workmen have greater security.

These characteristics of industrial conditions in Europe apply only partly to Great Britain and not at all to Russia, where the fundamental structure produces different shop and business conditions. I should also except the three Scandinavian countries, where the wages and standard of living compare fairly well with those in our country.

In the installation of management methods in Europe among the obstacles to be overcome are: the necessity of working through interpreters in several languages and differences of mentality and psychology, but these can be overcome by carefully planning the installation.

In the application of American methods the following points are noticed:

In Europe more time is required to secure delivery of purchased materials.

Rearrangement of old buildings is more frequently necessary.

Reserved-time scheduling is more needed than chain production.

Market research and sales organization have not made much progress.

Budgeting is well understood.

Methods of executive direction are as much in demand as in America.

There is now in Europe a more general understanding of the fact that conditions are changing and that methods must be flexible.

Management Helps the Worker

The introduction of the new management into European plants has almost invariably brought about better working conditions, higher wages, and steadier employment, just as it has in America. It is fortunate that there is on both continents a growing recognition of the worker. It is particularly easy to see this in some of the older countries where there are so many reminders of the early stages of the industrial era, when a worker's time, health, and even life itself were held so cheap. The long hours he worked, the miserable wages he received, the inhuman punishments he suffered for any infringement of the rules, and the conditions under which women and children were employed seem incredible today.

Characteristics of European Industry and Growing Interest in American Methods

THE growing interest of European industrialists in American methods of management is well known. For a long time they believed that the purchase of the most efficient machines and equipment would bring them American prosperity, but they have learned, as we did over here, that management is quite as important as machines and processes.

As a body of technicians The American Society of Mechanical Engineers may be interested in some of the characteristics of European industry noted in the author's daily work of installing management methods and how those methods are adapted to foreign conditions. During the last three and a half years in the plants and mines of nine European countries, his organization's clients have been engaged in the following industries: mines of salt, iron ore and coal, blast furnaces, foundries, forges, rolling mills for steel, brass and copper sheets and tubes, locomotives, railway cars, automobiles, airplane motors, agricultural and textile machinery, cellulose and mechanical pulp, paper, lumber, printing, lithographing, clocks, screw-machine products, chocolate, cotton, wool and linen textiles, municipal tramways, tobacco monopolies, and state industries.

Mass Production

The characteristic of European industry most frequently discussed is that there is less mass production than in America. One reason is that the countries are smaller and the tariff walls prevent the distribution of manufactured articles to a body of consumers large enough to justify mass production. Consumption is also limited by the marked differences in habits of the people in the various countries. A third reason is that wages are low, and therefore the purchasing power of the average family is not sufficient to enable it to buy many of the manufactured articles which in America are purchased in mass. Consumers, particularly in France and England, also demand greater individuality of design than we do.

Nevertheless there is a good deal of mass production in Europe accompanied by strict standardization of design and the use of automatic machines and of moving belts for assembly. Where production of this kind has been successful it has so simplified the management that other manufacturers have looked on it with envy and have frequently installed the equipment for chain production when the volume of sales did not justify it, and as a result the fixed investment became so great that interest and depreciation swallowed up all the profits. Manufacturers in this situation have often taken the course of dumping their products on the market without profit in order to keep their machines running.

However, in a majority of instances the adaptation of mass or chain production has been extremely profitable. Most of our clients, by standardizing design, reducing the number of styles, and rearranging production to match the tempo of moving belts, have increased output by 25 per cent or more, and have so greatly improved the quality of product and lowered its cost that they have built up domestic sales, and some have opened up foreign markets which were not known to exist.

Turnover of Investment

A slower turnover of investment is another characteristic of European plants. Raw materials are kept in stores much longer than necessary and work moves deliberately through the process of manufacture, which in turn makes it necessary to keep larger quantities of finished goods in stock. This slower time of production requires more investment in proportion to the volume of sales than in the United States.

This difference in tempo between the industries of the two continents has of course a decided influence on resulting profits. European executives are learning that it is more economical to turn over their capital quickly than to secure additional capital on which dividends or interest must be paid.

The American technic of production invariably brings about a swifter flow of material and ideas, and therefore a better turnover of investment. In a Polish plant, for example, where about 3000 workmen are employed, the new methods of management increased production 55 per cent with the same number of workers, very small investments in equipment, and with no changes in executives.

Practice and Theory

Another characteristic of Continental industry is the tendency of the managing staff toward abstract theory, and therefore one of the problems which faces the consultant in organizing a European plant is that of securing a good balance between practical and theoretical men. The executives from the superintendent up almost invariably have engineering degrees with good theoretical training behind them, but seldom any actual shop experience in operating machines or processes.

On the other hand, the good shop men are very seldom promoted to positions of responsibility in the management. A workman expects to live and die in the class in which he was born. There is almost no training of good workmen to become foremen, and no classes to fit foremen for higher responsibilities. Evening technical schools are rare and the same is true of correspondence schools. The workman does not expect promotion from the ranks, and does little to fit himself for it.

In organizing American shops we do not have much difficulty in securing an even number of technically trained men and those who have been brought up in the shop. By placing them side by side we develop a management which is more sure of itself and quicker to make decisions and take action. In Europe this is more difficult to accomplish because of class distinctions, but fortunately it is becoming easier each year as class lines are relaxed.

In a Polish spinning mill we found a need for more supervision over some of the difficult operations such as doubling and twisting. The superintendent said there was no one who could be assigned as supervisor. On being asked who knew most about this particular operation, he replied without any hesitation by naming one of the operators, but said that she would not do because she was just one of the peasant girls and no one would respect her and follow her orders. However, he consented to give this girl a chance, and a few weeks later told us that the other operators were all willingly obeying her instructions, and that the production of that battery of machines had so far improved in quality and quantity that they were no longer holding back other operations. He then asked us to do the same thing for succeeding operations.

Such promotions from the ranks are not as frequent as they should be, and the reason is not so much that executives oppose it as that it does not occur to any one that it can be done.

Practical Application of Knowledge

Due to the theoretical bias of the average European executive, it is easier to get a matter studied or investigated than it is to get the resulting knowledge introduced into daily practice. In the United States we are more apt at making practical use of what knowledge we acquire, and therefore the results from research are proportionately greater than in Europe, although they have carried on their investigations and experiments for many more years. This fact is realized by the forward-looking managers in Europe, and they are devoting more attention to seeing that the

results of research are "introduced into the life," as they express it.

In a French cotton mill we found girls in the packing department doing all the heavy lifting, while one of the plant engineers for some months had been designing equipment to avoid this fatigue. But the girls went on lifting, while the engineer, enjoying his problem, went on refining point after point of his design. When the engineer was instructed to install the equipment without the final touches, the production of that department increased 45 per cent. Then the executive began to set dates for the completion of all work done on his instructions, and incidentally the girls enjoyed higher wages with a great reduction of fatigue.

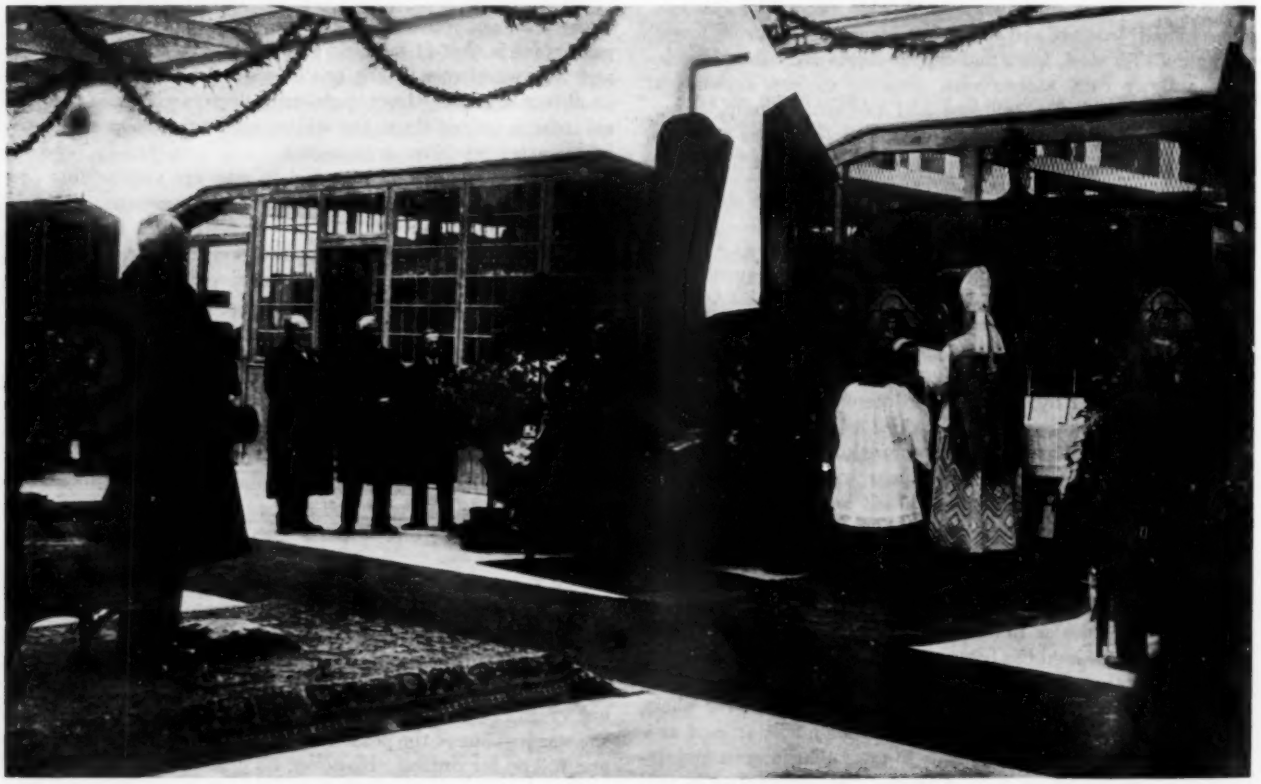
Waste of Labor

On the Continent there is extreme economy in the use of materials, which are expensive, and a prodigal waste of the time of workers because wages are low. This is the opposite of the practice in America and must be kept in mind by the consultant.

In a cellulose-pulp mill in Germany twelve men used to push railway cars from one point to another in the factory yard. Those cars are about one-third the size of American freight cars, but when filled with pulp wood they are quite heavy. One man and an electric truck, which was already in the plant but seldom used, were substituted, and eleven men were transferred to other work which was more important and required more skill. Similar examples could be cited without end.

Due to the lower level of wages it is obvious that many labor-saving devices which are economical in the United States will not pay for themselves in Europe within a reasonable time. This must be kept in mind in appraising the efficiency of a plant, and it is one of the reasons why the production per man is not so great as in America, where a workman has at his command more power-driven tools and transportation equipment.

However, the level of wages in Europe is rising, and we have in almost every case found managers willing to increase wages and to share with the workers the savings resulting from better management.



Respect for Knowledge

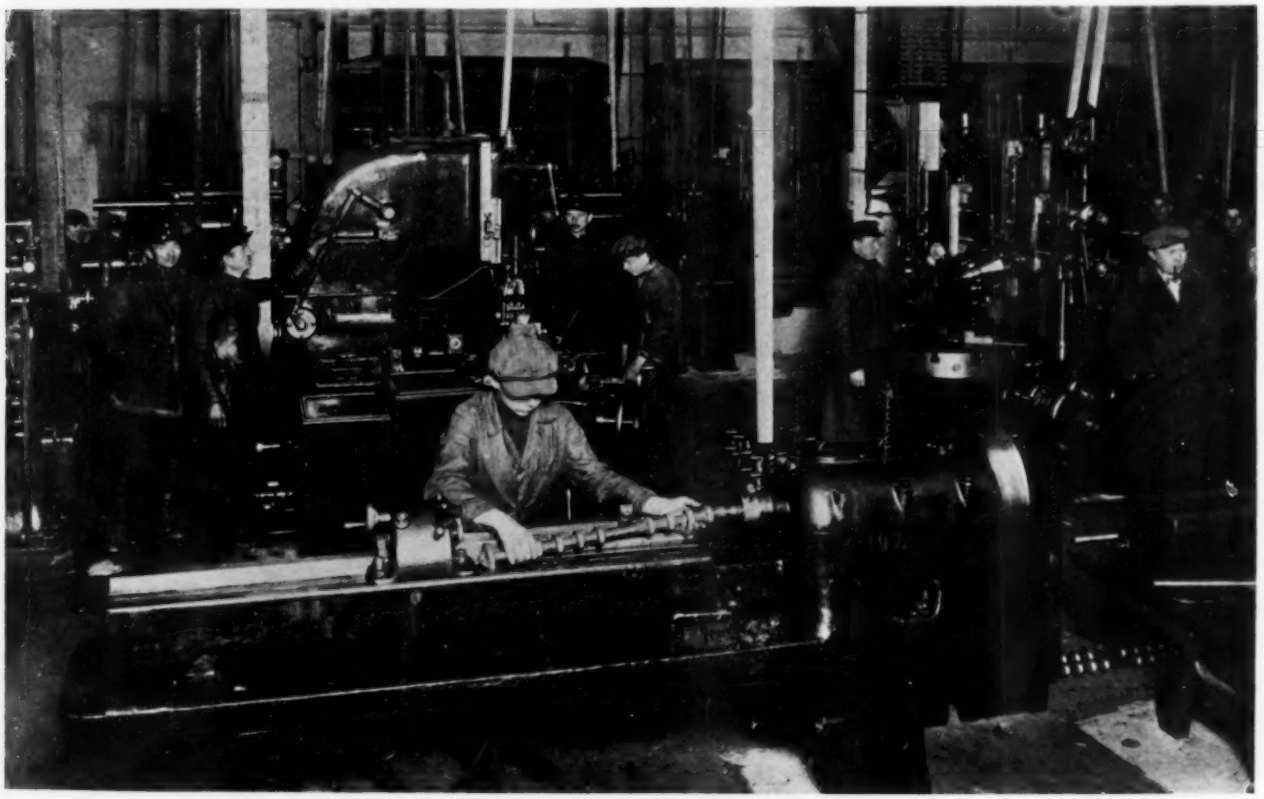
The respect for knowledge in Europe is probably greater than in America, where money and influence seem equally important. For this reason the work of the consultant is somewhat easier because he can usually be sure of a sympathetic consideration of his proposals.

Security for Workers

Europe provides for workmen greater security and continuity of employment than we do in America. A worker cannot be dismissed without notice ranging from two to four weeks, and consequently foremen do not depend on threats of discharge to maintain discipline.

In most of the countries workmen have old-age, sickness, and unemployment pensions administered by the governments. These things help to free the workman from worry about the maintenance and happiness of his family, and enable him to become more proficient in his trade. However, the dole both in Germany and Great Britain has serious disadvantages, and the difficulty of taking it out of politics seems almost insurmountable.

Blessing the New Machinery in a Polish Factory



Respect for Authority

European workers have more respect for authority than American, probably because of class lines. A worker will seldom disagree with his superior, and this often makes it difficult to get at the essential facts in regard to many conditions.

In parts of Germany and in countries east of it, whenever a

workman sees an important executive or visitor he takes off his hat, and the older men also bow from the waist. Etiquette requires the executive not merely to touch the brim of his hat, but to lift it.

In France and England this is not the custom, because workmen there are more independent and are not afraid to disagree with their superiors. In England the workmen are backed up by strong organizations, while in France, where workers' organizations are not so strong, the managers have found that their people do not work well in an atmosphere of repression. There is, therefore, more appearance of freedom, and in place of hat lifting and bowing one is more likely to hear a polite "good morning." A French workman may even disagree with his foreman, but he will express himself with the greatest politeness, and also with what we would consider a great many unnecessary words.

Modern Machinery in a Polish Plant

In all European countries there are, of course, plants in which the relations between the owners and the workers are extremely cordial, due to long years of wise and sympathetic consideration of the needs of the workers. As a rule, however, the bow of the workman and the hat lifting of the manager are not accompanied by any relaxation of the facial muscles. One longs for the smile and quick nod which flash through an American shop.

Great Britain and Russia

These characteristics of industrial conditions in Europe apply only partly to Great Britain and not at all to Russia. British shops are in many ways more similar to American than to Continental shops, as England was the cradle of modern industry and we have learned more from her than from other countries.

Russia is, of course, unlike other countries in its fundamental structure, and therefore shop conditions are quite different. For instance, class lines do not separate the workmen from the executives, because there is only one class. Very few managers and engineers have been left over from the old régime, so their places must be filled from the ranks of the workers. There is therefore a determined effort to train exceptional workers for the responsibilities of management, and to provide them with the best available methods. In no European country is there so much eagerness to learn American management methods as in Russia.

The development of managers and of technical engineers appears to be the key to the success of the much-discussed Five-Year Plan. It is a tremendous task to transform an agricultural into an industrial country within such a short time, but the difficulty of changing peasants into machine operators and skilled workmen is nothing compared to that of developing within such a few years a group of men capable of managing and providing the technical knowledge necessary for industry on so large a scale.

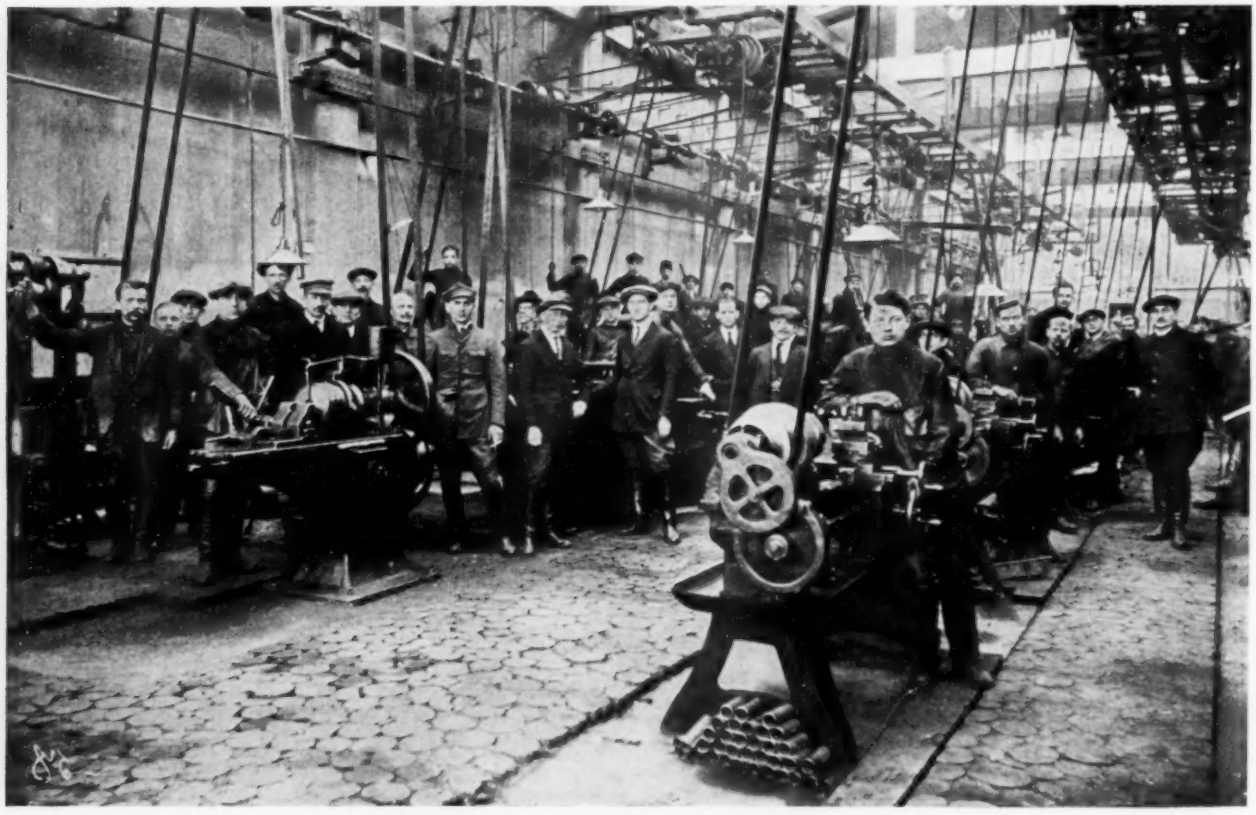
The developing of Russian managers is more difficult than usual due to the absence of rewards as a stimulus to improvement. A manager gets a salary which is frequently not more than 50 per cent in excess of the wages of a skilled workman. This does not enable him to provide for his family a home which will free his mind and energies for his responsible work.

In the early part of this year the heads of the Soviet Government realized that the workers' organizations were interfering too much with the authority of the managers, and they therefore passed new laws giving the managers more authority and at the same time providing prison terms or exile to Siberia for those managers who do not carry out their programs successfully. To an American mind the substitution of the fear motive for the desire for reward and self-improvement cannot develop the best managers. The most satisfactory results from scientific manage-

ment have been secured where the direction of industry is the most democratic.

Technic of Installation

There are certain obstacles to be overcome in the installation of American methods of management in foreign countries. One of the first to be met by one who does not speak the continental languages is the necessity of working through interpreters. Obviously it requires a little more time to repeat every speech, but, on the other hand, translating has a tendency to make a conversation more precise and to the point. While a paragraph is being interpreted one has a chance to think through the next point to be made.



It is of course necessary in our work for an interpreter to understand thoroughly the various phases of management and the special terminology in both languages. Frequently he has to stop and give a long explanation of a word. For instance, there does not seem to be in French a single word which translates "planning," and he must say: "the preparation, distribution, and routing of work."

In each country it is necessary to study the mentality or psychology of the workmen and executives in order to understand them better, and to know in what particular way any subject should be presented in order to create interest.

We have found that the best results are accomplished when the installation is made by a combination of native and American engineers, one being most proficient in the technique of management and the other knowing the national psychology and habits, as well as the developments in the past which have led up to present conditions. In each of the countries in which we operate, the staff is therefore made up in this way, and the native engineer usually spends twice as many weeks in a plant as the American.

Our consulting work consists mainly of the installation of management methods, that is, adapting methods to a particular situation and staying with it long enough to accomplish practical results. In some cases we analyze the condition of an existing company and recommend a plan for the future conduct of the business. In other cases, after our installation is finished, we supervise the maintenance of the methods and the progress made in the execution of the more important business policies which we have recommended. This service is applied to groups of plants as well as to single companies.

It may be sufficient to outline our technic of installation rather than that of analysis.[2] We handle several clients at a time, spending one week with A, a second with B, a third with C, then returning to A. We have found that an installation is more thorough and therefore followed by better results when we do not split a week between two clients, but devote the entire five days to a single plant.

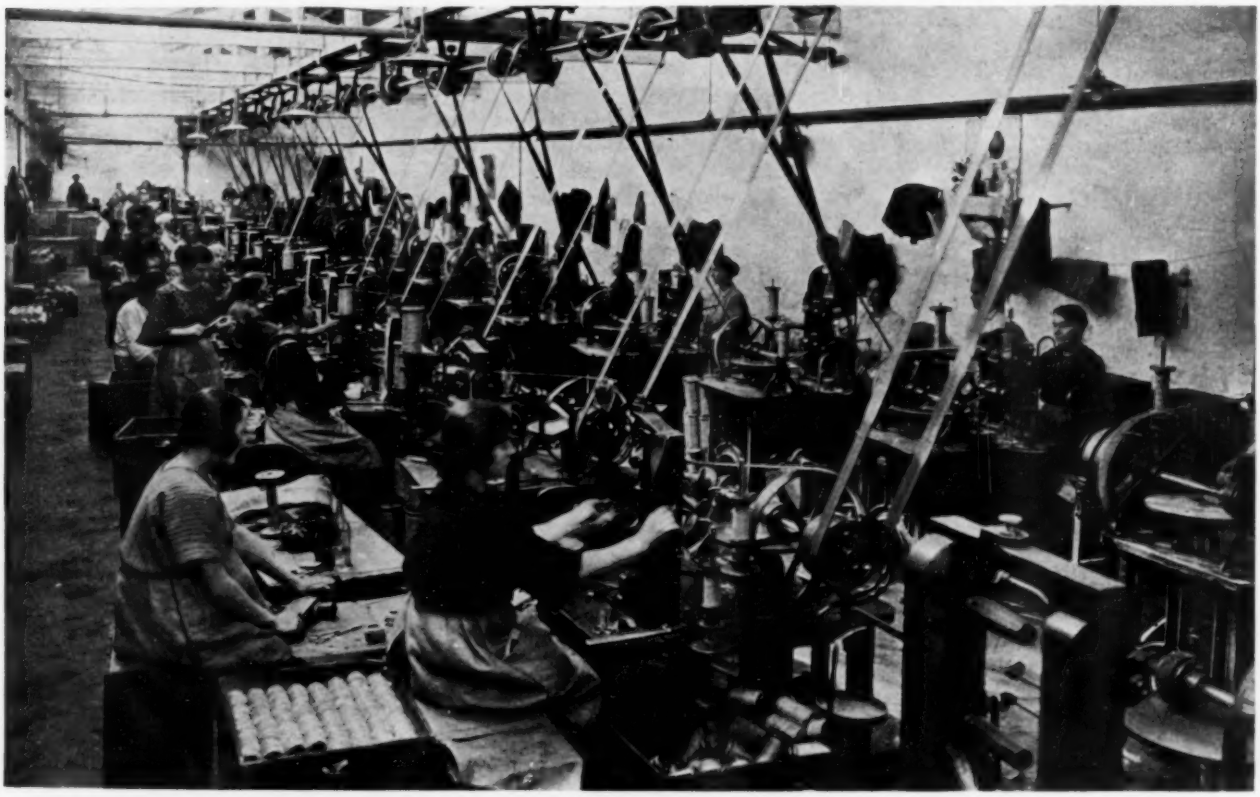
Group of Workmen in a Polish Factory

We work on the assumption that the increase in production, improvement in quality or service, and reductions in cost which are realized during the term of our engagement are less important than those which should follow after we leave. It is therefore necessary for the managing staff to understand these new methods and their principles, and how to get them accepted and used by the entire personnel. One of the most important duties of the consultant is to train some of the members of the clients' staff so that they can continue progress after his engagement is ended.

[2] A more complete description of methods is given in the author's paper entitled "The Technic of Installation of Scientific Management," presented before the International Management Congress in Rome, 1927.

When we begin our visits a client assigns to us for training one or more men from his staff, relieving them of all other duties so that they can spend their entire time on the new work. These understudies watch every step and soon are able to carry forward many things themselves. We ourselves do not do any repetitive or detail work which can be done by the employees of our clients.

During a typical week's visit to a plant we first go over with our understudy the things they have been doing since our last visit, explaining any points which have not been clear and improving the operation of the method. We then develop the next phase of the installation and begin its actual use. Several things are kept going at the same time, each one being looked after by a different understudy—for example, the installation of planning, storeskeeping, operation studies, costkeeping, and the physical arrangement of the shop. On Thursday a report is dictated outlining as clearly as possible what has been done during the week, attaching copies of all instructions, designs of forms, prints of floor plans, etc., and concluding with the statement of what we recommend to be done before our next visit. This report is presented in two languages, and on Friday afternoon is discussed in detail at a conference of the chief executive of the plant and those members of his staff who are concerned with the execution of the recommendations.



These reports therefore become records of progress or lack of progress, and are extremely useful in securing cooperation and the quick introduction of methods.

After we have spent a short time at a plant and understand the conditions and the personnel, we schedule our own work of installation on a Gantt chart, sometimes a year in advance, showing the various phases of the installation and the weeks we shall be at the plant. For each department in the plant there is a schedule on which a date is set for the beginning and completion of each phase of the installation. As the weeks pass, heavy lines are drawn on the chart to indicate the progress compared with the plan.

Each of the client's understudies has a chart showing the details for which he is responsible. Throughout the installation the time element is emphasized, because one of our major aims is to accelerate the tempo of the entire business, and the promptness with which the executives and staff make decisions and execute instructions determines the tempo of the plant.

Differences in Application of Method

In Europe, as in America, every plant is different, and in installing the so-called mechanisms of management it is quite impossible to impose any rigid set of methods; it is obvious that they must be carefully adapted to the individual business and also to the mentality of the workers and the executive staff.

Women Workers in Poland

We have found, however, that in general the mechanisms, such as planning, storeskeeping, salesmen's quotas, and so on, which were first developed in America, apply equally well to conditions on the Continent. Their application is apparently universal, and the changes which need to be made to fit local conditions are not fundamental.

Storeskeeping

In installing Gantt storeskeeping methods, for example, we find that the use of standard bins and boxes, the physical marking of order points, and the routine of ordering, receiving, and issuing materials is practically the same as in the States. There is, to be sure, a greater tendency to require signed receipts for items of small value, but this is not difficult to overcome. In Europe the tendency to save material is sometimes carried too far, for there is too much delay in selling scrap and in disposing of obsolete items which have little chance of ever being used.

The difference is most noticeable in determining "order points" and "quantities to order," which of course depend upon the time required to secure a new supply. Some countries are not self-contained industrially and therefore many items must be imported from other countries, and the delays in going through the customs considerably lengthen the average time of delivery. Even in the more highly industrialized countries the service from suppliers is not nearly so prompt as in the United States. Filling and shipping an order the day it is received is almost unheard of. In those countries in which cartels have eliminated competition, the service is noticeably poorer.

All these things cause the storeskeeping and purchasing departments to allow long periods for deliveries of materials—usually far longer than is necessary even under such conditions. It is necessary to get a purchasing department to adopt a more exacting and aggressive attitude in dealing with their suppliers, but even when the storeskeeping and purchasing departments have done all they can, it is not possible in the average European manufacturing plant to do as large a volume of business on as low an inventory of materials and supplies as it is in America, due to the longer time of delivery.

Plant Layout

There is little difference in the application of the principles of plant layout in Europe, for managers are just as anxious for straight-line production as in the States. Because there are so many old industries, the problem of rearranging the equipment and machines in old buildings is more frequently met than at home. In one plant we had to change the layout of machines in a building which was about 130 years old, and a direct flow of material was secured without breaking down any of the walls.

Planning and Scheduling

Since there is less mass production in Europe, there are fewer shops in which the rate of movement is set by an assembly belt. The need in most cases is for reserved-time scheduling, that is, the type of planning which reserves the time on all machines so that when material is issued from the storesroom it will move at a steady rate through the shop. Wherever installed this type of planning has brought large increases in the volume of production, ranging from 12 to 40 per cent.

Some of the delays in planning are surprising. When a new cupola was to be installed in a foundry we had to reschedule the work to allow a day for the building of an improvised altar on the molding floor, and another day for the priest to bless the new equipment so that it would be safe for use.

Costkeeping

In costkeeping no important alterations in methods are necessary to meet European conditions. We have found that the modern cost methods are more readily accepted than in America because executives are more willing to adopt a method as a whole without wishing to alter details. One client, the director of a municipal tramway company, said that he expected us to provide methods adapted to the peculiar conditions of his plant, and that the members of his staff would give us all the information which we needed, but would not attempt to mix their old methods with the new.

Methods of costing provide the most effective means of improving conditions. In a Polish pulp mill it had been the custom for years to send six men down into a digester to tramp the chips before cooking. At the end of their tramping these men would come up out of the digester on a rope ladder, stripped to the waist, dripping with perspiration, covered with sawdust, and breathing through handkerchiefs which were almost useless in protecting them from the dust in which they worked.

Without any reference to the welfare of the workers, a brief comparison of the cost of time lost in this way with the small gains of tramping quickly brought about the installation of a revolving spreader for the chips which made it unnecessary for any men to go down into the digester.

In the same mill, after the cellulose had been discharged from the digesters, workmen had to go down into the pits and shovel the mass into a chute. Their wooden shoes did not prevent them from getting wet to the knees and the fumes of SO_2 were so strong that they had to come up for air about every ten minutes.

The traditional attitude in such a case is that men are cheap and there are plenty of them. But in order to reduce costs a suction device was installed, and the men no longer had to work under those unhealthy conditions.

Many examples could be cited to show how American methods break through the European attitude toward cheap labor and improve conditions for the workers.

Improvement of Operations

In the study and improvement of processes and operations there is a great deal of inertia to be overcome. Usually the first reaction to a proposed change is that it is impossible, and the second that it is not worth while, because the time saved would be wasted some other way. However, as soon as the interest of the managers is aroused they become eager to make these studies with their own men, and after some training in the technique these men succeed in bringing about marked improvements.

The men chosen for this work sometimes have technical training, and in other cases are workmen who have developed exceptional skill. They are so close to the workers that they are able to stimulate creative ideas in the workers' minds, and as a result, the latter take much more interest and pride in undertaking and mastering new things.

Incentive Payments

The idea of incentive payments is not new in Europe, and in the majority of plants in the author's experience, piece rates are in common practice. The rates have not usually been set with sufficient care, nor has there been any attempt to determine the best method of doing the operation; therefore the rates are not successful in securing uniformly high production.

In applying a bonus system there are no unusual difficulties, except that simplicity is even more imperative than in the States because workmen are not so well educated. In Russia, where the equality of workmen is emphasized, piece rates in several shops were said to be a recent development.

Sales and Distribution

In spite of the wide acceptance of American methods of production, Europe has not yet awakened to the importance of distribution. The need for market analyses is even greater than in America, because there are more pronounced differences in the customs and buying habits of the people in the various sections of European countries.

In Russia there is no problem of selling because there is almost no private trading, but distribution is extremely difficult through such an immense territory.

Budgeting—Executive Control

Within the last few years Europe has taken a keen interest in the matter of financial budgeting. This was shown by the remarkably successful Budgetary Conference held in Geneva in July of this year under the auspices of the International Management Institute.

Even in plants where expenditures are closely watched, as they usually are on the Continent, it has been surprising to see how ex-

penses have been reduced by careful planning and the fixing of responsibility which the budgets have brought about. Accountants have welcomed them because they do so much to clarify the relations between them and the executives.

Recent developments in methods of executive direction have attracted the attention of forward-looking executives in Europe, who are eager to learn the most dependable technique of securing cooperation and of directing instead of following the progress of a business.

It is obvious that one of the principal duties of a chief executive is to prepare his company to meet whatever happens in the future, and this directs his attention to forecasting conditions in general business as well as in the specific business in which he is engaged. But European statistics needed to form a basis for forecasts are far from complete. The various governments keep records of imports, exports, bank clearings, and other matters which pass through their hands, and they publish figures which are usually prompt and accurate. Some Chambers of Commerce also provide valuable data, but the information about specific branches of industry, which in this country is secured through trade associations or the Department of Commerce, is rather meager. For this reason planning for the future of a specific business is more difficult in Europe.

One client owning plants in three countries and distributing his products in six countries, prepared forecasts for all those countries, and in spite of the incompleteness of the data he was able to secure fairly reliable forecasts of changes in business conditions.

Results

In order to illustrate the results obtained, other than in increased production or in savings, by a typical installation, part of an address delivered before the Engineers' Association of Warsaw by Mr. J. Zaporksi, Technical Director of Lilpop, Rau & Loewenstein, a company with 3000 workmen which builds railway passenger and freight cars, is given below. Mr. Zaporski says:[3]

One of the features of the new method as a whole and in detail is a considerable clearness and a simplification of work in all its phases. The installation was begun from the last phase of manufacture, the erecting shop, and this has brought about its penetration to all our needs which actually derive from that shop and are dictated by it.

The benefits obtained are general. The production has been entirely mastered, while the normal management duties connected with this production have been mechanized, that is, brought to quite determined forms and phases which put clearly defined responsibilities on the shoulders of each of the executives, and, in case of divergences from the normal flow, allow the fixing of responsibility for each of them.

By this mechanization of every-day duties, the initiative of managers and subordinates has in no way been limited; on the contrary, executives have today more time to study the improvement of production, since most of their every-day troubles have been taken off their shoulders and placed on those of less important men by means of planning.

A proper and accurately defined division of responsibilities between members of the management and employees and a strict control of the timely execution of the duties of each of them obliges them to bring to attention all difficulties which they meet in their work, which causes an automatic improvement of the whole organization.

In closing I wish to express some of the general impressions on the work done.

The entire personnel of our plant has become deeply interested in the new organization. It has penetrated into every part of the factory life, leaving everywhere its mark. Naturally there were some difficulties which, however, were easily overcome and we can say that the better a man understood the spirit of the methods and the more deeply he penetrated into those ideas, the more eager he became to follow them and the better results he obtained.

The organization breaks no one's individuality and harms no one; on the contrary, it develops personal efficiency, representing his progress in units which are easy to measure. Clear-cut duties and responsibilities allow each member of the organization, irrespective of the work he performs, to show his own accomplishment.

All unnecessary ballast, which appeared to be useful but in reality obscured the clearness of things, was removed. A sound foundation of management was created, that is, a plan thoroughly thought out and made in advance for all work. The principles of fair play are apparent everywhere; work is made easier, conditions of work are improved, and earnings are increased.

Progress of Management in Europe

In every large European country there is a national organization for the advancement of the science of management. These groups have received financial support from their respective governments, which have been anxious to obtain the advantages of good management in their struggle for export markets. The work of collecting information and broadcasting it to technicians, managers, and the public at large, as well as the translation of books and papers on management subjects, has been done by these national groups.

The International Management Institute in Geneva has shouldered the difficult task of coordinating the work of these national organizations and stimulating the free interchange of information among them and the American groups.

Four international management congresses have been held in Europe, presided over by such statesmen as Mazaryk, Mussolini, and Tardieu, and attended by thousands of delegates who have gone back to their homes in every industrial country with an added realization of the importance of management.[4]

At the present time there is in Europe a more general understanding of the fact that conditions are changing. Industrialists are realizing that the acceleration of change which has taken place since the Great War cannot be expected to slow down. They are therefore reorganizing their businesses, not only to fit changed conditions but to anticipate further changes. They are seeking more flexible methods, more effective planning for the future, running comparisons of what actually happens with those plans, and are training executives to see the tendencies thus revealed and take the action necessary to get the best results from those changes.

Technological Unemployment

In Europe more consideration is being given to technological unemployment than here at home. Labor is less mobile there because it is more attached to the land, and also because jobs are more difficult to find and therefore losing one's position is much more serious than here.

In many cases the head of a business gives his personal attention to providing positions for the workers who are displaced by labor-saving machines or processes. He does this in a variety of ways: by passing a part of the savings due to the new machine on to consumers in the form of lower prices in order to increase the volume of sales; by improving quality; by extending the service to consumers; by more intensive advertising; by taking on additional lines of manufacture, and sometimes by building entirely new plants to absorb the workers released by the introduction of new equipment or methods.

In those countries where there is a good deal of unemployment due to economic conditions, the introduction of better methods is particularly difficult, but it must go on because the high costs of production and ineffective sales methods have been largely responsible for the gradual decrease of business and the consequent increase of unemployment.

Management Helps the Worker

The introduction of the new management into European plants has almost invariably brought about better working conditions,

[3] See Appendix No. 4.

[4] In order to give a more complete picture of the progress of management in Europe, brief reports from leading industrialists in nine countries, summarizing what has taken place there and pointing out present tendencies, follow as appendixes to the paper.

higher wages, and steadier employment, just as it has in America. It is fortunate that there is on both continents a growing recognition of the worker. It is particularly easy to see this in some of the older countries where there are so many reminders of the early stages of the industrial era, when a worker's time, health, and even life itself were held so cheap. The long hours he worked, his miserable wages, the inhuman punishments he suffered for any infringement of the rules, and the conditions under which women and children were employed, seem incredible today.

The general welfare and prosperity of a nation appear to go hand in hand with the better appreciation of the worker. A realization of his importance as a consumer has done much to bring him better wages and a higher standard of living, which in turn has helped general prosperity. His influence as a shareholder is also beginning to be felt, and in many plants on both continents he has a good deal to say about management policies.

In Russia the satisfaction of the worker is regarded as one of the prime objects of industry. This year, when asked by the Soviet Institute of Management Technic to develop and install management methods in an entire branch of industry, the author was requested to keep the following objects in mind:

To provide safe and healthy conditions for the worker;

To remove from his path the obstacle which prevented him from doing good work;

To enable the worker to understand his part in industry and to have maximum freedom for self-expression.

This is of course a statement of aims and these conditions have not yet been introduced into industry; however, when her plans have been carried further, it seems quite possible that Russia may make a major contribution to the welfare of mankind by developing the worker and improving his position in industry, and, even though we may not agree with her political dogmas, the Western world should not hesitate to learn as much as it can from this gigantic experiment.

One of the greatest services the management engineer can render is to make existing knowledge and method available so that constructive minds will not need to go over ground which has already been covered: to simplify the routine so that it will require a minimum of time, and in other ways to free the creative energies of executives and workers.

The pioneering work of applying science to management has been done, and the mechanisms or technic of management have been developed. Much will be done in the future to improve this technique and extend its application to new fields, but the task of the management engineer now is to place this science of management at the disposal of every part of industry and then to concentrate his energies on developing the individuals and stimulating their creative brains.

Conclusion

When we read the reports of disarmament conferences, hear the threats and counter threats of government spokesmen, and watch the frantic building of tariff walls, the picture is discouraging.

The workman on the frame of a fifty-story skyscraper knows that his safety depends on his ability to focus his eyes and concentrate his mind on the steel beam immediately before him. It is the same with the engineer—he does not allow himself to be distracted by other things or to worry about the complexity of the maze about him. He takes one thing at a time and organizes that to the best of his ability, and then goes on to the next, building carefully, even if the extent of his work seems small.

The engineer is busy with his plans and charts, his records and forecasts, but nevertheless he is sensitive to what is going on around him and the changes which management is bringing about. He sees it provide machines to take the burdens from man's back, allowing him to use his mind rather than his animal strength, and to free himself from poverty. He sees industry teaching men to understand more clearly their aims and to cooperate in reaching those objectives; fair play becoming a daily habit rather than a text for a sermon; the authority of leadership going to those who are capable of leading without regard to class lines.

The engineer sees executives imparting to others the knowledge which they formerly kept entirely to themselves, and whole groups of industries overcoming their suspicions and exchanging information for mutual benefit. He sees commercial agreements being made which disregard boundaries and forget the fears and hatreds of the past. He hears the shouting of warriors and idealists exhorting people to follow them to freedom and happiness, but as he goes on with his work, he watches the machine age and the new management breaking down barriers, healing old wounds, wiping out poverty, and giving men more freedom to develop themselves and to prepare the next generation to lift higher the torch of progress.

Appendix No. 1—Management in the U.S.S.R.

By WALTER N. POLAKOV[6]

TODAY scores of leading American engineering firms, from General Electric to MacDonald Engineering Co, from Du Pont de Nemours to General Motors, are doing construction and equipment-installation work in the Union of Soviet Socialist Republics in the usual manner. The installation of management-engineering methods presents, however, many unusual peculiarities due to local specific conditions, the most important of which are:

1 The entire national industry is run strictly according to the plan prepared by the State Planning Commission for a 5-year period; everything from the production of fuel and steel ingots to fishing and fur trapping is so preplanned.

2 Industry throughout being run not for profit but for utility, its aim is to make goods in the quantities required and of qualities and at costs prescribed by the plan.

3 Industry is owned and managed by the workers themselves, and very inadequately directed by managerial staffs of limited experience.

4 Every department of every plant or factory is operated under a strict budgetary plan, as if an independent enterprise, with a foreman as the sole responsible head.

For these four main reasons, the former enthusiasm for "Taylorism" in planning and functional foremanship brought no results, because while satisfying condition 1, it was appallingly inoperative under condition 3, and not well adapted to condition 4.

For years, as well as at present, every industrial establishment was required to have an efficiency department (Rationalization Bureau) whose duty was and is to devise means for increasing production and reducing costs. Since mechanical ability is more readily found than managerial talent, most of the work was limited to the development of jigs, simplified operations, and the like in mechanical devices, all record keeping and organization problems being neglected.

[6] Consulting Management Engineer, Walter N. Polakov & Co. Inc., Moscow, U.S.S.R. Mem. A.S.M.E.

The recent popular fervor to accomplish the 5-year plan in four years disclosed most convincingly the managerial shortcomings, proving the old truth that good organization avails far more than perfect equipment, and that sound management yields more than large plants.

Under these conditions, especially in view of the dire shortage of managerial ability, it was inevitable that the principles of management as laid out by Gantt, including his charting mechanism, should become indispensable for the proper running of that great national industrial machine of the U.S.S.R.

Layout charts meet the need of condition 1, idleness charts help materially to satisfy condition 2, and progress charts and man-record charts assist greatly to live up to the task imposed by condition 3.

Budgetary departmental and plant control is adequately guided by the Clark's executive control charts, which offer even to inexperienced foremen and other executives a ready guide by means of which they may cope with budget and production programs.

Inasmuch as standards once adopted in the U.S.S.R. become industrial laws enforced by the state, the managerial methods and mechanisms which produce results also become laws.

Appendix No. 2—Scientific Management in Holland

By C. H. VAN DER LEEUW[6]

NEW methods in management and all questions touching the subject of efficiency are on the whole received with an open-minded interest in Holland. Several firms of consulting engineers are putting their services at the disposal not only of manufacturers, but also of organizations of public utilities and the like.

The Netherlands Institute for Efficiency, together with the Netherlands Institute for "Documentatie en Registratur," are holding yearly congresses at which different ways of improving efficiency, possibilities of rationalization, methods of planning, of budgetary control, etc., are treated in several short papers and in the discussions which ensue.

Contrary to practice in the United States, manufacturers are apparently reluctant to publish anything regarding steps taken in the new direction, so that many most efficient systems are being put into effect which never come to the attention of the public at large.

Another thing found frequently in Holland is the tendency of manufacturers to solve their own problems without calling on outside help. In fact, many would rather attain 80 or 90 per cent efficiency with their own staff than 100 per cent efficiency with outside specialists. A certain amount of secretiveness also keeps many people from calling on outside help.

Some of these tendencies are sound enough, provided they do not result in necessary improvements being left undone.

There is a trait in their character which makes the Dutch want things to be shipshape and run in the proper way without much talking about it; while this certainly opens the door to modern methods, it nevertheless renders communications as to results obtained rather scarce.

The relation between employer and employee is on the whole one of mutual understanding, making possible the cooperation of all in introducing new methods—a cooperation essential to attain ultimate success. The difficulty experienced here as elsewhere is in the following-up procedure after the system has been installed.

Appendix No. 3—Swiss Societies Devoted to Scientific Management

By ALOYS HENTSCH[7]

THE Commission de Normalisation de la Société Suisse des Constructeurs de Machines was created in 1918, and in the following year became the Association Suisse de Normalisation. The Bureau de Normalisation du V.S.M., which acts as a central office of this association, has achieved notable results in different fields, both from a national point of view and by contact with foreign organizations which deal with standardization, and it has published, among others, standardization tables which are current in Swiss industries.

The SFUSA (Schweizer Freunde des U. S. A.) organized in November, 1925, and February, 1926, a series of lectures on rationalization. Following these lectures, a commission was set up, the Kommission für Rationelles Wirtschaften (K.R.W.), designed to further measures helpful to rationalization in Switzerland. This commission organized a series of national and international lectures, whose success was noteworthy. It also installed a library and a lecture hall, and a number of pamphlets relative to rationalization were published under its auspices. Its efforts to create an "Association Suisse de Rationalisation" resulted in setting up a group of this kind, whose future is still uncertain.

The Union Centrale des Associations Patronales Suisses, at Zurich, after a conference in the Federal Polytechnic School with Mr. H. S. Dennison in 1927, inaugurated groups for research and information, now three in number. Group 1 is composed of seven large non-competitive businesses employing at the beginning 35,000 workmen and clerks. Group 2 is made up of twelve medium-sized metallurgical and engineering businesses, and Group 3 comprises nine medium-sized textile enterprises, the two together employing 9000 workmen and clerks.

The Société Suisse des Constructeurs de Machines established two groups for research and exchange of information which are at present attached to the Institute for the Rational Organization of Industrial Exploitation, established at the Federal Polytechnic School and dealing, under the first group, with seven manufacturing businesses of various kinds employing 100 to 150 workmen each, and under the second group with six metallurgical and engineering businesses, each employing from 500 to 1200 clerks and workmen.

In January, 1928, the Commission Romande de Rationalisation was founded in Latin Switzerland. Its principal aims are:

1 Coordination of all efforts relative to scientific management in Latin Switzerland.

2 Contact with similar institutions in national or international fields with a view to exchanging information and to concentration of research.

3 Study and dissemination of methods giving the maximum of efficiency in production and distribution.

4 Anti-waste campaigns, whether of raw material, machinery, or man power.

5 Study of "human factor" problems concerning work, hygiene, safety, insurances, industrial relations, etc.

6 Propaganda for rationalization: the principal aims being the lowering of costs and sales prices, and the increase of output, production, consumption, and profits.

7 Office for documentation and information relative to scientific management.

8 Study of specialized technical problems directly concerned with scientific management.

[7] Director of the Commission Romande de Rationalisation, Geneva, Switzerland.

Divers sections were planned (industry, agriculture, arts and crafts, commerce, private administrations, banks, and public establishments). One of these, the Industry Section, got to work at once and instituted a group for research and exchange of information, which now comprises twenty businesses employing a total of more than 9000 workmen and clerks.

The principal questions thus far studied are:

Wage payment	Rationalization of buying
Lighting	Heating
Guides for foremen	Insurance
Industrial accounting	Filing
Preparation of work	

Other organizations are collaborating in the spread of rationalization in Switzerland. First of all, the Institut pour l'Organisation Rationnelle des Exploitations Industrielles (Institute for Rational Organization of Industrial Exploitation), founded at the Polytechnic School, got in close touch with industry, commerce, and government, and devoted itself more particularly to the collecting of Swiss and foreign papers relative to the science of organization; collaborating in the exchange of various kinds of information between different bodies; undertaking certain researches corresponding to the needs of the economic life in Switzerland, instituting lectures and conferences on the science of organization; and issuing various publications.

Finally, certain organizations of a commercial character, as well as a number of independent experts, have also participated effectively in the organization and reorganization of businesses.

The J. J. Rousseau Institute at Geneva has given part of its time to the study of the psycho-physiology of work; similarly; l'ASORT has devoted itself to vocational guidance. The Fondation Suisse pour la Psychotechnique, established in Zurich, (Swiss Institute for Psychotechnic) has opened a number of institutions of psychotechnic to which employers (in industry or public service) frequently apply. In this field, other organizations, among them the Association Suisse pour l'Orientation Professionnelle et la Protection des Apprentis (Swiss Association for Professional Guidance and Protection of Apprentices), have attained noteworthy results by different methods.

As regards teaching, lectures devoted to the methods of scientific management and allied problems are given in the technical schools and certain universities.

In business, the organization of groups similar to the retail research associations is being considered; centralized purchasing already exists, as does also chain-stores distribution. The professional associations could serve in certain cases as groups for the exchange of information.

The Swiss Office for Commercial Development, with branches in Zurich and Lausanne, affords to business men, and more particularly to importers and exporters, much valuable help.

Finally, the public utilities, the CFF (Federal Railways), PTT (Post, Telegraph, and Telephones), etc., are applying more and more scientific management in their respective fields of action.

Studies have also been made by different bodies on questions of national welfare, especially in the field of apprenticeship, insurance, crafts accounting, building, commerce, and banking. Professional associations as well as employers' associations or syndicates are also studying questions relative to scientific management.

Exhibitions, some held occasionally such as the Schweizerische Austellung für Frauenarbeit (Swiss Women's Exhibition), others periodically such as the Foire d'Echantillons de Bale ou le Comptoir Suisse de Lausanne (Sample Fair at Bale or the Swiss Counter at Lausanne) make some contribution to the study of certain problems. Finally, efforts are being made to insure a certain amount of coordination in the clock industry, and in banking. In industry, individual endeavors proceed as circumstances offer, and within the limits possible under the particular economics suitable to Switzerland, which is a small country without raw materials, but with skilled labor, which has to devote its whole attention to exportation. Banks have also perfected their individual methods of work.

In Switzerland, rationalization has advanced more on the technical side than on the side of sales. Industrial agreements have as yet no very large place in the scheme of things (cf. Federal clock industry), but the research groups would seem to have a bright future before them.

Appendix No. 4—Results of Reorganization of Plants in Warsaw, Poland

By J. ZAPORSKI[8]

PRODUCTION in the plants of Lilpop, Rau & Loewenstein has, during recent years, been limited almost exclusively to the erection of various types of railway cars. The entire production has been concentrated on Bema Street, in the suburbs of Warsaw.

In May, 1920, a contract was made with the Ministry of Railways for the supply of rolling stock to the Polish State Railways, and the gradual rebuilding of the factory for that purpose was begun. In 1922 the first post-war freight cars were made, and in 1923 the first new passenger cars. Primarily the real work of the factory was the repairing of cars—in fact, their complete reconstruction. However, all endeavors of the management of the plant were now directed toward the building of new cars, and finally in 1928 the factory discontinued accepting cars for repair, as it was becoming more and more difficult to combine repairs with the constantly increasing number of new cars erected.

In the meantime a number of subsidiary shops were installed. It would be difficult to find more troublesome work than that of the erection of railway passenger cars. There are many different craftsmen needed in building a passenger car—blacksmiths, tinsmiths, boilermakers, hydraulic workers, glassmen, electricians, carpenters, furniture makers, upholsterers, painters, varnishers—while the number of operations in the erection of a car amounts to over 700, and there is an immense number of different parts. It is obvious that the organization of such a complicated task is not easy.

In 1928, in order to bring this production under the control of scientific management, which is the only rational method nowadays, the company sought the assistance of Mr. Wallace Clark, an American engineer well known for the exceedingly good results he had obtained in such work. Mr. Clark, together with Mr. A. Kucharzewski, started work in June of the same year.

Planning Work Ahead

The initial attack was made on the final phase of manufacture in the erecting shop. The first step was to show each foreman in this department the necessity for planning work ahead for the following day and for checking later to learn whether the work thus planned was actually completed. From that moment the foremen began to acquaint themselves with the graphical planning of work on Gantt charts. It was naturally difficult for a foreman, having his men scattered in small groups in several cars, to keep well informed as to every detail of the realization of the plan, especially since his main duty had always been to see that the work was well and promptly done. Therefore the preparation of the daily graphic schedules was delegated to planning clerks who were chosen from the shop inspectors. Of course the planned

[8] Technical Director, Lilpop, Rau & Loewenstein, Warsaw.

progress of work depended first of all on whether materials and tools were available for the operations in sequence, which the foremen were obliged to investigate beforehand.

The technique of making these plans was mastered fairly easily, and the foremen with the planning clerks began to teach the men to follow the plans, seeing at the same time that materials and tools were available when needed.

At the same time it became evident that much time was being lost by the workmen in getting the necessary materials and tools from the storesroom, and as a consequence this task was immediately delegated to unskilled workmen, while the duty of making out stores issues and other clerical work was delegated to planning clerks, so that the foremen could give all their time to their proper duties, such as supervision of the quality and prompt execution of work by the workmen, spending only an hour in the afternoon with the planning clerks on the preparation of the plan for the following day.

Due to the fact that the work in car erection had been divided into large units of time, covering groups of cars and ranging from 100 to 900 hours in duration, the preparation of daily plans at first met with difficulties, as these long units were not suitable for planning work day by day. The erection was therefore subdivided into smaller elements not exceeding 8 hours each. The succession of separate operations was revised and the operations were arranged so that they should not interfere with one another through an excessive number of men working on one car at the same time.

A study of the daily plans of the various foremen revealed differences in the sequence of separate erecting operations, and therefore a standard schedule was developed for the entire erection with the object of harmonizing the daily plans of separate erecting groups, such as carpenters, blacksmiths, painters, upholsterers, etc., so that one group should not interfere with the others.

The aim of this central planning in the erecting shop was to collect accurate data on the time needed for the separate elements of the erection and to prepare a general schedule of erection. The order of work made on that basis gave automatically the date of completion of the erection of each car. This further made it possible to simplify the making up of daily orders of work. The general plan of work gave also a true picture of how much time and how many men are needed for a complete erection of a car.

With such a schedule, it is possible for the head of a department to follow the progress of work with the greatest accuracy, and to learn the causes of delays and to eliminate or greatly reduce them by making rational alterations in the daily orders of work. The Central Planning Office, coordinating the progress of the general plan with the daily orders, could also determine proper dates of delivery of parts from other departments and the storesroom, which would result in a more even loading of other departments and a considerable decrease of stocks as they ceased to be overloaded with products which would remain for weeks on shelves without being used.

Endeavors to adhere more and more strictly to erection schedules showed that a large number of operations could be simplified. An Improvements Section was therefore created for studying all erecting operations with the view of simplifying them. Its procedure consists in accurately describing the existing method of work, and later in making recommendations as to simplification of separate processes, showing the savings in time which can be secured.

Improvements of Operations

It would seem that the erection of cars exclusively by hand by skilled workmen would be the best way to do it, and that a non-specialist would not be likely to improve upon that method. Yet, in reality, quite the opposite is true, and each study gives positive results, the whole giving very large savings. In order to illustrate the value of studies and improvements the writer will cite an example. The erection of the floor of a car took 188 working hours as per the schedule of the Technical Bureau. After a study was made and the existing method described, the latter was changed, and as a consequence the floor is now being erected in the erecting shops in 18 hours, while the increase in work in other departments due to the change amounts to only 51 hours, which means a total of 69 hours as compared with the previous 188 hours.

The complete erecting time of the Westinghouse brake has been decreased from 148 working hours to 71, and as a result a second-class passenger car is now being erected in less than 90 days as compared with about 180 days formerly, while a third-class car is erected in 60 days instead of about 130. It should be noted that the premiums earned by workmen have considerably increased in spite of the fact that labor costs per car have greatly decreased, this being due to eliminating the time wasted on unnecessary or insufficiently studied operations.

Working Conditions

Apart from the improvement of operations, general conditions in which the work is carried on such as floors, methods of handling materials, light, heating, ventilation, and sanitary equipment have a great influence on the decrease of cost of production.

It is a mistake to think that it is possible to produce cheaply under unsatisfactory conditions. Good working conditions are much more important for a man than for a machine. Our advisers have given much care and attention to the improvement of working conditions in the shops and of interdepartment and shop transport.

A layout or floor plan of each shop was made providing good, smooth roads for transport, places for storing materials before and after machining, lockers for workmen's clothes, toilets, etc. As a consequence a larger output per workman has been secured due to better conditions and easier supervision and a large reduction in the cost of transport, while the number of workmen engaged in transport has decreased from over 80 to about 30, and the investments made in materials-handling equipment have already largely paid for themselves.

Costkeeping

One of the most efficient and accurate tools for controlling the activities of superintendents of the various producing departments is a rational method of costkeeping. The method generally used does not provide sufficiently accurate figures for a comparison of estimated costs with the actual costs, due to the fact that it does not take into account the degree of utilization of the capacity of the shop.

The modern method applied in our plants introduces a so-called "idleness" account to which is charged a certain part of shop expenses which should not be charged to production account, due to non-usage of the full producing capacity of the plant. When this account is introduced, the actual costs correspond to the estimated or budgeted costs provided the budget was prepared correctly and the management directed the execution of a given order in a sufficiently efficient way. In case of disagreement, an investigation is made to determine which of the two is at fault and who is responsible for the state of things. One of the advantages of this method of costkeeping is that it affords the possibility of having a statement of costs completed three to four days after the finishing of an order. This enables the management to intervene promptly in case an increase of costs is noticed, and is exceedingly valuable for the management.

The above method requires considerable preparatory work, and therefore our advisers have from the very beginning of their work divided all costs chargeable to ownership and maintenance of grounds and buildings among the separate departments. Each department has then been charged with costs of supervision, lighting, heating, etc., on the basis of the square meters of floor space occupied. The cost of each square meter of floor space has been further charged to the area occupied by a car or by a machine or working place, according to the character of the shop. By adding to these costs the expenses of owning and maintaining a machine or a group of machines, we obtain the shop expenses to be charged to separate machines or working places during the year. This amount divided into the number of working hours in the year gives the cost of a machine-hour or the rate for a working place. The product is then charged with these costs multiplied by the number of hours of work of a machine or working place in the erecting shop. In the case of our plant this is for one car. The difference between the former method and the present one is that the product was previously charged with shop expenses in proportion to labor costs, which is the usual method in most plants. If we analyze the former method carefully we see that it is far from being right, as shop expenses do not depend on labor costs but only on the above-mentioned facts. The evident results of the new method of cost keeping are:

Results of New Method of Costkeeping

1 They make precalculation easy and accurate, as the accountant uses figures of materials, labor, and machines and work places already decided upon.

2 When an order is completed, comparison of actual figures with those of the budget is easy, no unforeseen increases of shop expenses being possible if the work is done in the time and under the conditions stipulated.

3 It is now possible for the management of the plant to secure the true cost of each order irrespective of the load on the shop, which is extremely important from the point of view of control of preliminary calculation, and from the point of view of the balance sheet of each separate order and the activity of the shop superintendents.

4 In quoting prices to buyers the method is exceedingly valuable with the present keen competition, as it shows to what extent prices can be decreased in an effort to diminish the losses due to idleness of the plant.

The technique of keeping the new costs up to date requires that the costs incurred each day by a given order be communicated to the Cost Department as soon as possible, that is, within 48 hours. In connection with this the workmen's earnings are calculated each day on production cards and sent the following day to the Payroll Department, whence they go one day later to the Cost Department. Production cards provide a very strict control of production and of the presence of workmen in the shop.

Storeskeeping

The reorganization of stores consisted first of all in the physical arrangement of materials, that is, in the application of a method of storage which gives a most economical use of the available space and easy service to the stores and shops.

With that object in view a rack consisting of 6 or 8 divisions was designed, each of which was provided according to the size of material with 2, 4, 8, or 16 exchangeable bins, this insuring a very easy handling of these bins. At the same time the bins used by the shops were standardized to make it possible to exchange an empty stores bin for a full bin brought from the shop. Due to the installation of this system the erection of a new stores building was found unnecessary.

Much attention has been paid to the decrease of the investment in stock, at the same time keeping in stock all materials needed to insure a normal flow of work through the plant. Strict adherence to the principle of maximum and minimum resulted in a decrease of the value of stocks by 5 per cent and an increase of production of 27 per cent. A continuous method of control of stocks has also been applied which enables all errors to be discovered every two or three months and not after a year has elapsed, as is usually the case.

The handling of the paper control of the stores has also been considerably improved by eliminating all those operations which have only had the appearance of a control of stocks, and in fact have only made the matter more complicated; a clear and accurate control has thus been obtained with a decrease in the personnel.

Conclusion

In the foregoing the writer has endeavored to present the salient features of the newly installed method of management without going into such details as forms, blanks, charts, etc., which would take too much time and, for that matter, are peculiar to our special work. However, it should be stated that one of the features of the new method as a whole and in detail is its clearness and the simplification of work in all its phases which it effects. As mentioned at the beginning, the installation was begun at the final phase of manufacture, the erecting shop, and from there it has penetrated into all our activities which actually derive from that shop and are dictated by it. The benefits obtained are general. Production has been entirely mastered, and the normal management duties connected therewith have been mechanized, that is, brought to forms and phases which put clearly defined responsibilities on the shoulders of each of the executives, and, in case of divergences from the normal flow, allow the fixing of responsibility for each of them.

The initiative of managers or subordinates has in no way been limited by this mechanization of every-day duties; on the contrary, executives have today more time to study the improvement of production, since most of their every-day troubles have been taken off their shoulders and placed on those of subordinates by means of planning.

A proper and accurately defined division of responsibilities between the members of the management and employees and a strict control of the timely execution of the duties of each of them serves to bring to light all difficulties which they meet in their work, the result being an automatic improvement of the whole organization.

The entire personnel of our plant has become deeply interested in the new organization. It has penetrated into every part of the factory life, leaving everywhere its mark. Naturally there were some difficulties at first, but these were easily overcome and it can be said that the better a man understood the spirit of the methods the more eager he became to follow them and the better results he obtained.

The organization destroys no one's individuality and harms no one; on the contrary, it develops personal efficiency, recording its progress in units which are easy to measure. Clear-cut duties and responsibilities allow each member of the organization, irrespective of the work he performs, to manifest his accomplishments.

All unnecessary procedure, which appeared to be useful but which in reality obscured the clearness of things, was removed. A sound foundation of management was created, that is, a plan which was thoroughly thought out and made in advance for all work. The principles of fair play are apparent everywhere; work is made easier, conditions of work are improved, and earnings increased.

Appendix No. 5—Application of Modern Management Methods in France

By SERGE HERANGER[9]

FRANCE has not been behindhand among European countries, especially during the last decade, as regards the application of modern methods of industrial organization, although the progress that is being made is perhaps not as rapid as might have been expected, considering that France was one of the foremost countries in Europe to interest itself keenly in scientific management at the time when Taylor and Gantt were proceeding with their pioneer work in the United States.

This is due, therefore, not to a lack of interest in modern methods of management, but rather is a consequence of the mentality of the French. France is an old country with old traditions, and the French executive is apt to be overprudent and cautious with regard to new ideas and new methods, and hesitates to invest his money in reorganizing his plant. This is a psychological problem that the American engineer must carefully bear in mind when he is consulted by French executives. Another important factor is that the current opinion in France couples American industrial organization exclusively with mass production, and a question put very often is whether modern American methods can be applied to the small-series or irregular production work more frequently done in France.

In spite of this, there has undoubtedly been a steady progress in the application of new management methods to French industries. The phase of management which has been more particularly developed is that relating to plant production, and there are now many plants that have a more or less elaborately organized planning and scheduling department, modern storekeeping and cost systems, etc.

Office organization has also been well developed. On the other hand, practically nothing has been accomplished with regard to the application of sales organization, distributing, marketing, mergers, etc., although these questions have raised a great deal of interest and there is every probability that in the next few years and independently of the much greater development of plant organization these problems will also be taken up progressively in view of their application to French industry. The great incentive which will insure this and which is always present in the minds of French executives is the unequaled industrial development of the United States.

Appendix No. 6—Scientific Management in Great Britain

By B. SEEBOHM ROWNTREE[10]

THE war and its post-war consequences at one and the same time increased the need for more scientific management in Great Britain and made the attainment of this object more difficult. Britain is more dependent than any other nation upon foreign trade. During the war Britain was compelled to give up a large part of its overseas trade, partly because of the necessity for concentrating upon munition production for itself and its allies, and partly because of the submarine menace. Other nations which had continued to buy from Britain largely as a matter of routine either found other sources of supply or learned to produce for themselves, and at the end of the war they proceeded to protect their new industries by tariffs. For these and other reasons it became imperative that Britain should reduce its costs of production, and in particular, its labor costs.

At the same time, circumstances made this more than usually difficult. In the first place, there had been under the voluntary system the loss of the best part of a generation which should have been contributing enterprise and new ideas to industry. Then industry had to bear the heavy financial burdens left by the war. Moreover, these burdens were seriously increased by the pursuit of a social policy designed to improve the living conditions of the general mass of the people. Thus, either in direct contributions or in increased taxation industry had to contribute toward the cost of unemployment insurance, pensions, improved housing, and so on. At the same time capital was dear and enterprise was compelled to offer attractive terms in order to induce investors to put capital into industry rather than into gilt-edged stocks. On top of all this British producers had not only to face the handicap of falling world prices, but the special handicaps arising from the return to the gold standard in Britain itself.

Meantime wage rates had risen very greatly, and for some years have stood at from 70 to 75 per cent above prewar rates, while in the two years succeeding the war average weekly hours of work in British industry fell by some 10 per cent. While therefore there was obviously the most insistent need for more scientific management in every direction, and particularly in the reduction of labor costs, conditions made it difficult to carry through the necessary changes to the same extent and with the same rapidity as in certain other countries.

It is impossible to state the achievements in any statistical form because the necessary statistics do not exist. There has undoubtedly been a notable increase in the use of payment by results in the engineering and kindred trades. The official view expressed by the Balfour Committee some two years ago was that in the exporting group of industries, those paid by results were not far short in number of those paid by time. These, however, are the industries in which trade unionism is more highly developed, and the probability is that payment by results is much more extensive in the less highly organized industries, and it would not be surprising to find that in British industry as a whole there are now more workers paid by results in one form or another than those paid purely by time.

In certain directions considerable progress has been made in the application of psychology to industrial problems, and in the study of the physiological effects upon workers of methods of work, useful work having been done in these two directions by the National Institute of Industrial Psychology and the Industrial Fatigue Research Board. A good deal of this work is still at a pioneer stage, and many employers have yet to be convinced of its value, but there are prospects of its yielding results of outstanding importance in the sphere of industrial efficiency if it is judiciously pursued, and in particular, if it carries along with it the consent and cooperation of the worker.

In this connection it may be said that great efforts have been made in the post-war period to secure a greater measure of real cooperation between employers and employed. Probably more progress has been made in this direction in Great Britain than in any other. Not only have individual employers gone a long way in the direction of taking their employees into their confidence and in giving them a share in the prosperity of the business in one form or another, but the great organized bodies of employers and employed have been meeting in council on this subject over a considerable period and have achieved some considerable measure of agreement. This is typified by the work of the Melchett-Turner Committee, a joint committee of the National Confederation of Employers Associations and the Trade Union Congress, which incidentally has unanimously recommended the setting up of a National Industrial Council.

[9] Hotchkiss & Company, Paris.
[10] Chairman, The Rowntree Cocoa Works, York, England.

As regards industrial processes, there has been some development along the lines of mass production typified by the motor-car industry, and some considerable progress has been made in standardization and in simplification, particularly under the inspiration of the British Engineering Standards Association, but progress along these lines has probably been less than in some other countries, and certainly less than in the United States. This is no doubt due to some extent to conservatism and to Britain's post-war difficulties, but it is also justified to some considerable extent by the fact that Britain manufactures for such widely diverse markets that standardization can only be carried up to a certain point. The situation is quite different from that of the United States with its great homogeneous home market. As regards equipment, there has of course been a great development in the direction of the use of automatic machinery, but here again this has been limited by the facts just mentioned. In particular the use of automatic machinery is limited by the extent to which the product can be standardized. As regards power, there has been a very substantial increase in horsepower, the figures for 1924 showing an increase of 58.9 per cent over those for the last Census of Production in 1912.

With regard to the application of scientific management in individual factories, the situation is very "spotty." A number of plants can be found in Great Britain which have made an intensive study and an energetic application of scientific methods over a long period. These are comparable with undertakings of equal size in any part of the world, and are well distributed among different industries. On the other hand, there are a large number of small, backward factories which from the management standpoint are still medieval. While there has been notable progress in the last decade, the country has lacked the leadership provided in the U. S. A. by the report on "Waste in Industry" and subsequent work by the Department of Commerce and by private institutions. Consciousness of management as a separate issue, distinct from the technical evidence of this, is to be found in the inadequate volume and character of the management literature. The rapid growth of management research groups, modeled on the Manufacturers Research Association, of Boston, indicates, however, a growing appreciation of the need for scientific study in this field.

Appendix No. 7—Scientific Management in Italy

By DR. FRANCESCO MAURO[11]

THE difficulties special to Italy, among them lack of the most important raw materials, high taxation, and the restricted purchasing power of the internal market, have combined to compel Italian industry to push to the furthest the spirit of enterprise and initiative.

Without considerable ingenuity and keenness to work it would have been impossible to live, even less to develop.

For this all-important reason Italian industry has quite naturally been only too ready to set about studying new methods of scientific management and business administration.

Thanks to the drive and propaganda work of the E.N.I.O.S., the national institute of which the writer has had the honor to be president since its foundation, an even greater development is taking place in the attitude of mind which must exist before scientific management can be applied with good results.

It is necessary to keep in mind several factors which indicate that the problems to be solved in Italy are quite special and sometimes of great interest owing to their original characteristics. Among these factors the writer will limit himself to mentioning:

1 The large population, and therefore the plentiful supply of labor, which means that much account has to be taken of the unemployment problem, technological and otherwise.

2 The relative scarcity of capital, which necessitates making the utmost possible use of existing equipment and the careful study of any change to avoid unproductive expenses.

3 The comparatively small size of many businesses and the fact that they are distributed throughout the country makes it advisable to proceed with caution in order to avoid the social and economic difficulties which would follow a too extensive and hasty relocation of industries.

Changes are now in process and, in spite of inevitable obstacles, are giving satisfactory results which encourage considerable hope that further and deeper changes will be forthcoming.

[11] President of the International Committee of Scientific Management, Rome, Italy.

Appendix No. 8—Scientific Management in Czechoslovakian Industry

By ING. DR. EMANUEL SLECHTA[12]

THE principles of modern works management were known in Czechoslovakian industry in prewar times. However, industry was only induced to study it carefully and to use its methods after the war, because of many reasons which influenced the growth of manufacturing costs. In the first place, Czechoslovakian industry lost a great part of its original home market in former Austria, and had to start exporting more than half of its production (in some cases even not less than 75 per cent). This brought it into competition with foreign countries, for instance with German industry. Furthermore, the effects of tax burdens and debts to the banks dating from the times of inflation should be noted, and finally also post-war social legislation, which because of the dues which must be paid for accident, social, and pension insurances requires up to 12 per cent of the amount of wages paid. Sales conditions have made it impossible for our industry in general to think of mass production. There are of course some exceptions, such as the shoe factory of Messrs. T. & A. Bata, at Zlin, where 120,000 pairs of shoes are now manufactured a day. Management has made an effort to decrease manufacturing cost in all its items—material, wages, and overhead charges—this, of course, without large investments, since the greater part of Czechoslovakian industry is composed of small and medium-sized concerns. (According to the statistics of 1926, the average industrial concern employed 16.5 workmen; there are, however, several works in Czechoslovakia each employing over 20,000 workmen.)

Since in Czechoslovakia, as also elsewhere in Europe, materials used in manufacturing are considered of greater importance than are wages, works managements have given especial attention to economy in the use of matter and of energy, and particularly to heat economy—witness the excellent results obtained by Skoda Works and the Vitkovice Iron Works. Materials are also economically utilized in all Czechoslovakian works, not only as regards raw materials, but also waste products. It may be said that, especially in the regions far distant from the coal-mining districts, heat economy will be striven for still more, since coal represents a large item in manufacturing costs.

As regards the part which wages play in manufacturing costs, it may be said that the modernization of our works was first manifested in the installation of new automatic (labor-saving) machines, used either directly for manufacturing purposes or for transporting and auxiliary work. The war prevented many works

[12] Consulting Engineer, Prague, Czechoslovakia.

from renewing their machinery plant, but after that old machines were replaced by new ones, this being made possible by special exemption. Coal mines, machine shops, chemical works, etc., could be mentioned here in which the percentage of machine work is constantly increasing as compared to hand work. At present this is true of the larger concerns only, but it will soon extend also to small- and medium-sized works, as may be seen from the interest which they are taking in small materials-handling equipment.

The laws in force limit to some extent the use of certain systems of wage payment, so that thus far there has been little or no application of time and motion study in most of the Czechoslovakian factories. However, some of the large concerns have of late given these matters attention, and as a result are getting ready to introduce in their works either the Halsey, Emerson, or Bedaux system of wage payment. This, however, is exceptional, and in the majority of cases day wages based on time and piecework fixed by experience are being paid.

Preparation and planning of work according to the principles of modern engineering practice has been brought to a high degree of excellence only in several of the leading concerns, especially in the engineering line (precision and mass production) and in the chemical and textile industries, which latter up to the present have employed the principles of modern management to the greatest extent. Future development will be in the direction of establishing planning departments, as may be seen, for instance, from the interest—especially of the medium-sized concerns—taken in papers presented on the subject.

Control of the works on the part of the management is effected in the majority of cases by periodical statistical reports. Only a few leading factories have introduced the modern graphical control system, and these only because of the pressure of the economic crisis.

It is evident from what has been said that the lack of preparatory and planning work is responsible for a lack of documentary data for use in calculations. It is apparent that the calculation of costs and prices is another question which is receiving much attention.

As for the Czechoslovakian factories, it is necessary to bear in mind that while there are of course very modern concerns complying with all requirements of work, in the majority of cases old works are involved, and therefore also old buildings, which only after the war were slowly adapted to the changed conditions. For this reason it is difficult in the old works to adjust the working conditions to the modern requirements of manufacture, i.e., arrangement of the machines and plant in the workshops, departments, etc., so that this circumstance should be taken into consideration.

A greater advance may be seen in the organization and management of office work and offices.

On the whole, one cannot speak of an intensive use of modern principles of management in the Czechoslovakian industries, the few large and medium-sized concerns in which they are employed being exceptions. However, the era of more scientific management will start with the arrival of the younger generation of engineers in the field of works management.

Appendix No. 9—Scientific Management in Poland

By CZESLAW KLARNER[13]

WHAT methods have you used to increase the productivity of those enterprises which you are leading?

One of my first aims has been to introduce methods of scientific management. In this I have had as a goal the bringing of waste under control and the putting of the particular business dealt with on a basis of right management. In this respect I am seconding the work of American engineers in Poland, helping our industries to make use of their knowledge and experience.

Are there any conditions which you find prerequisite for the introduction of up-to-date methods of management?

For the work of such experts it is absolutely essential that the men at the wheel of these enterprises understand the principles of the new management and are willing to introduce them into daily practice.

What is being done to help bring about conditions favorable for the introduction of better management?

The Institute of Scientific Management in Warsaw, headed by Mr. P. Drzewiecki and Prof. K. Adamiecki, has done a great deal in this direction, and as a result the necessity for scientific management is now more and more penetrating into the minds of leaders of our commercial and industrial enterprises.

Could you quote a specific instance where scientific management has been successfully applied in Poland?

In a company of which I am president and in another of which I am vice-president, together employing about 7000 workers, the introduction of scientific management has effected great savings and at the same time has given higher wages to the workmen. Organization of this kind requires a larger number of brain workers than formerly in order to deliver the task to the workman in a prepared and well-digested form, so that he will not lose time in overcoming difficulties which prevent his progressing with the job.

Do you find any differentiation necessary in Poland in applying these methods?

We must remember that under Polish conditions it is not possible to copy blindly American examples, because the costs of money and of labor in Poland differ entirely from those costs in America. We Poles must use good judgment in applying those methods, especially in costly labor-saving investments.

What do you think of the possibility of improving the management of state-owned enterprises and increasing in this way the budgetary income of the Polish Republic?

When private enterprise has accepted on a large scale the right kind of organization, the state will also become interested, and will apply the same methods to its enterprises. The principles of scientific management are well adapted to certain kinds of enterprises conducted by the state, such as cigarette factories, coal and salt mines, etc.

Appendix No. 10—New Management Methods in Germany

By DR.-ING. OTTO KIENZLE[14]

BOTH in the metal industry and in other industries in the last 10 years have scientific management methods been extensively introduced.

Much attention is being given to the new accounting systems which provide means for figuring gain and loss by setting up monthly balances. In these the overhead expenses are apportioned systematically and methods are presented for figuring costs with respect to the special conditions obtaining in a given factory. Much attention is also being given to the percentage of full running time of the different shops, and this has led to a differentiation between fixed costs—similar, though not equal, to

[13] President of the Association of Chambers of Commerce and Industry of Poland. Interviewed by Stanislas Lubienski.

[14] Koch & Kienzle, Berlin.

idle costs—and costs varying with the output. In quite a number of places where these methods have been installed the second step in budgeting has been taken.

In connection with this, methods of calculation and time studies should be mentioned. A committee (Reichsausschuss für Arbeitszeitermittlung, abbreviation "Refa") has collected and published in extensive handbooks rules and data for operating times in the metal and wood industries, foundries, etc. Accordingly, we use the so-called "Refa Methods" and have Refa engineers using these methods.

Technically in machine shops the method consists in providing for each part carefully prepared drawings with tolerances, operating plans, and control plans. As to the shops, the machine tools of recent design show great progress; in particular, cutting speeds have been greatly increased. Whenever it has been possible to adopt mass production, a great deal of special machinery has been designed and installed; e.g., the multi-spindle drill press is as well known in Germany as in America. One of the most important differences between a shop of today and one of 10 years ago has been brought about by the introduction of line work and means of transportation. Many important simplifications have been accomplished, and costs have been greatly lowered by the standardization of materials, tools, machines, and machinery equipment which has found its way down to the smallest shops and has consequently promoted specialization of production to a great extent. Internationally, in Europe a number of practical results have already been attained by means of standardization.

Continuously increasing attention is now being paid to the human element. Theoretical methods have been replaced by practical ones. Improvements in the equipment of shops, and especially of working places, have done much to facilitate work and to alleviate the working conditions, and the writings of our leading specialists in management are dealing more and more with these problems.

Discussion

G. S. Griffith.[15] During a three-month inspection of European factories made in the summer of 1929, the writer noted the following:

1 There is a general tendency toward the use of American methods and machinery in their factories. Some of the factories have about 40 per cent of our machinery, but they have found that this alone does not bring our prosperity. The gradual adoption of the American methods of management is bringing the desired results.

2 Some of the plants are using our progressive assembly methods with very good results. This method was employed in the Renault factory in France. However, the difficulty in employing this method of manufacture in Europe is due to the smaller markets for their products caused by the number of countries and the various tariff walls.

3 The worker's position in Europe in general is more secure than in the United States. The foreman is compelled to give from two to four weeks' notice to the employee before the latter can be laid off. He does not have to keep threatening the worker with the idea of being laid off as is done in the United States in order to hold the employee's respect for the employer. The workman has more respect for his employer principally because of the class distinctions which are so prevalent in Europe.

4 The layouts of the plants are being changed to permit the better arrangement of the machinery in order to increase production. The machines are placed in groups or run by individual motors, which does away with the overhead drives. Lighting conditions are being improved, and more thought is given to sanitation and better working conditions for the employees.

5 Storerooms are being centrally located and American methods of stockkeeping are being adopted, which has greatly helped in the matters of inventory and stockkeeping. It is necessary for the European concerns to keep larger inventories because many of the countries are not self-contained, and in order to get parts, some of which come from other countries, a longer time is required than in this country.

6 The wages of European workers are small compared to those of the American worker, but the former do not seem to require more money due to the standards of living not being the same. What the American calls an absolute necessity the average European worker would call a luxury. Do not think, however, that the writer means if their wages were higher that their standard of living would not be higher. The industries over there are placing many of their workers on the incentive-payment plan, which has increased the production.

7 The apprentice system is still in vogue in Europe, although it is dying out in our country. There are three classes of apprentices: the "regular," who applies to learn a trade but does not pay for the privilege; the "premium," whose parents pay to have him learn a trade; and the "pupil," whose parents pay in order to have him trained to become a foreman or an executive. The apprenticeship usually requires from 3 to 5 years.

8 Some of the employers are helping their employees to gain a better education by educational programs. Some of them have established training classes and schools for the workers, but not to the extent that our industries have done in this field.

9 The working hours are being lessened as the employers realize that long hours harm the employees. The average working day is from 8 to 10 hours. More and more the idea of giving vacations to the employees is gaining ground. Some of these vacations are with and some without pay, and vary from 1 to 3 weeks in duration, depending upon length of service and the position held.

10 Measures are being taken to prevent accidents. Guards and safety devices are being applied to the machines, and campaigns against accidents are being instituted. In Germany some of the industries are effectually working along this line and use many posters to illustrate their points.

11 Some of the industries have systems to help the employees save a percentage of their wages, as well as accident and unemployment insurance and old-age-pension plans. In a number of the European countries the governments now take care of men out of work and provide for old-age pensions.

In conclusion, the writer would say that American management policies are taking root in European industries and that the latter are showing a gain as the result of adopting these methods.

Lillian M. Gilbreth.[16] This Society and all engineers in the management field are fortunate to be represented abroad by the author, who interprets Europe to us and us to Europe.

The paper furnishes, tactfully but explicitly, many lessons to engineers. Some of these come through advice on how to handle European problems. The author says that the former emphasis on machines rather than on management has shifted. This means that we must be prepared to send management *with* machinery or perhaps even management *before* machines. And the same thing holds true of mechanism. He says that while mass production is increasing, many industries still handle small diversified lots. This means that our management, mechanisms, and machines must be adapted to the small lot.

The author notes a difference in tempo in Europe from what we have here—a slower speed. This affects both machine speed and man speed—and we should have the matter in mind as we

[15] Roselle, N. J.

[16] President, Gilbreth, Inc., Montclair, N. J. Mem. A.S.M.E.

send over machines and equipment, as well as the men who will sell, install, demonstrate, and perhaps maintain them.

The author notes the distinction between the theoretical and the practical man—which implies the need of our men knowing both theory and practice and being able to present either to any group—if they are to retain leadership. Our engineers must not only be prepared to demonstrate what they say, but to persist even though they find such demonstrations greeted with astonishment.

The greater lag between being convinced by the theory and initiating the practice which the author finds abroad, implies that our engineers must be ready and able to push things across against both inertia and custom.

And so on through the entire paper. The differences which the author has observed, reported, and explained are regarded by him not as hindrances but as challenges—and challenges which he shows us how to accept and meet successfully.

Much of the author's material can be used to cope not only with situations abroad, but here. This he makes clear, for he recognizes not only the differences but the likenesses. Many of our workers, plants, and industries are more European than American, even yet, and his techniques of recognizing and handling these are most serviceable. Others which might be rated by some standards as typically American in origin, organization, and efficiency, are European in psychology. And the writer means no criticism of such plants—as Mr. Clark means no criticism when he says "European . . ." Through them all exist identical problems, i.e., of measurement, standardization, and teaching—which make the author's varied and extended experience invaluable to every one ready to use it.

Recent observations in Europe, Asia, and this country by other engineers who specialize in management all confirm the author's findings—and emphasize the value of his paper.

FRANK M. RYAN.[17] The author has given us a very clear picture of how European executives react to American management methods, so it may be of interest to examine the reaction among the workers.

Class consciousness manifests itself in many ways and sometimes acts as a serious handicap to the increase of individual production, thus delaying the accomplishment of the management engineer's task.

In practically all European countries the Socialist party is a strong factor in politics. As a result, social-insurance laws are common and the worker is accustomed to seeking financial aid from the government for childbirth, sickness, old age, unemployment, etc.

This influence tends to dampen individual initiative and the desire of the worker to attain the maximum production of which he is capable. It leads him to consult the government agencies on many problems which the American worker handles individually or upon advice from the employee relations department of the plant in which he works.

The governmental contact, through state-owned railroads, post offices, telegraph and telephone systems, and compulsory military training, in addition to all the agencies of state aid, is a factor in the worker's life which the average American does not appreciate.

This background makes it more difficult to stimulate the cooperation of the workers in better methods of production, but once this has been accomplished, given the same working conditions and a proportionate wage incentive, a good European operator will turn out 60 to 80 per cent of the production of a good American operator.

[17] Works Manager, Norton Grinding Wheel Co., Ltd., England. Member Ingénieurs Civils de France; Former Secretary of the Association of American Engineers in France. Assoc-Mem. A.S.M.E.

It has been reported that the man-hour production of the Irish workers in the Cork Fordson plant has exceeded that of the American tractor builders.

As a rule, European workers react most favorably to American methods of management and, once the introductory period is passed, sincerely appreciate the greater interest which American-trained executives take in bettering working conditions and eliminating fatigue and working hazards, and all those factors concerning the worker which American management has come to realize are so important.

CHAS. M. MILLS.[18] Any one who has been in Europe in the past five years and has been in touch with industrial organization and management there, knows the reputation which the author and his associates bear among the leading industrialists in Germany, France, Switzerland, Poland, and England. His methods and personality have won him clients and friends in many corners of Europe. His desire at all times to work with people, to outline projects and not to superimpose them, have built his character and reputation upon firm foundations. He has become a worthy international ambassador representing the best in American traditions of thoroughness, accuracy, and cooperation.

It is therefore with considerable trepidation that a casual observer, making only two extended trips to Europe in the past five years, attempts to comment upon the author's excellent summary of European conditions in management.

The writer is inclined to ask the author what effect international agreements, syndicates, cartels, or pools have had in the regulation and promotion of mass production, not only on domestic consumption, but with regard to exports. Has there not been a development from an economic point of view toward the furthering of mass production by international agreement in certain basic industries? What attempts have been made toward an economic United States of Europe or common consuming and export market? The writer has reference, for example, to syndicates in steel and iron, coal, and petroleum.

The author mentions the tariff, habits, wages, and desire for individuality in design as restrictions in mass production. Is there not another important factor in the decrees or national acts that restrict importation—acts in addition to regular tariffs? In Hungary, for example, only three hundred Ford cars can be imported per year. The reason given is to afford protection to a state automobile factory—to a home industry supposedly created for mass production.

Slow turnover of investment is of course recognized as an outstanding European characteristic. In this connection, the writer would inquire how far European industry has been hindered by foreign capital, chiefly American. The word "hindered" is used, for many experts believe that the availability of American capital and the eagerness with which American investment banks have sought to offer money has caused some European industrialists to expand in projects of rather risky and unstable nature. The availability of such capital would naturally lessen the chances of economies through a more rapid turnover of investment.

The author cites the waste of labor in employment in moving freight cars by hand and in treading shavings into pulp in a paper mill. Is it not true that the average European industrialist, largely because of class distinctions, has not recognized the dollar-and-cents savings in the development of human relations in the plant? Has not the enactment of compulsory social legislation—forced upon the employer—blinded his eyes to the potential

[18] Formerly Assistant to President, Standard Oil Company of Ohio, Cleveland, Ohio.

saving in his own plant under the provisions of such laws?

Social legislation has provided greater security and continuity of employment in Europe than in our own country, according to the author. How far has such legislation restricted the employer in management control, say, for example, in Germany? How far have these laws affected the work of the consulting engineer?

In storeskeeping, in plant layout, in planning and scheduling, and costkeeping the methods of application are more or less the same as in the United States. In sales distribution a great field seems to be open to American marketing specialists.

The author mentions the International Management Institute in Geneva as the one group coordinating national management associations. As one who visited this organization last summer and who is somewhat conversant with its scope and purpose, the writer would say that there is a fine opportunity for American engineers to support this institute. We have some things to learn from Europe as well as to give to Europe.

It has been said that American engineers should not be so willing to promote better management methods in Europe which may result in increased competition with foreign nations. The author has most ably answered these critics in his conclusion. International peace can be promoted better by ambassadors of knowledge and scientific approach like the author, and by an international institute of scientific management, than by naval treaties and international politics.

ALLAN H. MOGENSEN.[19] I should like to stress the value of travel and observation. I think we in America do far too little of this. As for our going abroad to visit plants and study processes, we seldom visit plants even in our own vicinity. Before we feel secure in our superiority, we should at least see the others to be sure that we are correct. One of the reasons for our present economic dilemma is our belief that we can proceed by ourselves without regard for what the other fellow is doing, or getting all the facts before going ahead.

Mention has been made of the rapidity with which the European plants take hold, and it is stated that the foreign manufacturer can undersell us because of his low labor costs. These are of course due to the lower standards of living in these countries. These standards will eventually rise. They have always risen in the past and we should expect this trend to continue. We should expect our own standards of living here to continue, despite the pronouncements of even some of our financial leaders to the contrary. When European living standards approach or equal ours, there will be no problem. But what are we to do in the meantime? How are we to meet this competition?

I think that we can find the answer in the proper selection of machine equipment. While it is true that in many fields we are overequipped, it may be that we have the wrong equipment. The textile industry offers a case in point here. We need more careful selection of machinery and equipment, purchased on a scientific basis, and the problem of depreciation handled properly. No machine or tool should be purchased unless it can be economically justified. But on the other hand, if there is a machine available that will enable us to produce more effectively and economically than we are doing at present, we cannot expect to meet competition unless we secure it.

I should like to ask the author how he feels about the question of control in industry. Is not the sort of control exercised by the government in Poland over the salt mines the answer to our problem?

We should not attempt to limit production, but do we not need some sort of control to prevent excessive expansion of plant capacity? We know that the coal industry is in a serious situation because of excess capacity. If the bituminous mines can produce 750,000,000 tons a year, and we use only 500,000,000 tons as in 1929, we have excess capacity, and some one must suffer. Each mine must operate inefficiently, as long as no one is willing or can be forced to shut down. Exactly the same situation exists in the shoe industry. We have capacity enough to produce almost twice as many pairs of shoes as we do produce. Therefore, each pair of shoes we buy carries so much direct labor, so much material, and overhead for two pairs. The author himself has often told us of plants operating at only 40 per cent of capacity.

Is it not this lack of proper planning and exercise of control that puts us in our present situation? Procter & Gamble are buying new equipment and building new plants, but are doing it as justified. They have a definite long-time plan, and follow this closely. When they build a new plant it is not because some one in the organization is overenthusiastic because business is good, orders are coming in, and there is money in the bank, but because the facts show that it will be needed at a certain definite date.

I want to emphasize the difference between failing to modernize at the right time, and expanding unwisely and blindly at the wrong time. Can we do this ourselves, or shall we require some super-controller to tell us when and how much?

AUTHOR'S CLOSURE

Mr. Mills inquires as to the effect of international cartels and syndicates on mass production. These agreements have undoubtedly brought about some standardization of product which has favored mass production and also they have been successful in minimizing dumping on export markets, but in the various domestic markets it seems that they have not been good for industry. The rigid control of prices at rather high levels has prevented any marked increase in the use of products of cartelized industries, and the apportioning of orders to plants without regard to efficiency or costs stifles initiative on the part of executives and results in a lower grade of service to customers.

The tendency during recent years has been to raise the tariffs of the various European countries as in the United States, and in addition there have been the national acts restricting importation mentioned by Mr. Mills. These tariffs and restrictions have been designed primarily to foster domestic production, but they result in limiting markets to a single country and restricting the possibilities of mass production and the consequent cheapening of the daily necessities of life. Tariffs encourage wasteful production, and the consumer has to pay for it.

It is difficult to say how far European industry has been "hindered" by American capital. It is the author's opinion that on the whole both have benefited by the collaboration, although it is true that money from this country has sometimes been provided without any attempt to study the markets, the plants, or the ability of the management staffs. The resulting losses have been painful to the Americans and discouraging to the borrowers. In the majority of cases, however, the lender retains experienced counsel to study the situation, agree with the borrower as to how the money is to be used, and then to see that the plan is carried through wisely. An outstanding example was the recent three years' service of Charles S. Dewey, who, as financial adviser to Poland, not only assured the security of a loan of many millions, but by his guidance of that government through a difficult financial period made a notable contribution to the welfare of the country.

It is undoubtedly true, as Mr. Mills suggests, that the social legislation in Europe causes many employers to go no further than the law requires in developing their relations with workers, whereas it would be to their financial advantage to do so. For example, when accident insurance is paid into a government

[19] Assistant Editor, *Factory and Industrial Management*, New York, N. Y., Jun. A.S.M.E.

fund at a certain per cent of wages without regard to the accident rate in that particular plant, the employer often feels that there is no incentive to carry on a safety campaign, whereas if he did show an interest in accident prevention, the increased running time of his machines and the improved morale of his workers would bring substantial savings.

Within the author's experience social legislation has not directly restricted management control to an appreciable extent, although it has strengthened workers' unions which in turn have restricted employers, sometimes wisely and sometimes unfairly.

It does not seem that social legislation affects in any way the consulting engineer. On the whole it is good for industry, and the consultant merely arranges the details of his client's business accordingly. For instance, in several cases the so-called social allowances, comprising sickness and accident insurance, vacations on pay, pensions, unemployment insurance, etc., average 12 per cent of the payroll. Therefore, in all calculations of costs and in payroll budgets this 12 per cent is added to the wages. Even with this addition the wages are low, and one can hardly say that such legislation is a burden on industry.

Mr. Mogensen brings up the question of control in industry and asks if government monopoly is not what we need in America. There is no doubt that we need a more wise and far-seeing direction of industry, but this can be built up better by industry itself than by federal or state governments, because politics so often places control in the hands of men who do not know how.

A "super-controller to tell us when and how much" is suggested by Mr. Mogensen, and perhaps in some future age such an all-wise being or group will appear, but in the meantime it is possible to introduce more complete planning in the various sections of industry, particularly in regard to the distribution of money and purchasing power.

Modern management has provided a technic which simplifies the most complex situations and plans their control. This can be applied to the direction of the changing forces of industry, and benefit not only one class or one country, but mankind as a whole.

MAN-53-2a

Apprentice Training in Virginia

By C. F. BAILEY,[1] NEWPORT NEWS, VA.

Virginia, along with the rest of the South, is becoming industrially minded. This stresses the need for education for the industries and the arts. The transportation companies, iron works, and shipbuilding concerns require skilled mechanics, trained through apprenticeship. The primary principles in apprentice training are, first, careful selection of candidates; second, importance of the supervisor; and, third, the sympathy and aid of the management. The advantages of apprentice training include recruiting skilled mechanics, with a spirit of loyalty and service, some of whom will develop to foremen and higher officials. To promote this, training schools, on company's time, are advisable. The apprentice group should be self-governing. The conclusions are that the wages should be liberal, with opportunity for increased earnings through premium or bonus work. The prospects for apprentice-trained men were never so bright as now. Virginia manufacturers are taking increased interest, and they recognize the necessity and value of apprentice training. The business of building involves both materiel and personnel—the building of men as well as of machines and ships.

THE South, including Virginia, is rapidly becoming industrially minded. With this come the problems arising from mass production and the need of education for the industries and the arts. Business prospects which were quenched and blighted by the Civil War are now far in advance of any previous period. Development of the large natural resources of the South, such as timber, iron, coal, and water power, is demanding skilled mechanics and engineering talent. In the Virginia Section such talent is principally required by the transportation companies, bridge and iron works, and in shipbuilding, wherein 20 or more independent trades are practiced in the building of a modern high-class ship. In other industries where mass production is the order comparatively few mechanics skilled in the trades are employed.

We see, then, in the Virginia Section a few towns widely separated in which are industries requiring skilled mechanics, and therefore presenting opportunities for apprentice training, which involve somewhat different problems from those found in densely populated sections wherein a single city may constitute an entire section of the Society. This does not excuse the widely separated and less populated sections for neglecting the issue, although the adoption of a general rule is probably not workable for all.

The purpose of the present paper is to create an interest in this subject in the Virginia Section and elsewhere. This has been attempted through correspondence with the principal industrialists in the State, through a meeting of the united engineering societies, through interchange of visits of officials of several industries, and through the Department for Vocational Education, wherein the acceptable principles of apprentice training have been presented, discussed, and illustrated. Considerable interest has thus been created which, with the proper nutrition and fostering, will doubtless be increased to a marked degree.

There are only a few towns in the section where apprentice training is established to any considerable extent. However, there are a number of smaller organizations and contractors who take a few apprentices in certain of the basic trades.

The State Department for Vocational Education is largely directing this matter, and through the influence of its agents great benefit has resulted. There are no very complete data compiled as to the number of apprentices in the State. The report of the Department of Labor and Industry, September, 1929, gives some information, but it is difficult to classify accurately. There would appear to be about 600 apprentices in the different trades that are practiced in the State.

The Principles Involved

In the discussion of this subject by the author at a joint meeting of the engineering societies at the Virginia Polytechnic Institute on April 26, 1930, certain important principles and qualifying factors were brought out which control to such an extent as to constitute the laws governing successful apprentice training.

First, the careful selection of the apprentice group with particular reference to initiative, self-control, and determination; scholarship (completion of high school), moral sense, and physical fitness.

As then stated, since our objective is to train and equip young men to become highly skilled for industry and the arts, it is vital that only those of certain physical, mental, and moral traits be received. We might therefore state the first law of apprentice training as follows:

First Law: Candidates must be physically fit, mentally superior, morally hopeful—hand, head, and heart.

We should include in this intensive apprentice training no boy who has not these desirable characteristics in an outstanding degree. The mediocre candidate displaces one of the promising type who might become an effective influence in industry and the community.

Second, the selection of a supervisor whose heart and mind are in sympathy with the work and with the apprentice and who has the vision, initiative, and organizing ability to devise and carry through a comprehensive training program. We may then state the second law as follows:

---

[1] Engineering Director, Newport News Shipbuilding and Dry Dock Company. Mem. A.S.M.E. Mr. Bailey was born on Aug. 29, 1863, in Greensboro, Vt. His education was received at Worcester Polytechnic Institute, S.B. in M.E., 1888; Dr. Eng. Hon., 1928. He was a machinist, Northern Pacific Railway, Tacoma, Wash., 1888–89; draftsman, Tacoma Foundry and Machine Co., 1889–90; Neafie & Levy Ship and Engine Building Co., Philadelphia, 1890–91; chief draftsman, 1891, chief engineer, 1900, and engineering director, 1918, Newport News Shipbuilding and Dry Dock Company; consulting engineer, Westinghouse Elec. & Mfg. Co., 1915–21; director, Newport News Shipbuilding and Dry Dock Company, Newport News Construction Corp., Newport News Land Corp.; school trustee, Elizabeth City County, Virginia, 1912–16; civil member, member council, 1924, Am. Soc. of Naval Engineers; representative, National Council of American Shipbuilders on Committee to Coordinate U. S. Marine Boiler Rules, 1929–1930; trustee, Worcester Polytechnic Institute; member, Technical Committee, American Bureau of Shipping; trustee and vice-president, The Mariners' Museum; vice-president, Society of Naval Architects and Marine Engineers.

Contributed by the Committee on Education and Training for the Industries and presented at the Annual Meeting, New York, N. Y., December 1 to 5, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

FIG. 1 THE 235 APPRENTICES, 24 INSTRUCTORS, THE CHIEF INSTRUCTOR, AND THE SUPER-
(The legend on the monument reads: "We shall build good ships here, At a profit—

Second Law: The supervisor of apprentices and the instructors must stand forth prominently in manipulative skill, intelligence, training aptitude, mental resourcefulness, application, and in the high principles of self-control, citizenship, and interest in and vision of the possibilities of the boys' future.

Third, in order to make apprentice training successful, not only must we have the choice, selected personnel, but there must be a realization on the part of the management of the need—an inspiring interest in young men and a willingness to spend time and means to promote such training not only for the good of the company, but for the benefit of the individual, the community, and the country. We may therefore state the third law:

Third Law: The management must be imbued with a hearty interest in the apprentice, visualize his possibilities, recognize the mutual interest existing, and provide both matériel and personnel to foster his training.

ADVANTAGES OF APPRENTICE TRAINING

With care used in the selection of the teaching personnel and the apprentice personnel, the management may confidently look to having eventually a high class of employees imbued with a spirit of loyalty and service who will develop into first-class mechanics and many of them later into supervisors, foremen, superintendents, and even higher officials. It is for this reason that such care should be given to the selection of the candidates.

The management should keep in sympathetic touch with the supervisor and as far as may be with the individuals, lending encouragement to the young men by showing interest and by cultivating a personal acquaintance where feasible. It is vital that the supervisor should follow up all of his students and apprentices throughout the course. Not only should these men be followed during their course, but also, with advantage to both the men and the organization, throughout their service, either with the company or with others. No employer can hope to retain in his organization all of the skilled men which he may train; many will leave, some for a period only and others for their life work in kindred fields. This, however, should not be looked upon entirely as a loss, and many examples might be cited where apprentices have left the company after completing their apprenticeship and have risen to responsible positions in other concerns throughout the country. They thus form a contact and an advertisement for the parent company which is of considerable intangible value. In one's own organization the policy of the careful selection and training of apprentices will encourage and emphasize a study of the history and policies of the company, its founders and leaders, as an inspiration to zeal and loyalty. Such men, so trained, are particularly valuable for promotion to higher positions within the company.

The policy of training is one to be left by the management to the supervisor, who should outline the blocks in each trade which the apprentice should learn and in which he should become practiced and expert. These blocks need not, however, be taught in the consecutive order in which they are naturally grouped. They also serve the purpose of valuable training in emergency for special-purpose men wherein a man may be taught a particular part of the trade and become skilled in this, whereas the apprentice will be trained in block after block until he has completed the educational part of the trade and thereafter will acquire more skill, dexterity, and speed by practice throughout the remainder of his apprenticeship. Such training furnishes the management with a reservoir of potential personnel for the upkeep and development of the organization.

In order to carry on such a course of training it is also advisable to establish in the company's time a school with teachers and trade instructors, and it is here that high-school graduates are eminently fitted to carry on with great interest and value studies directly related to the problems with which they come in contact day by day in the shops. These studies should include physics, chemistry, economics, the principles of accounting, psychology, mathematics, drafting, effective English, accident prevention, and other branches related to the work in hand and to the affairs of the company. In order to develop the morale of the group it is necessary and advisable to make the organization as far as feasible self-governing, which may be done through an apprentice association with committees, officers such as president, vice-president, secretary, treasurer, athletic committee, and honor council, who shall consider all important questions arising as to policies, infractions of the rules of the association, and the discipline to be applied, which may even be as severe as a recommendation for dismissal from apprenticeship. The cultivation of the apprentice traditions forms an incentive; the inculcation, not by direct instruction, but by practice and precept of a broad, correct labor policy is wise and enlightening. The promotion of efficiency as a means of increased earnings for both the company and the apprentice must receive attention, together with improved quality.

CONCLUSIONS

The matter of the apprentice wage is of vital importance. The wage at the beginning and throughout should be liberal, although at first the apprentice may not earn much. This tends to attract the better class and gives a far superior list of applicants from

VISOR OF TRAINING OF THE NEWPORT NEWS SHIPBUILDING AND DRY DOCK COMPANY
if we can; At a loss—if we must, But always good ships."—Collis Potter Huntington.)

whom to choose. It is the policy now in some cases to select only high-school graduates or those who have had the equivalent of a high-school course because of their proved capacity for development.

The inspiration coming to any manager in watching the progress and development of the bright young men is one of great uplift and value. There comes to be a feeling of interest in the boy which is reciprocated by him and which is a great factor in the labor problem of the time. The apprentice should be taught the value of efficiency and given incentives which will develop intense reaction in this respect. These incentives may take the form of the assignment of choice jobs to such as show the ability, interest, and willingness required; the increased interest of the supervisor and the management, without danger of partiality; and later as skill is developed increased remuneration by the adoption of a system of payment whereby the regular hourly rate is supplemented by a bonus or premium based directly upon the character and amount of work performed, which may be established either by contract or in other ways.

Because of mass production in some cases the need for skilled mechanics may seem to be declining; however, one need not be discouraged, since this machine age requires the skilled hand, trained in practical application of the trades, associated with minds trained to straight thinking, with healthy viewpoints of labor policies, which enable young men to advance. The prospects for such a young man thus trained and educated in industry were never before so bright as now. He takes his rank in a different squad, but he takes it just the same along with the college graduate, and often he can outclass the college man. Examples might be cited of these young men occupying positions of supervisors, foremen and superintendents, salesmen, and others. One young man who served in the pattern shop and who is now in a sales department of a high-class machine-building company says that, as he looks at it, there are two types of trained men with whom to compete; first, the purely technically trained man, and second, the practically trained man. The course which he pursued in his apprentice training he considers to be a middle route, and now he expresses his deep appreciation of the advantages which he enjoyed in this training. With the skill gained both by practice and theory he has risen without embarrassment to a leading position.

Another graduate is in a large, successful building corporation furnishing important machinery for marine work. He is a diplomat in adjustment of difficulties, which may be fancied or real, with the purchasers of his company's products. Others who have remained with the parent company have risen to high positions as foremen, as assistant superintendents, and (one) as superintendent. They are now of great value to the company in that they are in sympathy with the broad system of training which is so advanced over that which they enjoyed. These men, familiar with the company's traditions and policies, are the backbone of the organization as representatives of the company in dealing with the inspectors and supervisors sent to the works by its clients.

One apprentice in the civil engineering department lost his job soon after graduation due to drastic curtailment of work in the company. This young man took a minor position in the city engineer's office, and within three or four years he became the city manager, which position he still holds and in which he has made a greater success than any former incumbent—a pride to the company where he was trained and an honor and asset to the city of which he is manager.

A number of letters have been received from manufacturers and operators in the Virginia Section in which is unanimously acknowledged the value of apprentice training. The transportation people express great interest in this and are anxious to progress with it. They admit that it requires much more thought, study, and consideration than it has formerly received.

One Virginia manufacturer says that he considers apprenticeships as becoming more and more a necessity in American industry and that apprentice schools are necessary in the solution of the modern industrial problem; that while mass production has in a large measure changed the need for skilled mechanics, yet its leaders and master mechanics and foremen must be skilled.

One Virginia railway official stresses the importance of examinations physically and along educational lines in order to select the best material for training. Another railroad superintendent states that apprenticeship training cannot be worked out along general lines to meet any working conditions and that no cut-and-dried plan for one works can be adopted in its entirety for some other. He thinks that self-improvement work can be effected and must be largely initiated by the apprentice under suitable encouragement by the management. All of this can be greatly fostered by the management in its dealings with the apprentice.

The vice-president of a large foundry company in the western part of the Virginia Section writes as follows with regard to his newly established apprentice system:

This program has been in practice only about four months, and of course it is impossible to give an intelligent idea of the worth of a program of this nature with the short experience that we have had. We are, however, more than pleased with the progress made thus far

and feel more convinced than ever that our training program will prove to be one of the most worth-while things that we have undertaken for many years.

The products of a well-planned and directed apprentice training course where the attractions offered are such as to draw the brightest, most intelligent material, are greatly improved labor conditions, highly skilled mechanics, an intelligent, happy citizenship, and a supply of potential supervisors, foremen, and even superintendents. When we see this illustrated and stop to consider, we realize the great importance of this training. The supervisor or foreman occupies a dual position of great significance and influence. It is he who represents the management of the company to the men under him. As some one has said, "He must be familiar with the company's policies on the one hand and on the other represent the workmen to the management." Therefore, his own training is of great importance. Not only should he interest himself in teaching the apprentice the trade in all its branches requiring hand, head, and heart, but he also has the rare opportunity of touching the other vital chords of the man's being.

The Chamber of Commerce of the United States considers that foremanship holds the key to production. The foremen can create a sympathetic contact with the men and be an inspiration to them, a service to the company, to the men, and to himself. With such foremen the management gains in spirited team-work, morale, loyalty, lower turnover, reduced accidents, greater output, and an improved spirit of orderliness.

While we honor the outstanding professors in engineering colleges and recognize the great influence which they have upon the development of the engineers of the future and the personnel coming up to take the places of us here today, still many manufacturing concerns today present opportunities which challenge the best in any man to take a large share in this upbuilding of our engineering organizations and personnel. If there can be created in the executives of the many fine industries of our sections an intense love for and interest in the young men whom they are training, they will find that it stimulates the faculties and gives enjoyment and recreation of a satisfying character.

With the right spirit pervading an organization there is a place without jealousies or friction for the development side by side of the well-trained mechanic and the technically but less practically trained college man. Many industries, like the great electrical manufacturing companies, have positions where it is essential that men with eminent knowledge of the sciences are required, but in these same organizations and in most organizations involving the trades are numerous enviable positions for the properly trained apprentice.

In order to carry out such training a company must make a set-up particularly for it. The smaller companies, however, may not be able to do this. In any case, there is one source of great help which should not be left untapped, and that is the assistance granted by the practical application of the Smith-Hughes Act which is fostered and administered in the State of Virginia by the Department for Vocational Education. In the Virginia Section this department has been of great service in helping to develop, establish, and promote the apprentice course and the training of foremen. It is only a step from the training of these well-balanced and bright apprentices to the development of skilled mechanics, supervisors, and foremen which should take its turn.

A few years of a young man's life at this age is not wasted in service before he rises to the position of greater authority. Eugene R. Grace says: "Not only is the hard work, in humble jobs, a test of these young men's endurance, but it serves to give them a background of sympathetic understanding of the workman's point of view which enables them as executives in later years to strike a just balance between their duty to the corporation which employs them and to the men who work under their direction."

In all this training are many opportunities to create loyalty for the company by briefly reviewing in an interesting way the history of the company, dwelling upon its outstanding personalities, past and present, and the policies which guide it.

In any organization or in any large group of young men there is always latent, unnoticed talent in one direction or another, some in special skill, some in leadership, some in individual development.

These qualities are to be looked for and noted, and they can be found in the shop, in the schoolroom, and in the games and sports, which should be largely fostered. The great business of building involves quality in matériel and personnel; the building of men as well as machines or ships.

Throughout the country the most successful manufacturers and engineering concerns are surrounding themselves with staffs of the brightest minds, who by means of conferences, study groups, and lectures are learning the vital principles of the organization and the company's policies.

To many, and particularly to those engaged in small industries, the foregoing may seem impracticable. It has, however, been demonstrated that this is not so. Results obtained under the principles and conditions outlined are encouraging and inspiring and demonstrate that, with the proper spirit of management, the rare supervisor of training, and the selected group of apprentices these results can be realized and improved upon.

Discussion

D. S. Jacobus.[2] Mr. Bailey's paper radiates his enthusiasm and keen insight in the training of young men as carried on in his department. There is a fascination in this work. The principles brought out by Mr. Bailey and his conclusions are in harmony with ideas that have come to the writer in his career as a teacher for over 20 years and his longer contact with the outside field. Hand, head, and heart must strive together in the young man, and the instructors must stand forth prominently in training aptitude.

In viewing teaching in its broad aspects the writer is more and more convinced that the success of any course is more directly measured by the amount of effective work done by the students than in any other way. To learn how to work effectively one must himself work effectively. There is no short cut to success which will bypass hard work. Some may challenge this statement, but where one may claim to have reached the top of the ladder through natural ability rather than effort, there will be a hundred who will acknowledge the benefits of hard work. It is feared that in some cases our modern training is along too idealistic lines. The goal is often set so high that the great majority fail in its achievement. Young men with the sort of training outlined in the paper may outdistance many of those who are looking so far afield that they cannot see what is at their feet.

Some of those reviewing engineering education have laid much stress on character. All know that character is indispensable, but with it should go a fundamental training in the principles of one's profession, and above all a willingness to work hard in applying them.

Character cannot be taught by precept. There are no keener or fairer critics than a class of young men, and any amount of advice on the bearing of character on success by one not having a high character will fall on empty air.

[2] Advisory Engineer, Babcock & Wilcox Company, New York, N. Y. Former President, A.S.M.E.

The writer is happy to endorse all that Mr. Bailey says in his paper and hopes his experience in the training of young men will carry with it as many happy recollections as his own.

E. W. KEMPTON.[3] When reviewing a paper, one might take the stand that there must be something about which he should be critical. The writer thought that he had such a point in Mr. Falk's paper when he stressed the control of the apprenticeship system in Wisconsin through a commission established by law. However, before concluding the paper the author states that the passage of a law is unnecessary, and in this the writer concurs. Mr. Bailey's summation of policies and attitudes for effective apprentice training is well made. It is a pity that there is not a greater appreciation of the benefits to be derived when such advice is followed.

The writer is an ardent believer in apprenticeship, and inasmuch as the papers of Mr. Falk and Mr. Bailey set forth specific plans, principles, and benefits of apprenticeship training, he can but add substantiating evidence.

The reason why there are not more apprentices in training is not because of failure to legislate the control of apprenticeship training, but rather because of the impatience of American industrial superintendents and foremen and their interest in little that does not create immediate results. It takes time to develop an apprentice into a mechanic, and time is the one thing of which we have the least. It requires giving thought and consideration to something that is not a specific production problem of the moment; hence there is too great a willingness to let some one else develop mechanics and then we shall hire them away when we want them.

To secure an idea of the number of skilled all-around machinists (not operators) that exists, one needs only to talk to an employment officer who was in the field for such workers during 1928 or early 1929.

Of machine operators there is no scarcity, but when one looks for the so-called all-around worker such as is needed in the maintenance and repair shops of industry, one does not have to be convinced of the necessity for apprentice training. The reason for this condition is not difficult to find, for in maintenance shops where foremen and superintendents are pressed quite as much for costs and other economical factors as in production shops, there is little immediate interest in taking a man who has developed into a good lathe operator and giving him experience on some other type of machine such as the milling machine or planer. In mass production shops there is no possibility of this.

Furthermore, there is little opportunity today for a young man to go through that process that was formerly known as "stealing a trade." Once a young man could secure a position in a shop, acquire experience, and learn how to operate a lathe, and then if he were not given an opportunity on some other machine, he could leave, secure employment elsewhere, and bluff his way until he had obtained further experience. By repeating this process a sufficient number of times, he eventually became a good mechanic. Today, with well-developed employment departments, it is quickly discovered that the experience of a man has been limited to one particular type of machine, and he is either turned away as not required or is employed for work similar to that which he has been doing, with practically no opportunity to broaden his experience. Even in the limited number of shops where this is still possible, there is no appreciation that this is the most expensive and inefficient method possible. Hence, there has been during the past two decades a very appreciable decrease in the relative number of all-around mechanics, notwithstanding the fact that the total number employed at the machining trade has increased. To secure further corroborative information, one need only make inquiry pertaining to the average age of mechanics employed in any maintenance, repair, or jobbing shop where there is necessity for something more than operators. He will find that the average age is constantly increasing. He will further find that potential material for foremanship positions is relatively scarce, if a foreman is required who has had a wide experience as a mechanic.

The strange part of this picture is that corrective measures are not difficult nor expensive to take. There appears to be an impression upon the part of executives that apprentice training is expensive and cumbersome, but it need not be so. In fact, it may be quite the opposite.

In almost every community there exists some part of the public educational system that may be readily adapted to the training of apprentices, the teaching of that auxiliary knowledge necessary to a good mechanic. Modern-minded educators connected with public educational systems are usually pleased at the opportunity to cooperate. It has been this writer's experience that there is altogether too much said about the unwillingness of the public schools to cooperate in the training of young men and women for business and industry. As a matter of fact, it is usually the other way around. Business men and factory executives will not cooperate with public schools.

With such cooperation and a little conscious effort upon the part of the machine-shop foreman or superintendent or some other executive, in the matter of diversifying experience, the training of apprentices is neither complicated nor expensive.

The apprentice system developed through the cooperation of manufacturers and the public school system in the City of Cleveland is a good illustration. Here the embryonic mechanic attends a school that has been set apart for the purpose, full time, 8 hours per day, for the first year of his apprenticeship. One-half of this day he spends in the classroom studying mathematics, blueprint reading, and other auxiliary material, and the other half of the day in the shop of the school. At the conclusion of this first year the instructors, who are men who have been successful in their chosen trade, are able to distinguish between those who will and those who will not succeed as apprentices. At the conclusion of this first year the successful apprentices are employed by manufacturers in Cleveland, who are always willing to take them, even anxious to get them.

The second year of apprenticeship is devoted to a cooperative plan whereby the apprentice spends two weeks in school and two weeks in the shop of his employer, boys being paired in teams, one being on the job all of the time.

In the third and fourth years of apprenticeship the boy spends all of his time in the shops of the employer, with the exception of four hours a week which he spends in the school on school work.

The success of this plan is evidenced by the fact that it is constantly growing, and those employers who are using it are becoming more satisfied with results as time goes on. However, there are still manufacturers in the metal trades of the City of Cleveland who complain because of the scarcity of all-around mechanics, but who will not exert the effort to participate in this plan. Some manufacturers appear to believe that mechanics simply sprout from nowhere to be plucked at the employment office as required. It is the experience of those conducting apprenticeship courses, whether fully under their own control or in cooperation with public educational institutions, that their best mechanics are from the ranks of their own apprentices.

A discussion of the means for securing a well-rounded training of an apprentice would not be complete without mentioning the fact that apprentices may secure the auxiliary knowledge that goes with their trade, through correspondence school courses.

[3] Educational Director, American Steel and Wire Company, Cleveland, Ohio.

Some employers are today conducting very effective apprenticeship courses and requiring their apprentices to take a correspondence course, which has been developed for that specific purpose, correlated to their trade. Utilizing this facility, no employer need say that he has not the means for properly training an apprentice.

There is just one more idea often expressed against the young men of today that should be exploded, and that is the idea that applicants for apprenticeship are scarce, that young men will not take apprenticeship courses, and that they want white-collar jobs. Wherever a systematic apprenticeship course has been organized, with reasonable guarantees to the young man that he will secure an adequate training, there are always more applicants than can possibly be employed.

It is the experience of the American Steel and Wire Company in the various communities in which it operates that in no case need we take any apprentice who has not graduated from high school unless we so choose. Applications are always on the waiting list.

There is a bountiful supply of good material for apprenticeship courses. Apprenticeship courses are not difficult to organize; they are not expensive to conduct; properly conducted, they easily pay for themselves; and they furnish the best source of material for advancement to higher positions.

Morris S. Viteles.[4] Apprentice training programs are, in most instances, being developed for use in plants employing a large number of apprentices. The small plant employing a few apprentices has, in the main, been overlooked in the formulation of such training programs. This omission has made it practically impossible to exploit the full possibilities of such plants in increasing the corps of adequately trained machinists. This problem has been faced by Philadelphia Electric Company in the organization of a training program for apprentice machinists.

The training program was organized for the generating and operating maintenance section, employing no more than six apprentice machinists at one time. The nature of the job is such that there is no opportunity for production work. There is no way of foreseeing the kind of work in which the apprentice will be engaged at any time in the future and no way of bringing systematic training to the job so as to insure organized practice on the various trade skills in a definite, logical order. There are difficulties in insuring centralized supervision, inasmuch as an apprentice may be shifted rapidly from one location to another. Moreover, the fact that there are so few apprentices makes it impracticable to organize classes for instruction in the related subjects with which the skilled machinists should be familiar.

To overcome these difficulties and still provide systematic training for these apprentices, the following training program has been developed.

In this training program each apprentice works approximately 48 hours per week in the different shops and plants throughout the system over a period of four years. He is transferred periodically from one station to another, in order to familiarize himself with the maintenance work from all its angles.

Each week 4½ hours is devoted to formal training under the direct supervision of an especially assigned instructor. The remaining time is devoted to regular routine maintenance work under the guidance of a foreman or mechanic or as part of a crew working on larger jobs.

The formal training program is divided into main parts, as follows:

(1) *Machine Shop Projects.* This includes a series of shop projects by means of which each apprentice may become familiar with the operation of every machine and with all the bench practices which should be familiar to a skilled machinist. These projects supplement such casual instruction on the machines and on bench-shop techniques which the apprentice may receive from his foreman while working on the job.

The program includes a series of projects ranging in complexity from a simple grinding job to one involving the use of practically all of the machines and all of the bench techniques which the apprentice has practiced in working earlier projects.

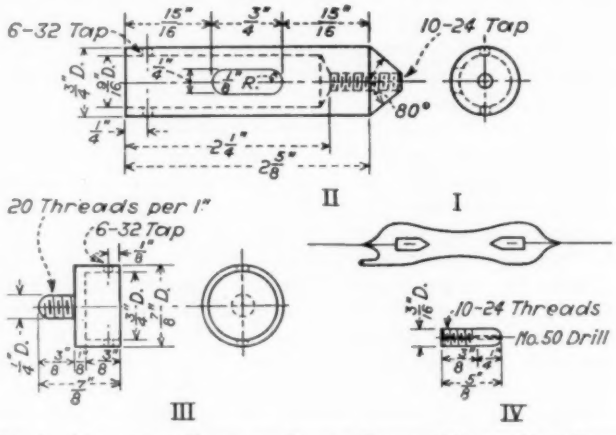

Fig. 2 Apprentice Training Course Project No. 22, High Volt Detector

(Material required: Part I, one Neon tube. Part II, one piece of 7/8-in. round fiber 3 in. long. Part III, one piece of 7/8-in. round brass 1 in. long. Part IV, one piece of 3/16-in. round brass 5/8 in. long. Part V, two 6/32-in. round-head brass machine screws 1/4 in. long. Procedure: Part I: The Neon tube is furnished by the storeroom. Part II: (1) True up fiber in lathe; leave approximately 4 in. extending out of chuck. (2) Square end and turn diameter. (3) Center with center drill and drill 9/16-in. hole. (4) Drill small hole; use extension drill. (5) Cut off at correct angle. (6) Lay out, drill, and file sight hole as per blueprint. (7) Tap small hole. Part III: (1) True up 7/8-in. round brass in lathe chuck; leave approximately 1¼ in. extending out of chuck. (2) Square end. (3) Center and drill hole. (4) Square bottom of hole with bottom drill. (5) Set cutting-off tool ½ in. back of face and feed in to within 17/64 in. diameter. (6) Move tool ahead and make a second slice, leaving approximately 1/8 in. metal in between. (7) Move tool back and cut the metal left between the grooves. (8) Repeat these operations until you have a groove approximately 9/16 in wide. (9) Turn the diameter to 1/4 in. with the same tool. (10) Cut off. (11) Move the bench vise and cut 1/4 in. 20 thread with hand stock and die. Part IV: (1) With hand stock and die, cut thread on 3/16-in. round brass. (2) Cut off to length with hacksaw. (3) Clamp in V-block and center-end with center punch. (4) Drill in drill press. (5) Chuck piece in drill press and round-end with file. Assembly: (1) Assemble parts II and III and drill and tap holes as per blueprint. (2) Mark relative position of parts with scriber and remove cap. (3) Solder wire of Neon tube in cap. (4) Assemble parts I, II, III, and V. (5) Slip part IV over protruding wire and screw it in place. (6) Solder protruding wire to part IV and cut same. Remarks: Considerable care should be taken in the soldering operation, so as not to bend the filament wire of the Neon tube too near the glass, as it will break easily. Questions: (1) How do you grind a drill for drilling fiber? (2) Describe the construction and the use of the Neon tube.)

The character of these projects is shown in the diagram (Fig. 2). The gradual progress from instruction and practice in simple to complex trade skills is evident from a comparison of projects taken from the early and later phases of the training course.

(2) *Correspondence Work on Related Subjects.* A skilled machinist must be familiar with a certain amount of mathematics, with the fundamental principles of mechanics, etc., in the practice of this grade. Inasmuch as it is impossible to organize formal courses in these related subjects, instructions in these subjects are given by the correspondence course method. Arrangements have been made with Pennsylvania State College to furnish these correspondence courses. The arrangement is such that the college furnishes all of the text material and grades all of the lesson assignments. The ground covered by the correspondence work includes courses in mathematics, blueprint reading, mechanics, electricity, and shop economics.

(3) *Conference on Machine-Shop Practices.* In order to familiarize apprentices with the general aspect of machine-shop

[4] Director of Personnel Research, Philadelphia Electric Company, Philadelphia, Pa.

practices, talks are given at periodic intervals by members of the supervisory force of the maintenance section and by representatives of other departments who are asked to cooperate on this phase of the training program.

(4) *Conference on Assigned Lessons.* Provisions are made for conferences between the apprentice and the supervisor of the training program in the maintenance section on problems which arise in connection with the correspondence-course work and on other problems which grow out of the training program.

Length of the Training Program. The training program extends over a period of four years. The first six months of apprenticeship is considered as a period of probation for the apprentice. Accurate record of progress is kept.

L. P. ARDUSER.[5] So much attention is being paid, and must continue to be paid, to the problems of distribution, that it almost seemed that production, the goose that lays the golden eggs, might be neglected. In fact, the writer has heard business men and engineers who ought to know better say: "We do not need to worry about production any more. That job is done. We can forget it. Now we must distribute what we can make." Let us stick to fundamentals. We cannot forget production, for, argue as we will about sales quotas, advertising media, discounts, etc., it still remains true that efficient production is essential to effective distribution. Consequently, the papers by Mr. Bailey and Mr. Falk are significant. We are not going to be allowed to forget where the golden eggs come from even if we have no scientific means as yet for their distribution.

After going over both papers the writer finds very little with which to disagree. He is not quite so familiar with conditions in Virginia as he is with those in Wisconsin, but is sure that both states are on the right track.

There are many ways, aside from our former method of wholesale importation, in which we attempt in America to produce skilled draftsmen and all-around mechanics. We have the mechanics institutes such as Franklin for evening courses, the free trade schools such as Pullman, the two-year day and evening institutes such as Pratt Institute and Ohio Mechanics Institute, technical high schools such as Cass, Brooklyn, Lane, Milwaukee, Omaha, Central Toronto, and Roosevelt at Los Angeles, cooperative high schools and colleges, two-year engineering courses such as exist at Carnegie Institute of Technology in the School of Industrial Arts, a host of company apprentice schools such as at General Motors, General Electric, Westinghouse, New York Central, and Pennsylvania Railroads, R.R. Donnelley, and others too numerous to mention, many Y.M.C.A. day and evening trade schools, college-extension and private correspondence-school courses for employed craftsmen, and finally the nation-wide system of vocational schools operated separately by each state, but guided and stimulated by the Federal Board for Vocational Education largely through the power of granting or withholding federal aid.

Many of these methods and combinations of methods are very effective, but our production of trained all-around mechanics for the various industries is still very spotty. We do need additional organization along state and national lines to provide opportunities to compare notes and share experiences and to add weight to our pleas. The Department of Manufacture of the United States Chamber of Commerce, the various national trade associations, the American Vocational Association, the National Manufacturers Associations, the S.P.E.E., and our own engineering societies are all working on the problems of correlation of effort, while the peculiarly effective set-up of the Federal Board for Vocational Education, with its regional traveling agents, gives it the power to assist all of the other agencies in guiding their efforts in training along proper lines.

Like the U. S. Bureau of Education, the Federal Board for Vocational Education is a great clearing house. The writer has seen technical schools in corporation, private, and public systems here and in Canada modify their methods to conform more nearly to those advocated by the Federal Board. Some of these have had a century of tradition back of them. He has seen much engineering college teaching influenced directly and indirectly by the Federal Board and the American Vocational Association. So whatever agencies are used in apprentice training, do not forget to use state and local departments of vocational education and to see that all agencies cooperate.

As an example of cooperation in Brooklyn, the Brooklyn Union Gas Company sends selected employees to our evening school for a year of preliminary training, after which these men go to the evening classes at the Polytechnic Institute of Brooklyn and then to those at Columbia University. We tend to sift out the impossibles in our first year of preliminary training. In this way men with company trade experience are trained as gas engineers. In addition the directors of all of the important private and public educational systems in Brooklyn are united in one organization which deals as a unit with educational problems.

In connection with apprentice training, the writer's experience leads him to say that it is a relatively easy matter to impart principles, but that intangible something known as trade skill cannot be imparted by a teacher to a learner. Job skill is only acquired on the job itself by monotonous repetitive effort.

Not only skilled mechanics but a host of machine operators (and this applies to office as well as to factory work) are required by modern industry. In fact, as specialization increases, the relative need of trade training as such decreases, but the problem of supervision becomes complicated and acute. And that puts a new job up to the foreman.

When Arthur Mann of the New York State Department of Vocational Education was training a number of Brooklyn business and industrial executives as conference leaders at Brooklyn Central Y.M.C.A., one of the things worked up by the group itself was a table, as follows:

	Plan	Direct	Supervise	Train
Manager.....	75%	15%	5%	5%
Foreman.....	10%	15%	55%	20%

We also agreed that any superior must follow the teaching process in giving orders. Fully 90 per cent of all operator failures are foreman failures if traced back properly. They are largely due to wrong methods of giving orders.

The experience of the group also led it to agree that the study which revealed the following was largely correct:

Fully 98 per cent of all industrial accidents are preventable, and 88 per cent of these are due largely to faulty management. The foreman is an integral part of management. He has some job these days, has he not?

Foreman training has amply justified itself by results. It is believed that the trend in methods of foreman training is toward the conference method. Expert lectures and textbooks have their place in conferences, but they must be subordinate to the conference itself for good teaching.

Before any company institutes conference methods of foreman training, however, the top management would do well to search its heart for sincerity of purpose. The conference is a two-edged sword; it cuts up as well as down. When members of a group of foremen are once started to thinking cooperatively, they may not only think about themselves and their operatives, but they may also think about the top management itself. They

[5] Assistant Director, Education Department, Brooklyn Central Y.M.C.A., Brooklyn, N. Y. Assoc-Mem. A.S.M.E.

may even come to discover for themselves that management can throw more efficiency out of the window in five minutes with a teaspoon than the foremen and men can bring in the doors in eight hours with shovels. So if one starts foremen's conferences, he can be sure that his actions speak louder than his words. He will have to work hard and play the game straight if he uses the conference. Preaching or telling is ineffective in any field.

It is quite apparent, therefore, that when foreman training is discussed, one must necessarily bring in top management training as well. All the closed minds in industry are not in the lower ranks.

Mr. Falk stated that the training of apprentices must become a general institution in as many business and manufacturing establishments as possible. The writer would like to emphasize the word "business." We operate business and technical schools in the Y.M.C.A. in Brooklyn. The problems in each are quite similar. In fact, if one will write for the 1930 pamphlet on "The Necessity of Closer Relations Between Business and the Schools," by Cameron Beck, personnel director of the New York Stock Exchange, he will be struck with the general similarity of the training problems encountered in the office and in the factory. Which leads to the remark that the apprentice method, or the cooperative method if one wishes to call it that, can be applied to training in business as well as in industry, and with decided advantage to business and industry, and the schools. The writer well knows the problems that come up such as coordination, vocational guidance, placement, and the like, but these things have to be done somehow, so why not do them as well as is known how in a cooperative way? The writer's guess is that the trend in education is toward the cooperative or "sandwich" method.

There are many reasons for this, economic, pedagogical, and otherwise, but if it is thought that the writer is wrong just consider M.I.T. with three such courses, N.Y.U., Marquette, the University of Cincinnati, Georgia Tech., Detroit Institute of Technology, and some other schools in the engineering field alone that any one can find out about for himself. The same method is also used in some schools of medicine, liberal arts, and business, and quite effectively, Dr. Abraham Flexner to the contrary notwithstanding.

Bryan Houston, manager of training for the Standard Oil Company of Ohio, led the sectional conference on education and training in the industries at the Conference on Industrial Relations conducted by the Industrial Department of the National Council of the Y.M.C.A. at Silver Bay, New York. Mr. Houston remarked that salesmen, because of their greater articulateness and because they have been beaten into acceptance of the idea that they do not know it all are frequently more ready to accept training than the manufacturing groups. Think that over. But to ward off all criticism, let it be seen that apprentices are taught oral expression. The English language is one of the most effective tools if used properly.

In closing, let it be said that the whole program of apprentice training is just a start. It is not only a means of training skilled mechanics, but also a way of interesting men and boys in continuing their education throughout their lives on a voluntary basis. And that is important for several reasons. An open-minded man is adaptable and can change his job if industry requires it. The man with a closed mind operating on the knowledge that he obtained, say, ten years ago, in high school or college and in industry, is a nuisance to himself and to others. He cannot change jobs to save his life and he is an important element in the social lag that complicates so many problems of the day.

Support schools. It pays to do so. We need a Federal Department of Education that will cover every branch of this great field, with a separate cabinet officer at its head. In this way we may get business, industry, and education coordinated as they must be to secure the balanced progress we so sadly need.

Let the writer close with the words of Harvey N. Davis in his opening address at the Silver Bay Conference: "The stake that industry stands to lose if a balanced progress, material, cultural, and spiritual, is not attained may be its own existence, but the stake that industry may play to win is an honored place in a civilization far finer than any of which this generation can even dream."

JOHN A. MCCARTHY.[6] While interested in this type of industrial training, the writer feels that he cannot with justice discuss any of the statewide problems in this development in Virginia since we in New Jersey have many problems in the same field which we have not successfully solved. Mr. Bailey presented an apprenticeship-training program which has been established under ideal conditions in the Newport News Shipbuilding Company. The main features of this program were outlined in a wonderful manner by Mr. Via at the American Vocational Association Convention in New Orleans just a year ago.

The writer is interested in the three laws which Mr. Bailey sets up for the guidance and administration of a successful apprentice program. The factors used in the selection of apprentices, such as initiative, self-control, and determination, are factors that are not easily measured in a selection process. It is true that these factors may be observed while the boy is still in school and before he enters his apprenticeship in the industry, but it must be remembered that these factors can be observed only through behavior, which is much influenced by environment. Those who come from industry realize that the environment of the pupil in the school is entirely different from that of industry. The things which are prohibited in school and which produce one set of behaviorisms are required in industry with probably a different kind of behavior resulting.

The writer is not sure that it is advisable to set up high-school graduation as a requirement for apprenticeship in all trades. Even in a shipbuilding organization there are trades which can be successfully mastered by boys who have completed only the seventh and eighth grades. Perhaps high-school graduation is set up as a measuring device which will insure a selected group with high intelligence. There are more scientific means of measuring intelligence, however, than merely requiring high-school completion, and many boys who have been retarded in school because of illness or migration of parents will be found to have an equally high I.Q. as those who have graduated from high school. In using high-school completion as a standard, we are confusing schooling with intelligence and are missing a group of boys who may have more desirable aptitudes for trade training than those who have had greater educational opportunities.

The second and third laws which Mr. Bailey establishes are fundamentally sound—particularly the third, which sets up management's responsibility in the program. At the present time it is unfortunate that many large manufacturing organizations are dropping their apprentice-training program because of a business depression. These organizations are not releasing their mining properties or other sources of raw products, as they know that there will be a return to prosperity with a demand for such raw material for the factory production. Only two years ago there was a decided shortage of skilled tool makers along the Atlantic Coast, and the very industrial organizations which have now dropped their apprentice-training programs were suffering because of that shortage. The shortage will be more acute when prosperity returns.

[6] State Supervisor of Trade and Industrial Education, New Jersey Department of Public Instruction.

Employers in the building trades are notable offenders in this respect, and as a result of the present depression in the building trades, hundreds of so-called "half-baked" mechanics will be found on building operations when building is resumed. Boys are engaged as apprentices and held on the job during a building operation to be dropped at the first ceasing of work on that operation. When a new job is started, in most instances new apprentices are engaged.

The writer is interested in Mr. Bailey's outline of studies for an apprentice group, particularly since such an outline included chemistry, economics, principles of accounting, and psychology. There is a responsibility for determining just what trade skills are involved in an apprentice-training program and then determining what mathematics, science, and drawing are necessary for these trade skills. Anything beyond that must be classified as broadening or cultural subjects. Too many apprentice programs are spoiled because the objectives of this program are to develop trained mechanics, and the technical training program set up is far beyond the needs of the mechanic, being intended for developing engineers. Of course eventually a far-seeing organization is looking to the development of supervisors and minor executives through their apprentice program, but the first job should be to develop the mechanic and then to set up another training program for those mechanics who give evidence of ability for supervisory positions.

The Federal Board for Vocational Education has made many wonderful trade analyses for the purpose of determining what a trade-training program should include. The most notable of these is Bulletin 52, an analysis of the machinist's trade. If attention is given to such analyses when a trade-training program is being developed, a more effective training program will result.

Mr. Bailey emphasized the development of the heart, as well as of the head and the hand. Recently those in trade and industrial education have considered this from the viewpoint of morale. It is expressed in the Allen-Richards formula, which also is outlined in Bulletin 52 as the factor "Mo." Morale has to do with the spirit of the individual or the group and should not be confused with morals. Morale may include some factors which are found in morals, but it is possible for good industrial morale and poor morals to be combined in the same individual. A study of failures of young persons in industry indicates that most of these failures are due to poor morale rather than to any deficiency in trade skill or technical knowledge. Most employers are ready to accept young workers with good morale even if they have limited trade ability.

Mr. Bailey also mentioned the importance of foreman training if a successful apprentice-training program is to be carried out. Foreman training assists the apprentice-training program because the foreman himself has a better view of his own job and a better appreciation of the difficulty of other workers in his organization. Then, too, the foreman is the individual with whom the apprentice has his industrial relationships. Unless the industrial organization is a very small one, the apprentice never meets the superintendent or representatives of the management. It is important, therefore, that the foreman know his job, and he should be trained in the best teaching methods to use during the learning period of the apprentice on the job.

The writer's chief comment on the paper prepared by Mr. Falk on "Apprentice Training in Wisconsin" is that we in New Jersey are envious of the Wisconsin apprentice law. We wish that we had a similar law; we are certain it would materially assist in solving the difficulties now experienced in apprentice training. The Wisconsin law makes it possible to properly organize and supervise apprentices. Without such a law, apprentice training is usually unorganized. No adequate training standards are established, and the ethical practices of both employer and apprentice are questionable. We have been attempting to coordinate the apprentice-training activities within the state, but unfortunately such an important training program is left to local districts and employers without any legal means for supervision and control.

We are hopeful, however, that some day we may be able to profit by Wisconsin's example and place our apprentice training on a more sound basis.

MAN-53-2b

Apprentice Training Movement in Wisconsin Industry

By HAROLD S. FALK,[1] MILWAUKEE, WIS.

The apprenticeship movement in Wisconsin has been made a concerted organized effort. In developing the work important considerations and tendencies have been taken into account, such as the shortage of skilled mechanics in American industries at the present time in spite of considerable unemployment, the requirements of production as well as of jobbing industries for trained men, and the importance of the human factor in all industry. Employers and employees have cooperated in the promotion and support of an apprenticeship law in the state which stabilizes and dignifies apprenticeship by preventing exploitation of boys and by setting standards of workmanship in the trades. As a result of public favor and the enthusiasm of influential individuals, apprentice training has developed rapidly in the state. There are 3350 apprentices employed and 2567 have graduated in the last 15 years. At the present rate of graduation, this number will be increased very much in the next 15 years.

However, neither the Industrial Commission nor the industrial leaders are satisfied with the progress which has been made. The number of apprentices in the state is inadequate compared with actual requirements for skilled men in the trade. Nevertheless, an excellent foundation has been laid upon which greatly increased activity may be built in future years.

THE apprenticeship movement in Wisconsin industries has attracted much attention in recent years, not so much perhaps because of the number of apprentices in actual training, although the number is considerable, but more particularly because apprenticeship has been made a concerted, organized effort. In most industrial and commercial communities there are and always have been employers who have given young men apprentice training on their own initiative and according to regulations and customs which they themselves have established, largely upon a basis of tradition. Such independent apprentice training programs include some of the finest institutions of the kind to be found anywhere. However excellent as these training programs may be, they can afford opportunity only to those young men who happen to be employed in these organizations. In order to make apprentice training a social factor on the one hand, whereby organized experience may be provided for the maximum number of those who wish to follow skilled trades, and on the other hand to provide a proper quota of skilled mechanics for the industries of the community, the training of apprentices must not be carried on merely by one or the other random employer, but must become a general institution in as many business and manufacturing establishments as possible.

An attempt has been made in Wisconsin to build an apprentice-training system which shall satisfy these requirements. Employers usually resent what is ordinarily called meddling in their affairs on the part of state government. However, Wisconsin employers were themselves largely instrumental in the passing of the apprenticeship law whereby the Industrial Commission of Wisconsin is authorized and enjoined to direct and supervise the training of young men in the industries. In many trades and industries committees have been appointed which cooperate with the Industrial Commission and direct the apprentice affairs of their respective organizations and promote the movement in every way practical. As a result of all this, apprenticeship in the state has achieved a dignity and a stability which would not be possible otherwise.

In the development of this apprentice-training work, certain fundamental considerations had been recognized and taken into account. For instance, organization seems to be a keynote of all modern activities. Business men depend upon organization, not only for success, but even for survival. They have organized their purchasing, their finance, their accounting, their manufacturing, and their selling. Is it not reasonable, therefore, that they should organize the training of men for industry? Men are the most important factor in industry. Accordingly, the training and development of men should be even more highly organized than other business and commercial departments.

Again, in spite of considerable normal unemployment at all times and a serious unemployment situation at the present time, the fact remains that there are not enough highly skilled mechanics in our industries. In fact, in some parts of the country, according to reliable reports, there is a distinct shortage of skilled mechanics even at the present time. The term highly skilled mechanic is here taken to mean an artisan who is fully qualified in all branches of his trade and not merely in one operation. It is taken to mean a man who can act on his own initiative, plan his own work and carry it out, and solve his own ordinary problems without assistance. According to this viewpoint, a machinist is not a man who knows how to operate a milling machine or a boring mill; he is a man who thoroughly understands the operation and the maintenance of all standard machine tools and is sufficiently familiar with their fundamental principles to grasp the construction and operation of all kinds of special machines.

It is sometimes maintained that men of this type are no longer needed because of the rapid introduction of automatic machinery in modern manufacturing plants. While it is no doubt true that the relative number of skilled mechanics in modern industries is less than formerly, nevertheless the skilled mechanic cannot be dispensed with and is required in great

---

[1] Vice-President and Works Manager, The Falk Corporation. Mr. Falk was graduated from the University of Wisconsin in 1906 and entered the employ of the Falk Corporation as assistant to the superintendent. In 1923 he was appointed to his present position.

Contributed by the Standing Committee on Education and Training for the Industries and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

numbers. Even the most highly developed mechanical manufacturing plant requires trained men for the planning and supervision of work, for the adjustment and repair of machinery, and for the building and maintenance of the many fixtures and appliances without which automatic manufacture is impossible. Moreover, many essential industries cannot be established on an automatic basis. In the manufacture of locomotives, ships, machinery for power plants and steel mills, for instance, skilled mechanics will be employed for years to come just as they have been in years past. After all, only a limited number of commodities are in such demand that thousands of units must be produced every day so that automatic production may be justified.

In the development of apprentice training for Wisconsin industries, these various factors and many others were kept in mind and they served as a basis for planning the work.

The Apprenticeship Law

The apprenticeship law of the state has a twofold purpose: to prevent exploitation of boys and young men and to establish and maintain high standards of skill in the trades and industries.

The decline of apprentice training with the close of the last century was no doubt due in large measure to certain abuses which had developed. Boys and young men were engaged as apprentices, but were actually employed as common laborers. In many cases no systematic instruction was provided and they were given no change of work. If a boy happened to become proficient in the operation of a screw machine or in the making of a certain mold of which a large number were required, he was kept on those operations indefinitely, regardless of the restriction thus imposed upon his training, merely because the foremen or department head was too indolent to break in another operator.

The law is intended to do away with this evil. It provides close supervision of the work of apprentices by the state, so that conditions of this kind are practically impossible.

Again, the standards of skill in a trade or industry will depend almost exclusively upon the training which is given. In those trades in which high standards of apprenticeship and instruction are regularly maintained, high standards of workmenship can be found. On the other hand, when training is neglected, a low grade of skill prevails, such as exists at the present time in only too many industrial and building trades.

In order to secure high standards of training, the law requires that the Industrial Commission of the state must approve all work programs for apprentices, and if these work programs are not sufficiently broad and not sufficiently strenuous, they are rejected, and the employment of an apprentice under the plan is forbidden.

The various provisions of the law have been established in order to carry out its twofold purpose. In the first place, the law requires that all apprenticeship agreements must be executed in writing in three copies, of which one copy goes to the apprentice, one copy to the employer, and one copy to the state, so that an official record of the apprenticeship and of the work to be done shall be found on file with the state. The agreement, or indenture as it is called, must contain the names of the parties and the age of the apprentice, the trade or occupation which is to be taught, the number of hours to be devoted to work and the number of hours to be devoted to school instruction, the schedule of work or processes, the schedule of compensation to be paid, a statement that a certificate will be furnished the apprentice upon completing his course, and any special provisions which may exist, such as the payment of a bonus for the completion of the course.

The law requires that every apprentice must be 16 years of age or over and that he must attend school four hours per day during the school year until he has completed 400 hours of school work. Hours of overtime work are limited. Also, a penalty is provided for violation of the indenture by either the employer or the apprentice. The Industrial Commission is appointed by the law to supervise apprenticeship in the state, and all public school officers are required to provide facilities for the instruction of apprentices in their respective communities.

The apprenticeship law was passed at the urgent request of representative groups of employers and mechanics in 1911. It has been revised a number of times since then.

Although the Industrial Commission of Wisconsin is charged with the administration of the apprenticeship law, only important and final decisions are left to the commission itself. The practical management of the apprenticeship affairs of the commission is intrusted to a supervisor and several deputies. It is the function of the Industrial Commission to issue such rules and regulations as may be necessary for carrying out the provisions of the apprenticeship law, to approve indentures or contracts which are not valid without such approval, to adjust grievances which may arise between apprentices and employers regarding the fulfilment of the provisions of the agreement and other matters, to issue certificates of graduation to apprentices who have completed their course, and to cancel apprenticeship agreements when it appears necessary to do so. After a probationary period of three months has been passed, the indenture may not be canceled except by the Industrial Commission and only for valid reasons.

The commission carries on a promotional campaign at all times in order to develop apprenticeship in the state as much as possible.

In the administration of the apprenticeship law, the Industrial Commission has been eminently far-sighted and reasonable. Decisions have been made carefully and with due regard for the attitude and position of all parties concerned.

The regulations and decisions of the Industrial Commission regarding apprenticeship are based very largely upon the advice and assistance of joint trade committees which have been established. These committees are made up of three or four representatives appointed by the employers' association of the trade or industry in the state and an equal number of representatives of the mechanics. These committees meet under the auspices of the Industrial Commission and determine, first, the length of apprenticeship which shall be standard in the trade and, secondly, in a general way, the course of work to be pursued by the apprentice during this time. Thereafter, the committee meets at suitable intervals to advise the commission in the adjustment of the problems which arise in the administration of apprenticeship and in the correction and adjustment of the apprenticeship policy of the commission.

In addition to these various trade committees, there is a general advisory committee, composed of representatives of employers and employees, which consults with the commission in those matters which affect apprenticeship in all trades, but which do not involve the peculiar problems of any one.

School Requirements

Compulsory school attendance for apprentices is one of the most important features of the apprenticeship law and probably the outstanding characteristic which distinguishes modern apprenticeship from the apprentice training courses which began to disappear about 30 years ago. This legal requirement places school attendance where it belongs as an essential and adequate training and not merely a finishing touch which the employer may add to his course or omit as he wishes. The law recognizes that schools for apprentices in the ordinary

shop are out of the question because of lack of organization of the work and lack of suitable instructors and equipment. Moreover, the atmosphere of the manufacturing plant is not ordinarily conducive to effective study.

Accordingly, the apprentices are required to attend the local vocational school four hours per week during the school year in order to receive the related instruction necessary for their apprenticeship, and the school authorities are made responsible for proper teaching of mathematics, blueprint reading, elementary science and mechanics, industrial subjects, and even some cultural subjects.

Individual instruction has been instituted in most of the apprenticeship classes so that each apprentice may progress as rapidly as his ability permits. Although the law requires that each apprentice shall attend school until he has completed 400 hours of school work, the Industrial Commission reports that the majority of apprentices are required by their employers to attend the vocational school during their entire apprenticeship, which is satisfactory evidence that the value of school work is appreciated by the employers in the state.

In those communities in which no vocational school has been established, special classes are arranged under the supervision of the State Board of Vocational Education, and part-time instructors for these classes are secured from the local trade or industry or from the members of public school faculties. In other cases a number of communities together engage an instructor in a given trade who divides his time between the communities. The salaries of these itinerant teachers are paid partly by the federal government, partly by the state, and partly by the local communities, just as in the case of regular vocational teachers.

Growth of the Movement

Favored by public interest and the enthusiastic support of influential individuals, apprentice training in the state of Wisconsin has developed rapidly in recent years. A total of 3350 apprentices are employed in the state, distributed in 10 building trades, 11 metal trades, 15 printing trades, 6 garment trades, 5 automobile trades, 11 railroad trades, and 22 miscellaneous trades. Between August 1, 1915, and August 1, 1930, a total of 2567 apprentices had completed their courses. This may not appear to be a great number, but two factors must be taken into account. In the first place, there were very few graduations in the earlier years of the movement. At the present rate of 325 apprentice graduations per year, the next 15 years will show a great increase in this number. Also, it must be remembered that Wisconsin is not one of the outstanding industrial states so far as total value of product and number of employees are concerned.

By far the largest group of apprentices is employed in the metal-trades manufacturing industry, and as this industry in Wisconsin is centered very largely in and about Milwaukee, the development of apprenticeship in the shops of the Metal Trades Association of Milwaukee may present a fair picture of the growth of the movement in the state. Apprentice training of one kind or another had been carried on in a limited way throughout the machinery-building industry of the state metropolis. It appears that the first concerted effort for the development of apprenticeship in the industry was made in 1901 when the Milwaukee Foundrymen's Association (no longer in existence) appointed a committee to investigate apprenticeship, and this committee recommended that all members of the association adopt a plan of apprenticeship which had been established by the National Metal Trades Association. Apparently there were very few apprentices in training at the time, and the training must have been haphazard and disorganized.

In 1905 the important machinery builders and foundries of Milwaukee united in an organization known as the Metal Trades and Founders Association, and one of the purposes of this organization was the promotion of apprentice training. A survey made at the time disclosed 217 apprentices employed in the shops of the members, although it is not known among which trades these apprentices were divided. In 1908 a new committee of this organization was appointed, and it recommended a uniform apprenticeship contract and the awarding of a diploma. In the following year this committee adopted 11,000 hours as the term of apprenticeship and established pay rates of 10, 11, 12, and 15 cents per hour during each of the successive four years of the apprentice course.

It was at this time that the need of a law was felt in order to stabilize and dignify apprenticeship work, and members of this committee took an important part in the deliberations which preceded the enactment of the law in 1911.

In that year there were 460 apprentices in the shops of the members of the National Metal Trades Association in Milwaukee. This number has grown to 1068 at the present time. The total number of employees in the member shops is ordinarily in the neighborhood of 20,000, so that there is about one apprentice for every 16 or 17 employees.

In these machinery-building plants, apprentice graduates have become an important factor in the development of strong organizations of mechanics, foremen, inspectors, engineers, and other highly trained personnel. In many of the plants, the apprentice graduates have become the principal source from which important members of the organization are recruited. In one large organization which operates three foundries, no molders have been engaged for a number of years other than graduates of their own apprentice-training program. This may be considered a singular achievement in view of the attitude of American people toward the foundry trade. In another large organization no foremen have been hired for ten years or longer other than graduates of apprentice courses in the plant, with the exception of department heads who have become members of the organization when smaller manufacturing plants were absorbed.

Evidence of the prestige which apprentice training has acquired in the community is the attitude toward apprenticeship of the people in the community in general. For instance, public school officials cooperate in the work, which is somewhat surprising in view of the fact that the traditional attitude of the school principal is that higher education is or should be the chief goal of all primary school and high school students. In three of the city high schools, apprentice supervisors have been invited to address the students on the benefits of apprenticeship in metal trades shops. Supervisors have also addressed students in three suburban high schools. In one of the high schools, which is located in a very fine residential district, the principal has permitted a foundry representative to recruit steel-foundry apprentices from the members of his senior class at the close of the school year. High school students are frequently conducted through shops under the supervision of apprentice directors in the plants. The result of this public attitude is that there are many more applicants for apprentice training in the shops of the city than can be accommodated, and practically every plant maintains a considerable waiting list from which the best applicants may be selected.

The apprentice-training work of the members of the Metal Trades Association of Milwaukee is carried on under the direction of a major committee of five plant executives who meet once or twice a year to direct policies and decide important questions and a general operating committee made up of apprentice directors and supervisors which meets monthly and

carries out the plans and directions of the major committee. These committees cooperate with the Industrial Commission, and through their efforts apprentice training in the Metal Trades Industry has been standardized to a large extent.

Moreover, excellent progress has been made in other trades and industries. The Industrial Commission of Wisconsin has available considerable information regarding the work in a number of the important trades. In the building trades, for instance, the plumbers have made great strides. Nine years ago there were only 20 indentured plumbing apprentices in the state. At the present time there are 458. This excellent showing has been the result largely of the influence of certain persons in the business who have taken an active interest in promoting apprentice training. The state advisory committee of the plumbers has been very active, and the state plumbers associations are in close contact with the Industral Commission. Four itinerant instructors for plumbing apprentices are engaged, and their services are available to 16 different cities. In 15 of these cities there are local joint apprenticeship committees for the plumbing trade.

There are 46 indentured apprentices in the painting and decorating trades. The promotion of apprenticeship in this trade has been rather difficult due to the fact that the majority of the employers are not members of any single association and many of them have not themselves completed a full apprenticeship in their trade. Three itinerant teachers are employed and serve 12 cities, although their services are not limited to the teaching of apprentices, but classes are held also for others in the trade. In an effort to develop apprentice training in this field, the Industrial Commission has held a number of mass meetings for employers and journeymen, and these meetings will be continued in the future.

In the electrical trade, 62 apprentices are employed in the state, and three itinerant teachers are provided for 12 different cities. Interest in apprenticeship has been stimulated largely by the itinerant teachers, as electricians themselves have as a rule shown little interest.

Although the carpenter trade is the most important of the building trades and has the largest number of workers, there is such a diversion of specialties and lines in the trade that apprenticeship has not flourished as it should and only 73 apprentices are indentured. In the bricklaying trade, conditions are much better, with 173 apprentices. Most of these are employed in closed shops, and the promotion of apprentice training in the trade has been the result almost altogether of the cooperation and energy of the labor organizations.

In the printing trade there have been labor troubles in recent years which have had a detrimental effect upon the development of apprentice training. Nevertheless, 72 apprentices are employed, and it is expected that this number will be increased very shortly.

Work Only Begun

It must not be inferred that the Industrial Commission of Wisconsin or the leaders in any single trade or industry of the state are satisfied with what has been accomplished in apprentice training. The extent and development of the work appear strikingly inadequate when it is compared with the number of persons engaged in the various trades and industries and the requirements of the trades and industries resulting from natural growth. In speaking before this society in 1924, Dr. Magnus Alexander, of the National Industrial Conference Board, pointed out that 5 per cent of the skilled employees in every industry are lost every year as the result of death, retirement, transfer to other occupation, and other normal causes. Accordingly, there should be graduated in every trade a sufficient number of apprentices per year to replace the 5 per cent who are thus lost. And to graduate 5 per cent of the total skilled mechanics per year, it would be necessary to employ a number of apprentices equal to at least 20 per cent of the total skilled mechanics in the trade. It is perhaps unnecessary to explain that such a large quota of apprentices is probably not employed in any single trade or occupation in the state. However, the movement has been started, methods have been established and proved to be successful, and upon this foundation it must be possible to build in the years to come a constantly increasing apprentice-training activity which should in time be adequate.

Law Not Essential

Also, it would be a mistake to assume that a state law is in any way essential for successful apprentice training. Excellent proofs to the contrary are the very fine apprentice-training programs which have been carried out in important industries for many years in states in which no apprenticeship law has ever been passed and in which none is contemplated. After all, the individual employer can establish apprentice training if he wishes to do so and is willing to give to the subject the amount of time and attention which is necessary. The law, after all, merely standardizes and recognizes the apprentice training and provides an agency through which apprenticeship may be promoted and controlled. Undoubtedly this is of great benefit to the apprenticeship movement, but it would be absurd to state that apprentice training cannot be carried on without a state law. After all, successful apprenticeship must always be the result very largely of the enthusiasm and energy of far-sighted individuals, and unless these are to be found in the trades and industries, a law would never come into being in any case. The Wisconsin apprenticeship law is the result and not the cause of such energy and enthusiasm.

Discussion

Fred H. Colvin.[2] An outstanding feature of the paper is the statement at the end of the first paragraph, "In order to make apprentice training a social factor," etc.

While more and more machine operations are bound to be done on automatic or semi-automatic machines, there always will be a need for skilled mechanics to set them up and keep them in operation. Likewise the need for, and the possibility of, improved machines is as likely to be realized by bright men in the shop as by engineers in the designing department.

The sooner it is realized that this is an age of cooperation in such matters rather than of haphazard individual effort the better.

There is, however, a place for individualism in apprentice training; in the handling of the apprentices themselves. Boys differ widely in temperament, which may reflect home conditions that vary greatly. This does not mean favoritism, but rather an intelligent study of individual characteristics and possibility. The diffident boy will benefit by encouragement and the overaggresive lad by judicious repression, to the improvement of both and the development of first-class material.

[Further discussion of this paper jointly with that of C. F. Bailey, by E. W. Kempton, Morris S. Viteles, L. P. Arduser, and John A. McCarthy, will be found following the Bailey paper.]

Author's Closure

In reading over the discussion and comments which were made concerning the papers by Mr. Bailey and myself, it is gratifying to find so many people, representing so many different attitudes and fields of activity, who apparently are fully in agreement with us. In fact, it seems remarkable that the movement does

[2] Editor, *American Machinist*, New York, N. Y. Mem. A.S.M.E.

not grow more rapidly when it very seldom if ever happens that any organized, coherent arguments against the apprentice-training system are formally presented under conditions which make it possible to answer them effectively. For instance, it is very seldom that a speaker appears at a meeting of this kind and opposes apprentice training.

Here and there something appears in the discussions which is startling in view of our experience at Milwaukee, but local conditions may be so different in other places that they may justify what would be considered radical procedure in Wisconsin. For instance, the question of limitation of apprentices to high-school graduates is raised once or twice. In Wisconsin it is felt that boys of common-school training can find a place as skilled mechanics in industry and may be trained for this work with much success. In fact, the majority of Wisconsin apprentices are not high-school graduates, and employers may even be found who refuse to engage high-school graduates, as they very much prefer the graduate of the eighth-grade course. It is generally accepted, however, that the high-school graduate apprentice is more likely to develop into the kind of man who can assume a responsible position.

Mr. McCarthy refers to the tendency of certain manufacturers to discontinue apprentice training at the present time because of the depression. Apprentice training, of course, must be a continuous institution. We would not close our public schools during a period of depression in order to relieve the taxpayer, because we fully realized that public education must be a continuous process. The same argument should apply to apprentice training.

Moreover, it is not merely important to maintain apprentice training during periods of depression, but it is even true that a period of depression is a better time to institute apprentice training in a plant than any other. In the first place, officials and foremen can give to the work the time which is required; secondly it is easier to find desirable candidates for apprenticeship; and finally, the public will appreciate that apprenticeship is a legitimate enterprise and not a method to get cheap labor.

MAN-53-3

A Generation of Progress in Human Engineering

By WILLIAM A. HANLEY,[1] INDIANAPOLIS, IND.

In this paper the author has considered two manufacturing plants of about the same size, and in the same state, and contrasted conditions under which labor worked in these factories 30 years ago and conditions as they are today. The subjects covered deal with nearly every phase of factory employment. Some interesting conclusions are drawn.

IN THE LAST 30 to 35 years there have been fundamental changes in the status of factory workers, many of which are not fully known to the younger generation, nor to those not intimately connected with factories. Some of these changes are so striking that conditions in the nineties will seem to many as representing a period much earlier. The object of this paper is to show the conditions which surrounded the worker at that time and those under which he works today. By worker is meant not only the mechanic or artisan, but also the man who has no trade and who is not skilled in any craft. They are the men who sweep floors, use picks and shovels, run wheelbarrows, unload cars, haul trash, handle coal or ashes, and do such other tasks requiring no especial experience nor training. Many men from the farms fall into this group. They have no unions to help fix working conditions. They are the first class reduced in numbers and wages in hard times and their employment is never very stable.

Because comparisons are sometimes unfair, the author in this instance takes two concerns with which he is very familiar. Both of these concerns were or are located in Indiana, not very far apart. The first concern manufactured iron and steel, and the second manufactured drugs and chemicals. The author's family has been intimately connected with both companies, so that the knowledge is first hand.

Both corporations had as workers a large percentage of native Americans, very few foreigners being in either organization. The concerns were about the same size, each employing about 1500 people. Both companies have been successful, although the iron-and-steel property was merged at the close of the century, and because of fuel conditions, later dismantled. Both industries were operated by men of high ideals who believed in the policy of fair play. Each concern had loyal and faithful employees.

The place of labor in industry, even of the poor common laborer, has changed and changed greatly in the last 35 years as these comparisons will show.

Wages

In 1895 the wage of the common day laborer was 12.5 cents per hr. About the close of the century this was increased to 15 cents per hr. The wage today is 45 cents per hr., or just three times what it was 30 years ago. Now 45 cents today buys about $1^7/_8$ times as much in useful and necessary commodities as 15 cents did in 1900. The purchasing power of an hour of labor has increased in just this proportion.

In 1895 all labor was paid either by the hour or by the piece. Today every job, where at all possible, is placed on a standard minutes basis and the employee is paid a bonus for all produced above the standard. This is true even of porter work.

Hours

The hours for common labor in the nineties were from 6:30 a.m. to 5:00 p.m. with 30 min. for lunch. A day was of 10 hr. and a week of 6 days This made a total of 60 hr. per week. Shopping and business transactions were limited to Saturday night; recreation and rest was limited to Sunday. In winter the worker went to the factory in the dark and came home in the dark.

Today the worker puts in $44^1/_2$ hr. per week; that is 8 hr. on Monday to Friday, inclusive, with $4^1/_2$ hr. on Saturday. Plant operations start at 8:00 a.m. and are over at 5:00 p.m. The lunch period at noon is 1 hr. The plant closes at 12:30 Saturday afternoon. It is interesting to note that the worker goes to his job $1^1/_2$ hr. later in the morning than he did in 1900, has 1 hr. at noon for lunch, where he had $^1/_2$ hr. before, and that he has Saturday afternoon where he formerly worked all day on Saturday. On a recent referendum (something unheard of 30 years ago) as to whether the employees preferred a 30-min. lunch period instead of the hour with 30 min. earlier closing, the majority vote was to make no change and to keep the lunch period 1 hr.

Hiring and Discharging

In 1900 the common laborer would be at the works seeking a job between 6:00 a.m. and 6:30 a.m. He would apply to one of the labor foremen, a man receiving about 25 cents per hr. Physical characteristics were usually his only recommendation. If hired at all, he might be kept for a long or short period depending on how he satisfied the foreman. He made no written application, his age and previous employment were not recorded, and he either satisfied the foreman or was dismissed by the foreman. It was a very simple affair, about as harvest hands are hired in the grain-producing states, yet many men advanced under the old system, crude as it was. Its principal drawback seems to have been that there was no real selection, no opportunity for the thinking worker, that many filled positions for which they were unsuited for years, and that foremen were given great powers of

---

[1] Director of Engineering, Eli Lilly & Co. Mem. A.S.M.E. Mr. Hanley was born in Greencastle, Ind., on December 13, 1886, and received his education at St. Joseph's College, Rensselaer, Ind., and later at Purdue University, where he received the degree of B.S. in Mechanical Engineering.

Mr. Hanley's first position was with the Republic Iron and Steel Co. in Muncie, Ind., in their rolling mills. He became associated with the Broderick Boiler Co. as assistant to the manager. In 1911 he joined the staff of Eli Lilly & Co., manufacturing chemists, at Indianapolis, Ind., for the purpose of developing a gelatin-capsule manufacturing plant. Some time later Mr. Hanley's duties were broadened to include the supervision of all engineering, construction, maintenance, mechanical design, power generation, and plant equipment, with the title of director of the engineering division. This is his present position.

Contributed by the Management Division and presented at the French Lick Meeting, French Lick, Ind., Oct. 13 to 15, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

discretion, and personal differences with the foreman often controlled the destiny of a worker instead of his value to the company. The records of the company showed no difference as to whether the worker was discharged for drunkenness or laid off because of slack business conditions.

At the present time the man seeking employment makes his application in writing from 24 hr. to a month or more before he expects to go to work. The application shows his age, family conditions, parentage, education, previous employment, and his own desires as to type of employment and wages expected. The man has a personal interview with an employment supervisor, especially trained in human relations. If the man is employed, this employment supervisor becomes his guide, counsellor, and friend in helping him to success in his new work. He will advise the employee on any subject from getting along with his wife and children to his family budget or buying a home. The employment supervisor has nothing to do with the actual duties of the man once he is assigned. He is then under the foreman of his department, but the employment supervisor is responsible for the employee being started in work for which he is suited, being transferred when the work is unsuited, and in getting a fair deal with the foreman. The employment supervisor is a staff officer rather than a line officer, and his rank is higher than the rank of foreman of a department. No workmen can be discharged except through and by the employment department.

Seasonal Changes

In times past there would always be a part of every year when business was very brisk and another part when it would be slack. The general practice was to hire and to lay off employees to meet these conditions. Two distinct advances have been made from the old scheme. The production demands are now anticipated, and merchandise at special terms is offered during slack seasonal periods, so that the variation in monthly factory production has been practically eliminated. This means steady work for the employees. It also does away with temporary help. The second change covers times of depression. Formerly departments were closed and employees forced into idleness. The new method is to reduce working hours instead of reducing numbers of workers. This gives all employees some income and keeps the whole organization ready to function as soon as normal conditions return.

Rest Periods

Formerly people worked 8 or 10 hr. per day continuously, stopping only at noon. Studies of fatigue, particularly on fast repetitive operations, have shown that rest periods are very beneficial. Accordingly two rest periods of 10 min. each, one in the morning and one in the afternoon, give the worker the relaxation which is so helpful to both muscles and nerves.

Safety, Hospital Facilities, and Insurance

Thirty-five years ago very little attention was paid to safety. It was expected that every man would take care of himself, regardless of the conditions under which he worked or the hazards which might prevail.

In the steel business there were several men who lost the sight of one eye and one or two who lost the sight of both eyes due to the explosion of the hot metal. There were no regulations as to the wearing of goggles, and no written instructions as to hazards which should be avoided. There was not even any provision for taking care of injuries. The author recalls very well witnessing an accident wherein a blacksmith striking at his anvil had a piece break, which made a very ugly wound on his leg. The man was bleeding profusely and the only bandage which could be provided was the napkin out of a fellow workman's dinner basket. Another injury to which the author was a witness left the workman in such a state that he could not walk. He was carried home, about two blocks away, on a door, as there were no cots or stretchers available. Another man had one arm severed on an alligator shears. No guard of any kind was provided on this shears, and when a guard was supplied it was taken off by the operator as being a nuisance to him.

The theory of the employee was that he was to take care of himself, and to this theory the employer agreed. There was no safety committee, no first aid equipment, and no medical attention provided.

Great progress has been made in 30 years, and now the plant has a well-equipped hospital with a graduate nurse on duty at all times. People who come to work in the morning with a cold or who feel indisposed from any cause are encouraged to go to the hospital and receive preventive remedies. A constant system of education is maintained in an attempt to keep the health of the workers on a higher plane. Warnings are given about living conditions which will result in tuberculosis, typhoid fever, pneumonia, etc. Minor casualties, such as scratches, cuts, or burns, must be treated immediately. A practicing physician is on hand 5 hr. out of every day to give advice and to treat the employees for minor ailments. The theory, of course, is not to replace the family doctor, but rather to help him and to keep the employee from falling into the hands of incompetent practitioners. There is no charge for any of this service.

A safety committee carefully combs the plant for hazards. Any accident causes a complete investigation, with the result that there are virtually no repetitions of accidents of the same type. Machinery is guarded carefully when it is installed, and it cannot be adjusted except when shut down. Goggles are provided where eyes are endangered, and gloves are provided where possible poisoning is involved, window washers have safety belts, and scaffolding is always erected with the thought of protecting the worker. Sometimes these goggles, gloves, etc. slow up the worker or cause him inconvenience, but the management has an iron-clad rule that these precautions must be followed out or the workman cannot go ahead with his duties.

In times of epidemics every employee in the plant will be vaccinated, have his throat swabbed or given such other preventive help as the occasion demands. The employer seems now to realize that it is just as necessary, or maybe more so, to keep his employees in good condition on the job, as it is to keep his machinery well maintained and ready for use.

Thirty-five years ago when a man died his family buried him, and unless he had provided for this contingency the family budget was given a severe blow from which it took many months to recover. For some years the company with which the author is connected has had group insurance for every person in the factory. The major cost of this insurance is borne by the corporation. For those receiving the smallest wage, there is provided $1000 for ordinary death with $2000 for accidental death. In addition there are weekly sick benefits, accidental dismemberment insurance, total- and permanent-disability benefits, and non-occupational accident benefits. The employee pays for all of the above about $1 per month. This covers the job of the least-paid employee in the organization. Those receiving higher wages go into classes Nos. 2, 3, or 4. The last class provides for $4000 ordinary life insurance with an additional $4000 in case of accidental death, and dismemberment and disability insurance. All this is at a cost to the employee of $3.20 per month.

This, however, does not tell the whole story. In the case of a person employed by the company for 5 years, who is head of a family, the company pays 6 weeks' wages to the family of such employee to cover the period in which the family are adjusting themselves and providing another income. Where the employee has been with the company 10 years, 10 weeks wages are paid,

and this keeps the family during the readjustment period from having to draw on what savings they have accumulated.

Luncheon and Recreation

Thirty-five years ago the workman had his lunch packed in a bucket or basket and brought it from home with him. The campaign of 1896 had as its popular cry, "The Full Dinner Pail." No facilities were provided around the establishment for the employee to get any food or even to keep food which he might bring with him. The corner saloon, and it is to be hoped that it is gone forever, was usually the only place he could get recreation and refreshments in or near the factory. The workman could use no recreation facilities in connection with the factory as the 30 min. provided for lunch was hardly more than sufficient to give him time to consume his food.

At this time a fine cafeteria provides food at a nominal cost to all employees, and they have one hour in which to eat, rest, or recreate. Different departments go to the cafeteria every few minutes, so that there is a steady line passing before the lunch counters and to the inviting tables. In the old days people had to eat what they brought in the department where they worked. Now a clean, well-ventilated cafeteria is the only place where lunches can be eaten around the plant.

For the interval after lunch there are provided recreation rooms for both men and women. The employees play cards, read, or relax. Each rest room is equipped with a piano, radio, or phonograph. In connection with the girls' recreation room, there is a room with cots where those who are indisposed can rest. In connection with both recreation rooms there are branch library facilities from the city library. This enables employees to use the facilities of the public library through the instrumentality of the factory.

Wash Rooms and Lockers

Thirty-five years ago scant provision was made around factories for taking care of employees' clothes and providing them with adequate wash-room facilities. Now every employee has a safe, clean place to put his clothes, and people leaving the factory are just as clean as when they come to the factory in the morning. Wash-room facilities have not only increased in numbers and been improved in type, but they are so located as to make them convenient to the employees.

The self-respect engendered in the individual, who can go on the street at the close of a day's work without the factory grime, is well worth considering.

Vacations and Holidays

In the nineties the only people who enjoyed vacations were those who worked in the office or who owned the industry, that is, salaried workers. Those who did piece work or who worked by the hour received nothing except when they were on the job.

At the present time every person, no matter in what capacity, who has been in the employ of the company one year, receives one week's vacation with pay. When they have been in the employ of the company 5 years, they receive 2 weeks' vacation with pay.

In addition to this (and the author knows of no parallel case) every worker is paid for 6 holidays in the year; that is, New Year's, Memorial Day, Independence Day, Labor Day, Thanksgiving, and Christmas. These are real holidays to the employees, and their pay envelopes do not reflect the fact that they have not worked on these holidays.

Pensions

In the old days when a workman could no longer carry on his regular task he was given some comparatively light work to do. He was compelled, however, although he had reached the age when he should retire, to continue to work.

Today a pension plan covering all employees that have reached 60 years of age is provided. This does not mean that all employees must retire at 60, because many are very active and can give good service for some years beyond that age, but it does mean that any one in the employ of the company 20 years or more, who has reached the age of 60, can retire if he so desires and receive an income for the rest of his life.

Promotions

In former times every job had a certain rate. The persons on such jobs got such a rate no matter how long they were on it. To get higher wages it was necessary to go to another job, either in the factory where they were employed or in some other establishment.

Much progress has been made, and now every employee is given a starting wage, and it is anticipated that this wage will be raised in 3 months if the employee has been satisfactory. Every 6 months the foreman of each department, with the head of the division, considers each individual case, as to whether the employee should be continued on his present job, moved to a better job, or be given a wage increase. Thus semi-annually the management carefully considers the status of each employee.

Attendance Bonus

Another feature of the modern factory is the attendance bonus. This is an extra payment over and above wages paid to those who are on time and present each day at their post of duty. This amounts to $4.50 per month and tends to create promptness and regularity.

Automobiles

In the old days employees came to work in three ways—that is, they walked, rode bicycles, or came on street cars. In a recent survey it was found that there was one automobile being driven to the plant for every four factory workers. These cars usually carry 3, 4, or 5 workers, so that at least two-thirds of all employees travel to and from the factory in automobiles. To care for these cars, parking and garage facilties have been provided by the management so that the owner can feel that his car is protected while he is performing his duties during working hours.

Methods and Standards

Another division in the organization not heard of 30 years ago is the group that visits departments, studying the duties of the different workers, and determining the one best way to do each job. Usually the one best way is both the simplest way and the easiest way. This department makes layouts, locating machinery and tools, so that the worker can perform his duties most efficiently and with the least exertion. Mechanical power, conveyors, and hoists are substituted in every case possible where human power was used in the past. Drudgery has been reduced to a minimum.

Sentiment

It has been said that there is no sentiment in business, but wherever the human heart is, there is always sentiment. On Christmas eve each year all employees are guests of the company at a turkey dinner in the cafeteria. Christmas decorations have changed the room to one of feast and pleasure. Christmas carols by trained groups of employees sing out the glad tidings. Those in the service for 25 years have a special table where they reminisce and dine with the president of the corporation. Each of the 25-year group is given a Christmas check equal to 10 per cent of his year's earnings. Following the dinner there are department parties as the afternoon is given over to recreation.

Happy faces portray happy hearts and all leave the company premises with the true Christmas spirit.

Conclusion

Having enumerated in detail many of the industrial changes, it is interesting to list the results both to the employee and the employer.

To the employee there has come: (1) The higher standard of living, (2) greater respect for himself and from his fellowman, (3) better health, (4) no uneasiness about the future because he is insured against accident, loss of heath, and old age, and (5) greater happiness and contentment.

Surely these things are worth while because they tend to raise the standards of health and citizenship, and to give greater happiness to workers and their families.

The results to the employer because of these changes have been: (1) A more highly selected class of employees, (2) fewer interruptions due to sickness, (3) no absences except for unavoidable reasons, (4) a real interest in company affairs by intelligent and interested workers, (5) a minimum of labor turn over, (6) a decrease in avoidable wastes, (7) better quality of merchandise, (8) more output per employee, and (9) no strikes and no labor problem.

The question will arise in the mind of the skeptic as to who pays for all these innovations. Are they taken out of corporation profits or are they added to the cost of merchandise? The answer is that nobody pays for them. The difference in output per employee of a factory having selected, contented, healthy, and interested employees is 25 to 30 per cent greater than the factory which regards its employees as human machines only, and this increased output pays the bill. Cost sheets for over 20 years verify this conclusion. After many years of study and experience the statement can be made that one of the most valuable asset of any corporation is a corps of loyal, intelligent, and satisfied workers, and that not only the corporation profits thereby, but a distinct service also is rendered to the community and the nation.

MAN-53-4

Management by Exception

By CHESTER B. LORD,[1] NEW YORK, N. Y.

The exception principle, as approved by the first leaders of industrial management, is expounded and advocated. It is described as a natural method of scientific management that directs when direction is sufficient and that compels when compulsion is called for, but that does not interfere with matters which are progressing in orderly compliance with a planned procedure, but which has positive methods of detecting and correcting variations from that procedure. Four rules of management by exception are stated.

WITH scientific management came the problem of its application to industry. The principles laid down by Taylor were epochal, but a positive method of applying them to industry was lacking. As a result each one who accepted the principles interpreted them and applied them according to his own experience or understanding. It is not surprising, therefore, that there sprang up almost as many schools of management as there were engineers. Neither is it strange that, in some cases, system became paramount and in the course of time was considered a major factor of management control instead of a mere expression of individual opinion or preference as to the method to be followed in applying management principles.

In his day Taylor was accused of not knowing how to handle men, while Gantt disagreed more or less violently with some of the higher executives and was called intolerant. It seems impossible today for any one to review the work of these two men and say that they did not understand other men or that they did not have the executive viewpoint.

Taylor and Gantt were practical. The principles they advocated were the result of many years' labor and experiment. Therefore they spoke a language different from that of many who attempted to apply Taylor's principles and who inferred the principles were at fault when the application failed. It seems more probable, in the light of the later work and utterances of both Taylor and Gantt, that both men were exasperated by opposition and disappointed because there was no existing mechanism into which they could permanently transfer the skill and knowledge they possessed. Hence Taylor's impatience and his insistence upon his own interpretation being followed. Gantt was similarly situated. He believed that many of the higher executives were opposed to scientific management. The real trouble, however, was that the executives could not visualize cause and effect on such a scale as Gantt himself could.

Robert T. Kent described the situation in his paper on the "Use of Economic Manufacturing Quantities" in the following words:

"In introducing scientific management methods, one of the prime requisites of success consists of so regulating the dose to be given that all the medicine will be effectively and completely absorbed. In other words, it appears essential that those who have delegated themselves to the job of introducing the application of science to industry must prepare themselves to be satisfied with accomplishment which falls far short of the goal which they are able to visualize. . . . Some of our most learned and accomplished disciples of scientific management have fallen far short in the accomplishment of results by not being willing to be satisfied with a 30 per cent accomplishment of the goal rather than 100 per cent accomplishment."

This is what both Taylor and Gantt failed to realize.

That Taylor, Gantt, and other leaders in industrial-management methods recognized the deficiencies in systematic management is proved by their continued advocacy of the exception principle. Taylor asserted that the extension of the principle to every field of industry was a vital necessity. Gantt labored continually to make it possible. Gilbreth visualized its necessity in management and the benefit to be derived from its use even more definitely. As far as can be learned, he was the only one who visualized its extension to minor executives. He declared that it apportioned the load to the shoulders which must bear it, that it made good executives of mediocre ones, and gave good ones more time for constructive planning.

Under the circumstances, the natural question is: If the importance, and even the necessity, of using the exception principle was recognized by these and other leaders who had the power and the opportunity to use it, why was not some definite action taken toward its introduction? The same circumstance that handicapped the introduction of scientific management and caused the teaching of Taylor and Gantt to be futile in many cases, also prevented the introduction of management by exception. This was the lack of the proper mechanism for its introduction.

The striking thing about the whole matter is that these men should have been so insistent upon the use of a method of management that had no history, no rules for its application, and not even a clear definition. In spite of these deficiencies, the desire for exception management has always been inherent in people of the executive type, and it is used by them to the limited extent that their businesses will allow. This desire for its use undoubtedly arises from an instinctive knowledge that there must be some natural method of management that directs when direction is sufficient and that compels when compulsion is called for, one that does not interfere with matters which are progressing in orderly compliance with a planned procedure, but which has positive methods of detecting and correcting variations from that procedure.

It is possible that the knowledge of such a type of management is inherited from a line of ancestors who used that method of bringing up their children, and it may also be possible that such a method of bringing up has been responsible for the executive type.

When exception management is contrasted with systematic

(The static chart without indicators is the permanent plan of the items shown across the top. The faint titles are planned exceptions, typed in red.)

management, it is no longer strange that the former has not been extended to every field of industry, as Taylor advocated. Systematic management assumes theoretical conditions and seeks to control exceptions by making those conditions paramount. Exception management, on the other hand, makes system subordinate to an exception, and must therefore visualize actual conditions in order to function.

The very first rule of exception management is that *"Consistency of procedure must never interfere with an obvious exception to that procedure or to its system."* Because it cannot be theorized or systematized, it has been utilized, as stated, only by the higher executives, and by them only as far as they can depend upon their immediate subordinates for accurate information.

Alford, in his "Laws of Manufacturing Management," reflects the former limitations upon its use by the way he expresses the law. The law of exceptions, as given in his book, reads:

"Managerial efficiency is greatly increased by concentrating managerial attention solely upon those executive matters that are variations from routine, plan, or standard."

It is obvious that, if the use of the exception principle is confined to the manager alone, and cannot be extended to include his subordinates and their subordinates in turn, it becomes merely a rule for managerial efficiency. Such is not the intent or limitation of the law of exceptions.

Because of the vagueness surrounding the history of the exception principle, the lack of rules for its application, and the apparent limitation of its use, it is natural to question whether it can add to systematic management anything that it does not at present possess. Briefly, the answer is that it gives, in fact compels, an entirely different management—one of exceptions instead of details.

In practice, the use of the exception principle separates manufacturing management into two distinct types, and these again into components having a common denominator. It divides the elements of manufacturing and management into constants and variants, and eliminates the constants from further consideration. It separates the variants into planned and accidental exceptions and ignores these also unless, and until, they vary from plan.

It plans permanently in terms of denominators that make all elements comparable regardless of their quantity or nature. It divides material, makes one portion a constant, and automatically balances inventory with much less investment than is usually necessary. In manufacturing, it eliminates schedules, progress charts, and calendar dates, and makes the use of work and material orders optional. It automatically separates the duties, directs the actions, and limits the responsibilities of different ranks of individuals in proportion to their capacity and authority. Further, it furnishes a basis of comparison for every item and provides a definite measure of individual and collective management by visualizing together the planned condition

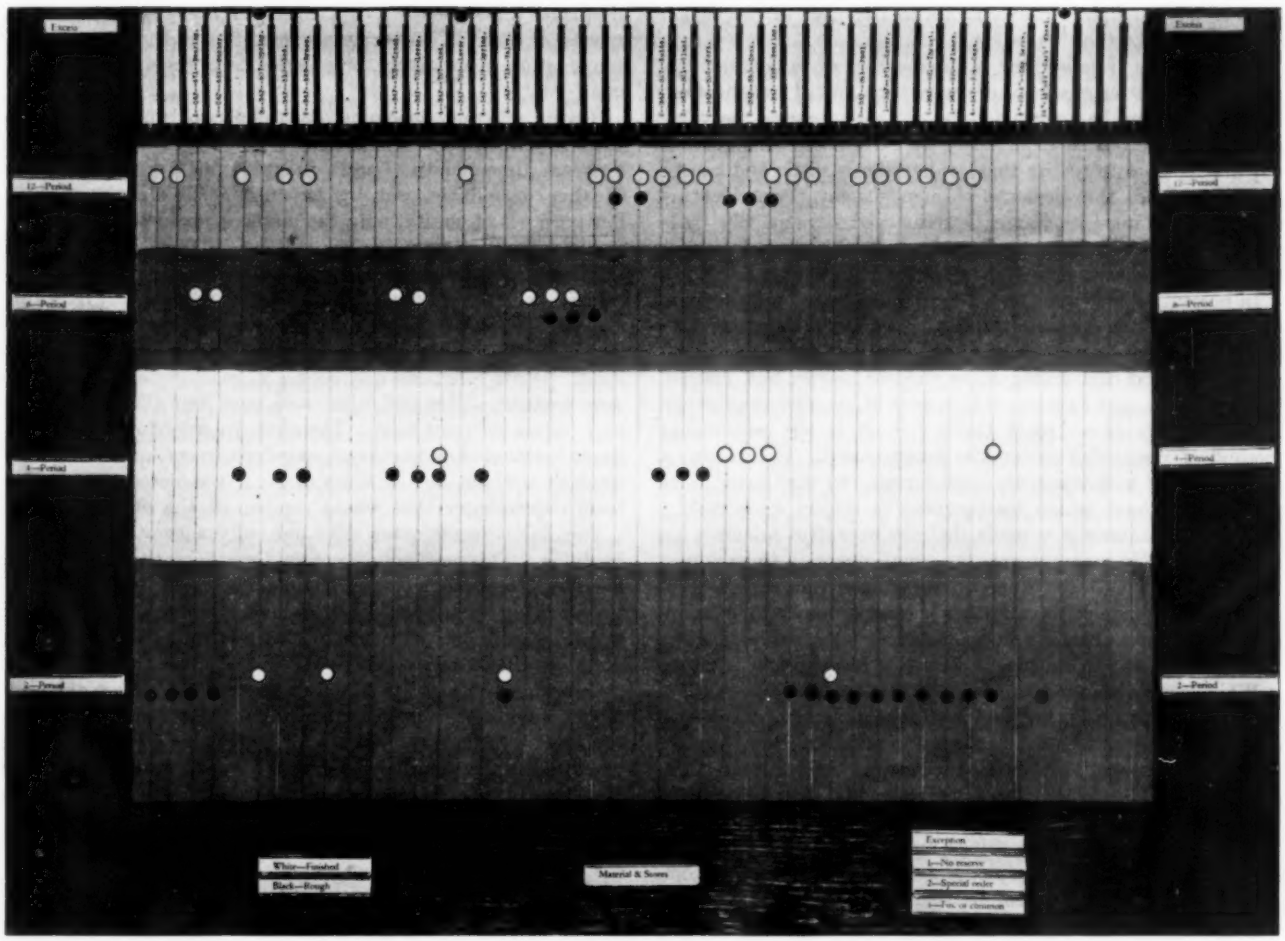

FIG. 2 THE BLACK AND WHITE PINS CORRESPOND TO THE INDICATORS USUALLY USED
(They contrast the actual condition of an item with its planned condition. The first two items from the left show planned exceptions which require no action. The next two show emergency conditions of roughly but eight weeks' supply of finished material.)

and the actual condition, emphasizing any difference between the two in definite terms. It does this by means of mechanisms into which skill can be permanently transferred, by a method of visualization that covers the entire range of possible condition, and by a forced coordination impossible under other circumstances. Summed up, it furnishes a self-corrective, compulsory method of management that functionalizes the processes of management by automatically apportioning the duties to those best able to perform them.

No longer is it necessary for the management engineer to be satisfied with a smaller percentage of accomplishment than a mechanical or accounting engineer can reasonably expect. Exception management simply cannot operate without controlling the function to which it is applied 100 per cent.

The natural reaction to such strong claims is to question whether exception management has any weak spots, and if so, what they are. Briefly, the exception principle is more dangerous in the hands of careless or mediocre executives than is system. There is such a thing as a weak system, but no such thing as weak control—it is either control or it is not. Exception management is an example of the permanent transfer of skill into definite mechanisms, similar to that transferred into an automatic machine. It follows the "law of the transfer of skill" in that "the attention and skill required to use a tool or operate a machine is inversely as the skill transferred into its mechanism."

Here also, as in the case of the machine, the "creator" must have had the skill to transfer. While it does, as Gilbreth said, "make good executives from mediocre ones," it does so because the skill of the planner has apportioned the mediocre executive a suitable load and a definite path along which to carry it.

Another drawback to exception management is that it cannot be applied theoretically. Systematic management concentrates upon influencing the mass of elements to follow a given path. It cannot visualize the stragglers. Exception management, after pointing the direction, ignores the mass and concentrates upon any items which show even a tendency to stray.

Experience shows that probably 70 per cent of manufacturing and management items will follow a planned path if not molested. Control consists in anticipating which 30 per cent will stray and when.

Reduced to its final terms, the art of management is to plan each element that enters into or affects its application. The problem of management is to forecast which of the elements will vary from its plan, when it will vary, and what will be the degree of its variation. The task of management, therefore, is to minimize and prevent variations from the planned procedure.

To do this effectively, three things are essential: First, a basis of comparison for each item; second, a common denominator that makes related elements comparable; and third, a method of visualization, in terms of the common denominator, that will compare and evaluate the different elements in such a

manner as to emphasize exceptions to the plan in proportion to the degree of their variation.

Gantt clearly visualized the requirements of exception management in the matter of a basis of comparison and of visualization, but so far as can be ascertained, he did not recognize the value of planning permanently in terms of a common denominator, nor did he seem to realize that, while plan is static and can be thus visualized, the elements of management themselves are dynamic and must therefore be visualized dynamically by a method capable of advancing or receding with the advance or recession of the element.

In presenting his chart, Gantt again emphasized the supposed opposition of the higher executives to scientific management and offered his chart primarily as a measure of management. Had he realized that management was not hostile, but, instead, was blind, he might have carried his work of visualization further. It is generally agreed that Gantt's chart is the outstanding method of visualizing systematic management. It furnishes a yardstick for measuring accomplishment, as contrasted with the plan, without which management is largely guesswork.

When the statement is made that the exception principle has not been used in management, the usual exception to rule must be allowed. H. Carter Harrison recognized its "supreme importance" in disclosing "variations between actual and standard costs," which, as elsewhere in management, means the difference between plan and execution, and applied it to cost accounting.

While accounting may be called a reflection, or result, of management, it is of prime importance as a means of visualizing conditions in systematic management. It will therefore be instructive to learn how the application of the exception principle to accounting was made possible, and why its general extension did not follow.

As has been said, three things are essential to the application of the exception principle: a basis of comparison, a common denominator, and emphasized visualization. Of these three essentials, accounting already had two—a common denominator and a means of emphasized visualization. The common denominator of accounting is value. Every item entering into accounting may be expressed in terms of the dollar or its fractions, and such items are comparable and intelligible regardless of whether they represent labor, material, overhead, or waste, because value is the product of time and quantity.

The results of accounting may be selectively visualized by grouping items into totals, by placing them in different positions, and by using different colored inks. Harrison found, however, that accounting lacked a basis of comparison and that it was not wholly effective as a means of visualization. He proceeded therefore, to set up "cost variation formulas" to compare and measure the difference between an estimated cost and the actual cost of the same item, or, as before stated, between plan and fulfilment. This made it possible to restrict the items demanding attention to those that were excessive or otherwise exceptional.

Like causes must produce like results, and if a common denominator, a basis of comparison, and a means of selectively visualizing them are applied to any other branch of management, the results obtained must be as definite as those secured in accounting relatively speaking.

As in the case of accounting, production management already had two of the three essentials. It had a basis of comparison in its planning, and it had its denominators in time and in quantity, but it lacked a means of dynamic visualization and could not therefore use its denominators.

Given these three essentials, the first thing their use does is to demonstrate that there are two distinct types of production management: one, where time is conserved at the expense of quantity and another, where quantity is conserved at the expense of time. These types are repetitive and contract type of manufacture, respectively, or as some term them, large lot and small lot.

Having different denominators, these two types of management require different treatment. There is a wide difference between time-quantity and quantity-time. Either type is equally controllable, but by an entirely different procedure. For purposes of clarity, only the methods necessary to the control of repetitive manufacture will be outlined in this paper.

The use of the common denominator of repetitive manufacture is expressed thus: *"Since time is the basis of repetitive manufacture, all elements must be presented in their relation to time."* This denominator applies only to production management. Other functions and phases of management have other denominators, and in still other cases, each item that is visualized may have a different base. Therefore, in order to visualize any single function of management, any department, or any management as a whole, on the same chart, it was necessary to use a basic denominator that would resolve all the others.

The basic denominator that naturally suggested itself was, *condition*. This not only resolves time, quantity, and value but any other denominator, factor, or element, tangible or intangible, in management or elsewhere. A moment's reflection will show why this is so, as well as how appropriate and universal condition really is.

Our whole outlook on life is in terms of the effect that different actions or lack of action will have on conditions that concern us financially, socially, or personally. When it rains, we visualize the rain not in terms of water, but in terms of the condition the rain will bring about. It is a good rain or a bad one, according as it affects conditions in which we are interested. When we refuse to eat a hearty meal just before retiring, we do not consult our desire: we reason in terms of the condition that will be brought about if we do eat it.

In manufacturing management while we plan in terms of time or quantity, we are really concerned with the conditions that will be brought about by a lack of time or quantity, or a surplus of either one. In short, from the time that we are able to reason, we do so in terms of condition. Condition, therefore, as a basic denominator, is not an innovation, but is the application of a universal basis of comparison and measurement. Everything is in some state of condition. To be able to visualize present conditions is to be able to forecast probable conditions, and thus forward or prevent them.

Condition being all inclusive, it was necessary, in order to use it as a definite measure of comparison, to have several different degrees of condition. Four were segregated and relatively evaluated. One extreme of any condition is normal; the other extreme is always called vital. Between these two extremes, two more or less arbitrary zones have been designated as attention and emergency condition, respectively. These four degrees of condition—normal, attention, emergency, and vital—are the standards of evaluation and measurement used for visualizing purposes.

The third essential of management, emphasized visualization, requires an unusual type of chart. It may be made in any desired form, provided it fulfils the requirements. The one used is of wire screen of any desired length and width. The indicators are permanently attached.

The chart that must be used has as its base the four degrees of condition mentioned above, arranged as horizontal zones. Each zone has a distinctive color, and its relative importance is emphasized both by the intensity of its coloration and by its width. The effect of this arrangement is to attract attention first to the vital zone and next to the emergency zone.

The colors used are green, blue, yellow, and red, for the normal, attention, emergency, and vital zones, respectively. The two upper zones are the operating zones. They are inconspicuous both in color and width, because they represent normal and near normal conditions. The two lower are the exception zones and are therefore emphasized.

These four zones not only indicate different degrees of condition, but also the relative rank of the individual who functions within each of them. The operating zones fall naturally into the classification of clerical and supervisory. A normal item is purely clerical. If for any reason it ceases to be normal and requires attention, a supervisor is the logical one to give it attention at that stage of variation.

The original planning does not contemplate that any item will go into the two lower zones; thus only exceptions to plan are visualized there. Such exceptions receive, first, the attention of a general supervisor or of an assistant to the executive that is responsible for the application. If this fails to arrest the variation or to restore the item to normal, it receives the attention of the executive himself, at a time and in a condition provided for in the original plan.

The four zones, therefore, when used for manufacturing management, are called normal-clerical, attention-supervisory, emergency-staff, and vital-executive. These are the basic characteristics of the chart. They are always used and understood regardless of the application and of whether they are indicated by legend or not.

Arranged thus, the chart serves a threefold purpose; first, the bare chart, with appropriate legends, acts as a common denominator and visualizes the planning. The top of the normal and the bottom of the vital zone are the extremes of the allowances of the plan. The two central zones represent stages in the plan or increments of time, quantity, or progress between the two extremes that are proportioned to the authority and capacity of those responsible for them. Legends denoting what denominators are being used and what proportion of the whole plan is assigned to each zone are placed in their proper holders. The titles of 100 per cent of the items belonging to a particular department or function are placed across the top, and the whole represents a complete plan with three different degrees of exception, each apportioned to a different degree of authority.

The third rule of management by exception states that: "*Positive control demands the visualization of 100 per cent of all factors, 100 per cent of the time.*" Such visualization is compulsory and necessary, because an exception cannot be detected until it happens, but if it is caught at the beginning of its variation it can usually be either controlled or discounted. The tendency to stray is shown by the chart, which therefore directs what action shall be taken and how long it shall continue.

The selective zone principle apportions the responsibility accurately, not by dividing the items numerically, but by dividing each item and observing the laws of specialization, division of effort, and responsibility. The net result is that the law of exceptions is amplified so that it may be read: "Efficiency in management is greatly increased by confining the attention of each individual solely to those matters within his own jurisdiction which vary from routine, plan, or standard."

The second function of the chart is to visualize the actual condition of the two elements which constitute each posted item, and to contrast them with their planned condition. Actual condition being dynamic, the means of visualizing it must also be dynamic. For this purpose, two separate but related elements of each item are indicated—one by a white indicator, the other by a black one. These related elements may be rough and finished, current and cumulative, time and progress, or any two dependent factors.

The reason for indicating two factors is the simple rule that, "from two known terms, the third, or unknown, term may be found." It is of no value to an executive to look at a chart and see that sales are above the average for the month, unless he knows what they have been for the year to date and also what they were planned to be at different intervals. Neither does it profit a production manager to be informed that a certain rough stock is exhausted unless he knows also how many finished parts are on hand and how long they will last. The "two known terms" principle is automatic and universal in exception management. Obviously it must be, if only exceptions are to be recognized.

This double indication does not require additional work or space, because they have but one title. The two indicators may have the same denominator or different ones, depending upon the application. In fabrication, for instance, they represent tools and material, respectively. In contract or similar work, one represents location or progress and the other the percentage of scheduled time that has been consumed, while on a coordinating application, where every item has either a different denominator or none at all, one indicates specific condition and the other cumulative or average condition.

A hospital is about as different from manufacturing as can be imagined, but the chart visualizes each with equal clarity. One indicator shows the temperature of the patient, 98.8 being normal and above 104 being vital; the other indicator shows whether his degree of condition is normal, below normal, emergency, or vital. Here, as elsewhere, the two known terms are necessary to arrive at an intelligent conclusion. Here, also, the zones divide themselves logically into tasks apportioned to the shoulders that must bear them. The different zones become normal-nurse, attentive-interne, emergency-house physician, and vital-consultation. In this case, the chart would be cleared twice a day to check the attention given each patient.

In applications where a deficit of time or quantity will eventually become vital, the maximum allowance or requirement is shown in the top or normal zone, and the indication is in terms of receding quantities. The chart has, when used thus, the inherent characteristic of automatically increasing the importance of an item in proportion to its decrease in time or quantity. In other cases, such as contract sales, the indicator for unsold capacity starts up from the vital zone, while the "time consumed" indicator moves down from the normal zone. The same is true of starting a contract or assembling an army. In other words, vital indications, whether receding or increasing with time, are in the vital zone at the proper time.

One of the results of indicating in terms of receding quantities is that exceptions stand out clearly. Possibly 2 per cent of the indicators get as far as the emergency zone, and less than one-half of 1 per cent reach the vital-executive zone. They are, therefore, quite conspicuous.

The third function of the chart is to act as a measure of management. The actual condition of the two related elements of an item, as shown by the two indicators, contrasted with the original plan, which is the chart itself, gives the efficiency of execution. Not only as a whole, but in four different degrees that represent the relative and actual efficiency of the individuals responsible for the different zones. This is the feature that Gantt considered so desirable. Any method of visualization that uses a basis of comparison is a measure of that part of management to which it is applied, but the visualization of 100 per cent of the items, a common denominator, and definite zones of action make measurement both comparative and definite.

The three functions of the chart—the permanent plan, the actual condition, and the efficiency of execution—constitute

a simple method of visualizing the requirements and results of management that is as plain to the messenger boy as it is to the manager.

Visualization of conditions, simple as it is, makes the use of the exception principle possible. The chart and the permanent methods it makes possible are the mechanisms into which skill is transferred to such an extent that management becomes directive and, when necessary, compulsory.

The foregoing epitomizes the difference between the two methods of management. Exception management takes any plan and reduces it to a common basis on a chart. The dynamic indicators show whether the plan is consistent, and, if not, which items need correction. Thus, over a cycle of time, the method is self-corrective, because all items having been planned to a common basis with all differentials allowed, they should normally follow a uniform procedure. Any item that lags behind or that proceeds toward the vital zone too rapidly receives the individual attention of clerk, supervisor, or staff, and each must explain to his superior the reason for the exception to plan unless he rectifies it himself. It is impossible to have a surplus or deficit of any item at any time without its being conspicuous as an exception. It is also impossible to neglect an item unless three people neglect it in succession. This and the fact that those responsible for the two exception zones are also notified by form when items are indicated in their zone constitute the compulsory feature of the method and insure action being taken to prevent exceptions as well as to rectify them.

Another decidedly important point remains to be emphasized. No method of visualization can be effective if it is used only for tickler and informative purposes, and no system of management can be effective unless it has within itself the elements of compulsion. Neither can it be automatic or definite without being compulsory, because the three terms are synonymous. No man, regardless of his station, does anything without an incentive. The only difference is that, with some men, the incentive is in front and with others it is behind.

The creative instinct of the executive type rebels at repetition. Only the detail man is content, or even able, to follow a routine day after day, and he is not considered executive material. As pointed out, this was part of Gantt's trouble. Executives, when given a task, would attack it with all the enthusiasm that they possessed as long as they could see a reason for so doing, but they failed five times out of ten in the attempt to follow a routine that was unnecessary.

The last of the four rules governing exception management covers this point effectively. It reads: "*A department shall not post any chart that directs its activities or that visualizes the results it achieves.*" This rule, like the others, is so simple that it requires no effort to observe it.

The chart applications, then, provide direction without comment and record failure without criticism. They also provide a pitiless publicity, by an independent agency, which is both an incentive and a compulsion. There are no rules as to what must not be done or what shall be done, except the four referred to. The compulsion lies in the inevitable progress of the indicators from zone to zone when actual condition varies from plan and in the notification of the staff or the responsible executive when an exception occurs.

Thus it may be truly said that exception management makes it possible for a few girls to direct the activities of a large plant. The uninformed accept this statement with wonder or skepticism, but a knowledge of condition shows the assertion to be without point because the skill of management has been transferred into a permanent mechanism, and the attention and skill required to operate the mechanism are inversely as the skill transferred into it.

At this point, three questions naturally arise. They are: How much does it cost in time and labor to post the charts? How can a large number of items be visualized? How much of the executive's time is required?

The answer to the first is that in the shop the departmental charts are the only records necessary. Because schedules, definite quantities, and dates are ignored. The production department, therefore, has practically no records to keep. It posts the departmental charts for dispatching and visualizing purposes.

The material charts usually require part time of one girl, who posts them, together with the storeroom records. The items showing on the chart are not posted every time the stock records are changed. As stated, definite quantity is ignored in planning and visualizing, and the indicators are changed only when the balance between the planned condition and the actual condition is disturbed beyond the planned limit. The visualization of material is in terms of periods of time, with an ultimate reference, of course, to quantity in the form of economical manufacturing lots.

The second question was asked by a manufacturer who had 110,000 items of material. Another asked how it was possible to visualize material with a turnover once a week. The answer in both cases was the same. Exception management has no system. It simply visualizes any system that can be consistently planned. Therefore, if a system is used, the chart will visualize it in terms of a common denominator, balance it, and forecast exceptions to it. If a plan is not followed, its adoption will make planning compulsory, and whether the material is kept track of in terms of individual parts, groups, or sub-assemblies, it will visualize the difference between actual and planned condition 100 per cent of the time.

It is not concerned about whether the turnover period is one day or one year. It merely makes the method used positive by forecasting shortages and excesses in time for them to be remedied. Preparation for a weekly turnover must extend further back than one week.

This leads up to the question of room necessary for visualization. One cannot expect to receive something for nothing, and while the method of visualization used in exception management requires less linear space than any other, it still requires room. The only application that requires any considerable space is for material, which is 20 linear feet for 1000 items. The charts, in any desired length, are usually placed against the wall or back to back in the aisles, with the bottom of the chart high enough not to obstruct the vision of persons seated. The reason for the small linear space required is that the two elements of an item are visualized under a single title instead of separately.

The third question is: With 100 per cent of the items visualized and any or all of them likely to go into the executive zone, will not the method require too much executive attention?

There are three reasons why items go into the executive zone. They are: Error in planning, failure of subordinates to rectify or prevent, and an uncontrollable exception. The first two are the responsibility of the executive, and they can be remedied by him.

Experience shows that, with material turnover periods of four, eight, and twelve weeks, less than five uncontrollable items out of a possible 1000 reach the executive zone after the material has made one cycle of turnover.

It still holds true, however, that there can be no management without a manager, and no transfer of skill without ability; but, granted these, there is no comparison between the systematic and the exception methods in economy of labor, overhead, and material.

Discussion

WM. H. GESELL.[2] There can hardly be any doubt that the modern factory that is run along lines of approved scientific-management methods does not in some degree make use of the principle of management by exception. The principle which advocates that executives and sub-executives should not be burdened with a mass of routine details connected with the execution of any function which is smoothly proceeding according to plans seems to be the quintessence of common sense.

A practical chart which would enable the executive to visualize variations from planned routine would naturally be of invaluable assistance. However, the question naturally comes to mind, How much does it cost to prepare these charts and to keep them in such a shape that they reflect the current conditions in the plant? The author contends that the use of these "visualization charts" will practically do away with records normally kept in the production department. It seems to the writer that the condition emphasized in the visualization chart can be determined only by knowing all the factors which bring about that condition. Using the author's illustration, one must first record the temperature of the sick man, and by comparison with the normal temperature then determine the condition of the patient. Similarly, one must record all the facts pertaining to the execution of a given manufacturing function. If that execution of function proceeds according to plan, there is no need to burden an executive with them. Yet they must be recorded for possible analysis and comparison should a function not proceed according to plan. In other words, records must be kept. Possibly the writer has missed the point of the author's contention because he never has used one of the proposed visualization charts.

Another thought in connection with the charts is that while they may be suitable for large businesses where thousands of employees are concerned, yet in the small factory of only several hundred employees it seems rather unnecessary to employ such a method. The introduction of the principle of management by exception into an organization is largely a matter of training the employees right down the line.

KENNETH MCGRATH.[3] The author has stated the benefits of exception management with such precision and logic that those who doubted its advantages compared with the conventional or systematic type of management are at least willing to try it.

For the last few months the writer has been considering how he could better portray certain angles of a production-control system through the use of charts.

Considering one form against the other, in the case of exception management through the aid of charts there is something which is an open book at all times and which every one from the highest to the lowest can refer to and pick off at a glance the items for which they are responsible. In the other type of management no one except the clerk actually responsible or working on the particular file in question really knows what the high spots are. Of course, he probably has been instructed to send a note to his superior when the danger point of any item in his file has been reached, but this does not have the same effect on the executive as the visual examination of charts at stated intervals.

In the early part of the paper the author spoke of the opposition that both Taylor and Gantt experienced in their installations. This is something with which one will always have to contend. Every one feels that he can give advice on management matters. Probably this is because it is not an exact science, and furthermore because of the experience all have had in managing their own affairs. Ask a man to drive a car or figure a problem on a slide rule, and if he has had no experience he will say so, but not so in matters of management.

We should not be disappointed on this account, because it is only natural when one considers that systematic management has existed as long as industry, and for that reason companies that have grown from a small beginning where their entire organization is acquainted with their existing system are naturally hesitant in what appears to them a radical, doubtful change.

The writer would appreciate it if the author would say where additional information on the make-up of the charts referred to could be had. In fact, it appears to him that the actual physical make-up of charts would be a worth-while topic for some future meeting.

GEORGE A. PAGE.[4] Historically the system presented by the author seems to be a routine successor to an executive function or individual common in factories, jobbing shops, and on construction jobs for more than 20 years in the writer's own experience and still in use in flexibly organized work. Indeed many of us have been "it."

The unconventional users of the fundamental method of management by exception were frequently men who were opposed or indifferent to Taylorism, and in one instance of the writer's own experience such an unconventional advocate of the principles of Taylor and Gantt retained the latter to promote this work only to have the alliance rudely broken because they "couldn't make sense of Gantt" and because Gantt on the other hand found them to be impervious to new ideas. Yet they were working in closer harmony than either realized.

Such "outsiders" would probably be classified in this meeting as using Taylor ideas and Gantt methods in a general way. But from the paper it appears that some would charge that to apply the principles set forth under his title through a human agency instead of as a statistical or signal system would be archaic and without method. Here the "radical" and the "mossback" began to concentrate on their differences and ignore their common views. One was charged with being "method minded," as would be said today, and the other with "standing pat" on results through inertia, prejudice, and ignorance.

But the "archaic" or "man power" application of all management principles had their particular virtues, and in the case of the "exception principle" such virtues are illustrated by four natural characteristics that the human agency possessed that were not inherent in any formal routine system. These four items are:

Versatility
Judgment
Adaptability to small jobs and concerns
Yielded more information.

For the report included in condition, for example, not merely position, as with a military map, but direction, rate of change, predicted position in advance interval of time, reported application of corrective measures, and current result.

Since this managerial detail has been known by many names, and its personnel by many more—most of them picturesque and none of them descriptive—the writer will merely recall that the personnel or individual charged with this work was usually a man thoroughly informed as to requirements and personally experienced in all the details involved.

Is it surprising that a conservative executive, competent but

[4] Consulting Engineer, Freehold, N. J. Assoc-Mem. A.S.M.E.

busy—or an executive board, the larger number of whom were less familiar with the internal operation of their business than with its external aspects and contacts—should look askance at a mere system without brains as a substitute for a man or a department that was able to help them with their thinking?

The writer submits that able scientific management experts frequently enter a concern when they are unhampered and provide systematic management while they remain with the outfit, and leave behind them when they withdraw their presence and services—merely management system. This seems to be an unhappy chapter in the history of rational management. Where the established management has not hospitably extended unlimited cooperation with the incoming change or to its ambassador, the story has been still more unfortunate.

Is it not true that much new light might be shed on ideal management by a thoughtful consideration of the examples where the application of modern principles of management has been hastily conceded as failure, with special regard for the institutions to be displaced and a sympathetic analysis of the human situations? Is this not, after all, the utility of detailed history of a subject like management?

DAVID B. PORTER.[5] It would be difficult to trace the origin of management by exception. It is used by every one of us in the control of many of our every day affairs. If we are in the habit of being home for dinner at a certain time, we do not telephone from the office every day that we will arrive at the usual hour; but only in case something has arisen to prevent the usual event from occurring do we find it necessary to notify our domestic headquarters. Of course some of us may be so irregular that there is no habit of being home for dinner, and consequently no established routine; therefore a non-appearance at this meal is not an exception, and consequently no notification is necessary.

It is perfectly natural, therefore, that this principle should be extended to the more complex problem of management in industrial and commercial enterprises. Taylor, Gantt, and Gilbreth recognized its importance and devised means for its application. It was the writer's privilege to be associated with Mr. Gantt at the time when he was developing his system of charts which give visual expression to the exception principle. He was able to do this by reducing the various factors to the common denominator of time which is the field of the chart, and by using bars to show their condition with reference to time. The normal condition is represented by bars which are up to or moderately ahead of the current date. Exceptions to the normal state are represented by bars which lag behind or are excessively ahead of the current date, and the degree of variation from normal is measured by the amount of this lag, or lead.

The author, in this paper and in earlier writings, has presented his tell-tale mechanism for visualizing exceptions from plan which appears very effective in its application of the exception principle. He accomplishes this by reducing all of the factors to the common denominator of condition which is the field of the board, and by using indicators to show their degree of condition. This technique compels the use of several fundamental principles of good management.

First, it depends upon 100 per cent planning of all the factors. This includes the determination of the allowed limits of variation from plan for each of the four degrees of condition.

Second, it transfers intelligence into the fixed plan in the same way that skill may be transferred into a machine tool.

Third, it transfers judgment into a routine by notifying the proper individual designated for taking care of each degree of variation from plan.

Fourth, this latter provision necessarily apportions and delegates responsibility in accordance with the ability to assume it.

Fifth, it conserves the time of all executives by bringing to their attention only those matters which vary from plan and over which they have jurisdiction. This liberates the higher executives from the useless attention to routine detail which ought not to concern them. In this connection it tends to develop executive material by training those in subordinate positions in the art of executive technique.

The writer would suggest that the use of too many denominators on one chart be avoided. The effectiveness of any method of control lies in its degree of simplicity. This was emphasized by Gantt, who hoped to establish through the medium of his chart a simple and universal language which could readily be understood in any of its applications.

JAMES C. TUCKER.[6] The subject seems too exhaustively treated to offer additions or criticisms. Management for the past thirty years or more has been very much talked about—systems and methods experimented with and variously tried out. Are we getting anywhere? Doubtless we are, for large industrial organizations must be better managed than formerly, else utter confusion would result, unbearable expenses would be involved all ending in sad failures with disrupted society and untold suffering among the workers thus deprived of their livelihood.

Better management, then, has become as essential as better machinery, better materials, and higher grade output.

The author has reviewed the exponents of various management systems scientifically evolved during the past thirty years, and now proposes renewed attention to "management by exception," as the inevitable and the most workable next step toward more efficient results. He notes that both Taylor and Gantt could not eliminate the law of exception from their advocated systems, and then develops a plan whereby the "law of exceptions" may be tied into a system so that management may be graded and assigned to executives of progressive rank.

Ten years from now will one wonder, as did Taylor and Gantt, why the idea meets opposition or indifference among leading managers, and will later students turn the pointer of better direction back to system or to some new plan yet undiscovered or to be evolved?

The writer ventures to say that some day it will be discovered that there is a fundamental or perhaps a divine principle so basic that upon it may be evolved a system of management as complete, unchanging, and unexceptional as the law of gravity and the law of centrifugal force, which keep our universe in consistent harmony.

The weekly system of labor and rest which, according to Scripture, was set up by the Supreme Being when He did all His creating in six days and rested on the seventh day, has been pretty much adhered to ever since. Only lately have some of our prosperous fellow workers discovered that in five days can they earn what they need to spend in their two-day week-end. Mr. Alford, in his reference to early instances of applied management principles as recorded in his new book, "The Laws of Management," apparently overlooked that remarkable example of "management by exception" set up by Moses under his father-in-law's direction, as recorded in the 18th chapter of Exodus.

One writer concludes that, after all, there is not much new to be known about the principles of management.

The author infers that we may have inherited, and therefore

[5] Assistant Professor of Industrial Engineering, New York University, New York, N. Y. Mem. A.S.M.E.

[6] Plant Superintendent, Plant No. 2, Carrier Engineering Corporation, Newark, N. J. Mem. A.S.M.E.

come naturally into the acceptance of management by exception through its being the basis of family government.

Another writer, after discussing various systems of wage incentives, concludes that, after all, the gross results are not much different than those obtained by the ordinary day-work-pay method.

Are we talking in circles, getting nowhere, but perhaps enlarging our horizon of vision, or is it the inevitable triangle in which we are brought up sharply at each angle to try a new direction of procedure, profiting by our experiences on the last leg, returning again to discover that the human element is eternally involved, and that our progress in management procedure barely keeps pace with the changing demands of business and industry?

The author, after presenting his plan with charts, whereby exception management may be operated infallibly by clerks, supervisors, staff executives, and managers, has cautioned that no plan can function successfully without capable managers.

Capable leadership is essential in successful management. Then we must have leadership. Ability and intelligence, plus training, will make leaders: then we must have training.

A paper entitled, "Training Minor Executives in a Rapidly Growing Organization," presented before this Society in May, 1928, by Mr. A. J. Beatty, Director of Training, The American Rolling Mill Company, and the discussions led by R. C. Forbes, C. S. Coler, J. O. Keller, and others, have ably outlined plans and methods for training leaders.

Craig and Charters, Tead and Metcalf, and many other writers on management have supplied us with ample source material to develop our potential leaders into trained managers.

Then, it seems, any good, workable plan of management, whether it be Taylor's, Gantt's, Emerson's, Ford's, or any other, will be adapted by trained managers to the particular type of business to be managed, with a reasonable, if not a high degree of success.

The author states that "exception management has no system." He also emphasizes that it is an effective aid to a system. That, it seems, is the point to keep clearly in mind. One also must be sure that any mechanism adopted by which the managerial line will function effectively must not be so complicated, expensive, or cumbersome as to absorb too great a percentage of management effort for its operation.

In spite of the author's assertion that the "skepticism" of the "uninitiated" is "without point," it is found that some are still skeptical as to the possibility "of a few girls to direct the activities of a large plant, by exceptional management." One may feel as did a certain gentleman who said of another he had eloquently presented an idea he wished to "sell," that "his argument is persuasive but not altogether convincing."

With the aid of "the professional manager" and with a better understanding of the "exception principle" reduced to terms outlined in the paper, amplified in future discussions, papers, and probably books on the subject, one should be prepared to meet every intricacy of management that modern business and industry will demand.

GEORGE G. BERGER.[7] The author is undoubtedly prepared for a difference of opinion in the discussion of so highly a controversial subject as management. His paper would have been clearer if it included a case example to illustrate just what he means by the term "element," what and how many elements are to be classified as variants, and how the zones for compelling various types of executive attention are set. These are points which require illustration by example in order to determine the practicability of his technique of management and determine the "standards" of discussion.

As the writer understands this technique of management by exception, which is designed to relieve the executive and subexecutive of numerous details and functions of management and to call their attention to those situations which require higher degrees of judicious action, the various elements or factors affecting the industrial organization, its operations, earnings, and growth are classified as constants and variants. It is taken for granted that the constants will be adequately controlled by standardized management. The variants are subdivided in turn into accidental and planned exceptions, and classifications or zones are established for these exceptions. These zones are intended to call for various kinds of clerical and executive action. If, by elements, the author means all the factors, functions, details, and phases affecting industrial operations, the making of an inventory of variants and constants will prove quite a task. Many exceptions cannot be forecast and are only known when they first confront the management personnel. Then to establish the limiting values for these voluminous elements in order that they fall into classifications calling for various types of executive action gives the work of organization for action a fearful aspect.

The author presents the idea that Taylor and Gantt were arbitrarily insistent upon the "use of a method of management that had no history."

The work of Taylor was to establish standards of the tool and of the worker in order to control the utilization of factors that had been previously neglected. This work following the period, which may be called standards of the product, is part of the evolution of management and the standardization trend for control. The evolution extending back some thousands of years is ample history to back up a method which is part of the evolution.

In the efforts to develop the science of management, there have been used the deductive process in endeavoring to hit upon general principles and apply them to the specific case. In the author's words, there is "an instinctive knowledge that there must be some natural method of management that directs when direction is sufficient and that compels when compulsion is called for, one that does not interfere with matters which are progressing in orderly compliance with a planned procedure, but which has positive methods of detecting and correcting variations from that procedure." This instinctive, deductive process is an example of the mental attitude of the medieval ages, when the search was on for the magic formulas and the inductive process for developing science was neglected. Bacon's masterly "Organum" was designed to curb this attitude, and John Locke in his "Essay on Human Understanding" warned that future investigators of science at all times would tend to this method.

There have been financial ratios, economic-lot formulas, and other general principles which completely conceal the fact that the science of management has for its object establishing the science for the specific organization which has its own set of standards (derived directly from its standards of the product, tool and worker, and which represent the particular set of facilities and attendant arrangements). Taylor assumed this same operating point of view when he decided to set standards of the worker by the time study, taking into account the conditions surrounding the specific situation, rather than set the standard by the average for that operation as shown by statistical data of output in his plant or other plants.

The object of management (considering the term in its broadest sense) is control. That is the object of any science—control over the phenomenon or objects it seeks to understand by cata-

[7] Consulting Industrial Engineer, New York, N. Y. Jun. A.S.M.E.

loged laws of cause and effect. To fix the laws of cause and effect in a science, there must be standards to fix the conditions surrounding both cause and effect. Management searching for control in all phases requires an increasing number of standards. Practice is now up to the standards of the management in the trend following Taylor's work; their development is logically compelled by the present status of industrial operations. On the basis of standards of the management, one may secure by some twenty-five or thirty operating policies the measurement of management for the industrial unit. In this rating there is incorporated the exception principle, with the "exception" that the industrial manager chooses what requires his attention, whether it is a constant or a variant, whether an accidental or a planned exception, and can determine in terms of the rating (a numeric of the standard) the importance of the variation of result from standard. This is in accordance with present practice in industry. It is also in accordance with the principle that the human factor is the most important in the future of the organization and that the measurement should be directly placed over the human factor. By taking the operating point of view, setting the standards for these policies on the basis of standards of the product, tool, and worker, one may have outstanding standards which not only serve as a basis for evaluating results, but as the basis of the practical measurement of management. This attainment is an object of scientific management.

Author's Closure

It will require at least two, and probably three, more papers to describe exception management and the method of visualizing it. Management is divided into four distinct branches, each of which has a different denominator, and therefore a different technique. The denominators are time for repetitive and quantity for contract type of manufacture, value for accounting. and condition for those factors of general management that cannot be resolved by the other denominators.

To describe the applications of these denominators and the different technique necessary in each case will require several more papers.

It is hardly to be expected, therefore, that the discussors can pass judgment upon the whole, from reading an introductory portion. On the other hand, it is not to be expected that the author can give a clear view of the whole in the same portion. The technique applied and the results achieved are so radically different that a general statement covering the whole of industry would be classed as exaggeration if not romance, and in the light of our present technique would not be understandable.

Most of the questions, other than those that are matters of personal opinion, will be answered in succeeding papers. There are some statements, however, that indicate that certain parts of the paper are vague. Mr. Tucker, for instance, states that "possibly some time a fundamental method will be discovered." It has!

The technique which is described in the paper constitutes management by condition. Condition is a universal state than which nothing can be more fundamental, except the factors that cause condition. Creation began with a nebulous condition; it will end with a chaotic condition, probably. Management must be based upon things as they affect our senses. Our imagination creates conditions; our intellect reasons conditions; our taste, smell, and touch define and measure condition. Our whole life, then, is a series of conditions which we visualize and emphasize according to our interests. In management, the tell-tale chart visualizes any condition that can be defined. The reaction to a condition, of course, varies in different individuals, and it is the nature of the reaction that indicates the degree of efficiency.

Mr. Gage thinks that an executive "will look askance at a mere system without brains as a substitute for a man or a department that was able to help him with their thinking." Mr. Gage has the wrong conception of the technique. The men and departments help the executive more, because the combined thinking results in a plan that is permanently and exactly recorded and statically visualized. The plan and technique are self-corrective over a cycle of time, because being planned in terms of a common denominator, any difference between the plan and the actual practice is shown conspicuously by the dynamic indicators. If the variation is slight, it is brought to the attention of a subordinate. If important, it is brought to the attention of an executive. Management has long sought a method of functionalizing duties. It has not fully succeeded, because importance increases with the passage of time. A detail that is a routine matter today, a month hence may be a vital factor. Functionalizing, therefore, must be in terms of condition, not items.

The medium of visualization that makes exception management possible is an automatic machine that takes the raw material of management and converts it into a finished uniform article by the law of transfer of skill, just the same as any other automatic machine. Alford, in the "Law of Transfer of Skill," quotes Roland as follows: "Intelligence may be transferred from the brain of the machine maker to the machine itself, to such an extent and with such permanence that the machine which the toolmaker has thus imbued with a portion of his own wits can subsequently, so long as it is in working order, supplement with this endowment the small mechanical skill of its tender." Any degree of skill in planning may be transferred into the mechanism of the chart, and the skill necessary to execute the plan "will be inversely as the skill transferred into its mechanism." What greater help could an executive have?

Finally, Mr. Beyer thinks that the paper would have been clearer if it had included a case application. It does. There is no base from which to theorize. Everything that has been said has been descriptive of the original installation in 1921. It is not necessarily the best technique, nor is it necessary to agree with it. The author is a practical shopman with 30 years' mechanical and management experience. As is usual in such cases, practice preceded theory. The things that the author has described were found out after the installation, not theorized before. Primarily the chart is based on that of Gantt, with the addition of a common denominator, dynamic indication, and two-factor visualization. It is a mechanic's idea of what Gantt would have eventually evolved from his line chart.

MAN-53-5

Training Apprentices and Foremen

BY FRANCES PERKINS,[1] ALBANY, N. Y.

The experience of the author in labor problems and in legislature affecting workers provides a background for recommendations as to the proper training of apprentices and the development of foremen. Foremen generally are ignorant of the labor law, the health requirements, or of safety. The personnel manager and the safety engineer of the plant should work in closer contact with the foremen. Under the Smith-Hughes Act, the University of the State of New York has a course for training trade, industrial, and technical teachers. The courses are offered in large centers. Should labor management be taught in addition to these other subjects, there would be provided a good course for foreman teaching.

THE far-seeing employer is building today not only his physical properties but his man power. At this moment, when we are in the slough of depression, none but the far-seeing does such things as these. Experience and insight tell him that the future holds expansion, as the present holds depression; he knows that now is the time to prepare for expansion. Industry is profoundly affected by the present surrounding gloom; for the manufacturer there is no tomorrow; there is nothing in the adage "In time of peace, prepare for war." Some think that now is no time to train men in industry, because unemployment gives us the pick of the market. But the time inevitably comes when the whole scene will change; factories will hum, sales will go up, and there will be the usual shortage of labor.

At such a time something must be done; high profits can be secured if only production can be obtained, but the employer perhaps feels that labor is not doing its share, either through reluctance or ignorance. The training of workmen is then considered hastily, but it is too late; the "system" only gets in full swing just as the pendulum begins to swing the wrong way. Many of our industrial problems follow the same course. We are now concerned with the condition of unemployment; ameliorative agents that should have been at work two years ago are now only blossoming just when the unemployed, by the mere passing of events, are getting back to work.

Let us consider industrial training from the broad point. It has not been too successful in the past. There is no integrated scheme which recognizes that most human beings are destined to work almost from the time school has been vacated till death takes them away.

Theoretically, every child who leaves school is educated; practically, it is not so. There is an effort to make the pupil mentally and physcially fit for his life's work, but the effort is defeated not only by the desire of parents to get their children on "the payroll," but the desire of some employers to get youth into industry at too early an age. How many employers there are who complain about the inefficiency of clerical help, for instance; yet they hire workers whose term of school life has been shortened by the call to the office.

It seems that the great limitation of industrial training, whether in apprenticeship or in shop, is due to the fact that it has been only haltingly, partially, and haphazardly applied by industrialists who are not teachers, to their employees from the production point of view. What would be thought of our teachers should they venture on any scheme to get out production; they would fail; they could only use a small part of their knowledge in the effort.

It is sometimes held that, if you stop production to train men, production is thereby irrevocably lost. But is it not apparent that if you should render a worker unproductive for a month while you train him, and by training increase his producing capacity by 10 per cent as long as he is in employment, you will have made a substantial gain? All this presupposes a certain stability of labor, but it is certain that if you train a man for your sole profit, turnover may be expected, and the whole scheme of training will be for the benefit of your rivals. If training is to have any significance at all, it should mean more profit for the employer and more wages for the worker than he can obtain elsewhere. Thereby you will have stabilized him by the most secure bond.

A Government document has been published recently; it gives the names of the trade associations of the country. Many famous and powerful organizations are listed among them. They are the leaders in their respective industries; they direct policy and are decisive factors in guiding their forces to success. I recollect few of them together, or any one alone, going to the great teaching institutions of the country and asking for guidance in the problem of training the workers under them, except in the most limited manner. What is more serious is that never has the problem of the transference of the youth from the school to the industry been planned out in anything like a comprehensive way. The result is, of course, chaos. The boy, released from

[1] Industrial Commissioner, Department of Labor, State of New York. Frances Perkins was born in Boston, Mass., educated in private and public schools in Massachusetts, graduated from Mount Holyoke College, studied as a post-graduate student at the University of Chicago, University of Pennsylvania, and Columbia University, specializing in sociology and economics. In 1910 she became executive secretary of the Consumers' League of New York City, conducting a successful campaign for the passage of the fifty-four hour bill, the law which limits the hours of labor of women to fifty-four hours a week or nine hours per day in the State of New York. She also urged successfully amendments to the labor law in regard to the protection of women and minors and regulations of tenement homework manufacture. In 1911 she conducted an investigation into cellar bakeries in the City of New York, in cooperation with the Commissioner of Accounts, which led to a thorough-going regulation of the sanitary conditions in cellar bakeries by the city authorities. In 1912 she became secretary of the Committee on Safety, an organization of private citizens formed after the Triangle fire, to promote various measures designed to prevent factory catastrophes, either from fire or other accidents. Representing the Committee on Safety, she cooperated with the Factory Investigating Commission in drafting the new provisions of the labor law, particularly those relating to the prevention of life hazards from fire and accidents. She is a member of the National Safety Council, of the Committee on Safety to Life of the National Fire Protection Association, and a director of the Consumers' League. She was Commissioner of the State Industrial Commission from February 18, 1919, to April 15, 1921. She was appointed a member of the Industrial Board in January, 1923. On January 19, 1926, Miss Perkins was appointed chairman of the Industrial Board, and on January 9, 1929, was appointed Industrial Commissioner.

Contributed by the Committee on Education and Training and the Management Division and presented at the Hartford, Conn., Meeting, June 1–3, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

the school, must wander objectless around until by chance he finds "a job."

An integral part of this work is vocational guidance, but that science is in its early infancy, and it will not be for many more years, unless some comprehensive studies are made, that we may expect any improvement.

Many of the larger industries of the country have been forced rather than led into sporadic efforts to train their workers, but whether it may be considered an evidence of strength on their part or of weakness in our teaching system is not so very clear. Our large industries cover only a very small proportion of the workers of the country. There is a vast number of small plants to which the torch of light never penetrates. Evidence of competence is demanded of doctors, chiropractors, and stationary engineers, but not of those who undertake manufacture; and there is no organization in the country to prevent fools from entering where angels fear to tread. The industrial structure is thus weakened from the start.

Now, when you have amateurs in industry shouldering the burden of manufacturing, what is to be expected from their ability to train the workers who have the misfortune to work in their shops? With very few exceptions men undertake to manufacture goods with only the most indifferent knowledge of the demand. They are perhaps setting out against insuperable competition and are wholly unaware of the fact.

The defects we find in the educational field in industry are not due to industry; they are principally due to the faulty structure of education itself. We, in America, are firmly of the belief that specialization is the secret of success. Foreign educators hold to exactly the same belief, but they attack the problem differently and with more success. We believe that the way to attain business, and even professional success, is to begin specialization at an early stage of our college careers. In Europe, it is believed that without a full general training it is not possible to begin specialization with any hope of success.

Our colleges turn out some specialists; they are now getting on the band wagon of research in industry; and because of this radical defect in our educational viewpoint, it is feared that there will be a great slump in the present vogue of research in industry—not because research is undesirable, but because with our present ideas in training, our efforts in research may be unproductive. It is noted, too, that research is generally confined to manufacturing and not to personnel problems.

It would undoubtedly seem that, if economically impracticable by plants, it would certainly be practicable for industries to consider the matter of training workers, especially in repetitive work. No man who has any appreciation of the value of time can endure doing repetitive work without a study of "the one best way," yet they nobly endure this in the workers under them. But training for such work involves careful selection. Certain types are fitted for such work and can make a success of it, while others would fail entirely.

The great stumbling block against the introduction of any sort of training in industry is the question, "How can the thing best be done, and what does it cost?" Now, training is not like a pound of butter; its cost cannot be obtained without effort. One would fancy that industry, asking "what does it cost," is really interested in the answer to the question, but that is not so; it is interested in putting off the issue by asking a question to which an answer is not available. The object of knowing costs is to determine whether training, on the dollar and cents basis, is worth while, because, whether one likes it or not, that is the criterion.

There are very few cases on record, it is believed, where a cost comparison has been instituted between the ordinary method of getting out production and that after a period of training. It is quite generally held that every man who is put to work is, in fact, being trained, but for the sake of clarity, two classes of training are recognized in industry: training by absorption and training by intention. As regards manual workers, at any rate, "it is apparent that the vast majority of American industries give the training of their manual workers little definite attention;"[2] that is to say, they train by absorption, which is really no training at all.

This brings us to a consideration of the foreman of whom we are told that "teaching ability is an essential qualification for the foreman," and if it be so, then it is apparent he has not exercised the essential qualification to any extent.

There is, in fact, an apparent difficulty here. If teaching ability be an essential, then how is it to be ascertained? That is an embarrassing question because it raises the whole issue of training in industry, yet out of the millions of foremen who have been operating in industry the past quarter of a century, no system of ascertaining teaching ability has been evolved.

We have, within the last two decades, gone from one extreme to the other and back again with regards to the position of foremen in industry. At first he was the supreme autocrat; he had the full power to hire and fire, and he exercised his prerogative to such effect that management then swung to the other extreme. The prerogative was pitchforked into the lap of the newly hired personnel manager. This plan, in theory conceived to be perfect, did not work out quite so happily in practice, but for a time it was endured, and in the meantime shop committees became the fashion, and with their introduction the foreman suffered a further eclipse. The main defect of shop-committee management was its failure to consider the foreman. In fact, it is now clear that, had the foreman been trained, many of the conditions that were responsible for the introduction of shop committees would have been obviated. The shop committee was mainly engaged in settling questions that ought to have been settled by the foreman.

The result of this situation was the movement toward foremanship training, and, in the main, it has been productive of good. The foreman has been reestablished in much of his former glory.

Training the foreman is a rather peculiar problem. There are colleges of pharmacy, schools for nurses, seminaries for clergy, police schools, dancing schools, mortician schools, hair-waving schools, and vocational schools and the apprenticeship system, but very few schools for foremen. All of the academic courses mentioned are for the youth who hope to become trained at their respective trades, but it is different with the foreman. The former have left school only recently; the foreman may never have graduated from high school, and even so, there will have been a long interval between the time he left school and the time when he has reached foremanship. His whole career will not have made him very receptive for any kind of formal training, although it is generally believed that foremen are willing to learn provided the teaching is interlarded with plenty of tact and diplomacy.

Since foremen are trained in industry and seldom in any kind of regular, full-time school, there is a difficulty in finding trained teachers to train foremen, if such a class has ever existed. Most teachers have, themselves, to get a diploma to teach whatever subject is to be taught, yet there is no regular school for foremen teachers, but of course there are many training courses throughout the country, unfortunately too limited in character. Nor, even if such a development were possible, would it be possible to bridge the gap between Mahomet and the mountain unless our present notions on the subject undergo a change.

As has been intimated before, production is one thing and teach-

[2] "Training Manual Workers," R. N. Keppel, Production Executives Series, No. 72, American Management Association, 1928.

ing is another, and unless there is a reconsideration of the whole teaching problem in industry, and some form of alliance established between our academic system and our industrialists, no solution of the problem is very apparent.

Looking at the problem from the viewpoint of the New York State Department of Labor, it is recognized that we have a long way to go before the training of foremen and apprentices is likely to materially assist in a solution of the many problems that confront us.

We have looked, from time to time, to the personnel manager for help without any very satisfactory results. The author has always felt that he, in the large plants of the State at least, should be the one person who should be acquainted with the legal aspects of our labor problems and that with him, as regards the administration of the Workmen's Compensation Law, should be the safety engineer. Neither of these influences has made itself palpably felt, either to us or to those with whom they come in contact in industry. Some attempts are being made along this line, and such a development is highly desirable.

We are still attempting to force on industry by means of the Labor Law established truths which aim to the betterment of the worker and, incidentally, the employer, whereas had the personnel manager and the safety man the right conception of their positions, we should find them seeking our aid rather than occupying a neutral or indifferent position. Their situation often forces them to take a stand which they conceive to be acceptable to the employer, but the very opposite is the truth. They misinterpret the position of the employer, as often as not, and merely because they have only a misty knowledge of the situation. Take a case in point. The law requires that the workshop shall be free from dust, fumes, and gases when they exist in harmful quantities, yet we have seldom had a single enquiry from a personnel manager or medical department in industry as to whether the conditions were harmful for workers or not, and, what is worse, we have never had any enquiries from such functionaries when a building was in prospect as to the proper sort of ventilation.

In view of these considerations it is not to be wondered at that the foreman is ignorant of the labor law, the health requirements, or safety.

One feature of industrial training might be brought to the attention of industrialists in the State of New York, because with comparatively little extension of powers, the same system might be extended to include the training of foremen in industry. If, as has been established, the worker gets no regular training, and the foreman, who is supposed to teach him, gets little regular training, then the whole hierarchy of training in industry is faulty, and some scheme is necessary to establish a real system of value to industry.

Under the Smith-Hughes Act the University of the State of New York, through the State Education Department, has a course for training trade, industrial, and technical teachers. The course requires 480 clock hours of work and 4 years of attendance at evening school in order to secure the certificate and license granted to graduates.

These courses are offered in New York City, in Buffalo, and in Oswego during the summer session, and elsewhere by arrangement.

Candidates should not be less than 21 or more than 35 years of age. They should have 5 years or more trade experience in the occupation in which they desire to train; they should at least have 1 year of high school and the other ordinary qualifications.

Should labor management be taught in addition to the other subjects, this would provide a good course for foreman teaching which might be accomplished through the Smith-Hughes Act.

It would seem that with the development of some such plan the plane of industrial training would be greatly improved and the employers would obtain incalculable benefits from this departure.

Discussion

FRED H. COLVIN.[3] Training should be general enough to give a general idea of the trade, but modern production demands considerable specialization. It seems best to teach the rudiments of machines in a school, either a public trade school or a shop school, and get the boy beyond the stage where he is a nuisance and a hindrance before inflicting him on the foreman. But the final training can best come in the plant itself, on regular work.

One railroad shop superintendent reversed the usual process of his time. Instead of starting a boy on the bolt cutter and disgusting him with the whole shop idea, he put him in the erecting gang as a helper. In this way he learned the names of parts, where they went, and what they did. He learned what parts had to be carefully fitted and where a loose fit was permissible or desirable. He also learned to work with men. Then when he went on the bolt cutter or the lathe he knew just what parts he was making and had a greater interest in the job.

Superficial training or too specialized training makes it difficult to shift men from one kind of work to another. They fear to tackle a new kind of job.

A. E. CROCKETT.[4] About this training of apprentices and foremen—the training of workers to do skilled jobs and of men to lead them—the Department of Education and Department of Labor should see if they themselves are not more at fault than is the industry. They forced laws upon the statute books to prevent the exploitation of young people by the unscrupulous. That was proper. They then went farther, and had laws extended to prevent employment and training in order to protect the adult from juvenile competition.

The inevitable has happened. The Department of Education and the Department of Labor, disturbed over conditions which they helped bring about, are complaining that industry is not doing the training that it ought to do. In fact, they are so disturbed that they are offering to go down into the plant and do the training themselves. And they will continue to be disturbed, because as soon as business picks up, there will be a shortage of persons capable of doing skilled jobs, and at the same time, as in the hectic days of 1928 and 1929, there will be a milling mass of unemployed, most of them being between 20 and 25 years, incapable of employment.

They will be incapable of employment largely because the State Department of Education and the State Department of Labor have helped put laws on the statute books that prevent the necessary training, and not only will do nothing about correcting the situation, but quietly or openly oppose any effort by any person else to correct it. The laws in New York State are such that boys and girls, instead of getting the practical education and training in employment that they need when they are young, get jobs, when they get any at all, only as errand boys, clerks, etc.

In New York State, up to 18 years, they cannot even sharpen the tools they work with. There is a long list of machinery at which they cannot be employed. There is the double compensation feature, too.

The result is that instead of the employer trying to get young people to exploit, he cannot be coaxed even to give them jobs at which they can acquire skill—in the precious years of their life, so far as acquisition of skill is concerned.

No wonder these complaints about training. The Education

[3] Editor, *American Machinist*, New York, N. Y. Mem. A.S.M.E.

[4] Manager, Industrial Management Council, Chamber of Commerce, Rochester, N. Y.

Department and the Labor Department do not seem to have realized the revolution that is going forward in industry; they seem to think of training in terms of 35 years ago. Preliminary schooling for college is not what the prospective skilled job worker needs either. It is not doing good to help make the young feel that if they are headed for work they are failures.

Parents are in part to blame. So many of them hate to think of the son working like the father did and they feel the bottom drop out of the world if the son does not want to be a doctor, a lawyer, a clergyman, or at the worst a mechanical engineer. It is bad enough to have parents that way, without having the educational system of the country operated on the same theory.

We shall have to go back to where training of body (the touch, the hand, the eye in a productive way) will go hand in hand with the training of the mind.

The writer believes we are approaching days when every youth will be taught some skilled job, even though we do not go as far as to give him the exact equivalent of our more or less obsolete trades.

If the schools get busy with our youths in the interest of that great proportion of them that must go into industrial or other manual employment, and if our State Education and Labor Departments will make it possible for them to get training on the job—on some part-time basis for those in their last public-school years, for instance—the better it will be for America and most everybody in it.

MAN-53-6

Value of the Safety Movement in the Industries[1]

By JULES PODNOSSOFF,[2] BROOKLYN, N. Y.

The paper outlines the various aspects of the industrial safety movement, its attractiveness, economies, and inherent possibilities. The safety movement has been long ago divorced from altruistic conversation and put on a basis of cooperative helpfulness. Accordingly, the subject has been treated from a "cold" business standpoint in terms of dollars and cents; that is, in the approach to the problem the center of gravity has been shifted to the economic rather than humanitarian aspects. A brief historical review of the growth of the movement is first made, followed by some statistics of the losses in life and property caused by industrial accidents. The principal emphasis in what follows has been placed on the thesis, at present conclusively proved, that efficiency in production and safety are inseparably correlated. To afford a better perspective of the actual values involved, illustrative examples taken from the experience of different industrial companies are introduced. The role of engineers in accident prevention is next considered, and the discussion is concluded with several recommendations.

THE essence of this paper may be condensed in the following: 1 Because of the tremendous burden of economic and human waste, safety becomes a problem of supreme national importance, in view of the increase in the frequency and severity of accidents with an increasing intensity of industrial activity.

2 It is possible to control industrial accidents under modern conditions of highly efficient productivity—"engineering revision" being the most effective means.

3 Efforts to improve safety performance do not interfere with production; on the contrary, the experience of large groups of industries throughout the country indicates that material reductions in accident rates can be attained simultaneously with an increase in production rate.

4 Apart from ethical, moral, or humanitarian motives or obligations, it is imperative that safety be made a major executive objective and responsibility, because:

(*a*) It is cheaper to prevent accidents than to allow them to take place

(*b*) Maximum industrial efficiency can be secured only when the accident performance is brought down to an irreducible minimum.

5 Engineers, thanks to their particular professional training, are singularly well suited to assume leadership in the safety movement, and thus effectively to cope with industrial accident prevention—a vast field of activity with tremendous possibilities.

The United States is rapidly forging ahead of other countries, mainly because of her industrial supremacy. In her industries the miraculous achievements and inventions of the scientific and engineering genius are reflected as in a magnifying glass. It is because of the large scales employed and because of the tremendous and ever-increasing intensity of production that American industry can afford to have a working class that commands higher wages and maintains a standard of living superior to that of the workers in any other country, and at the same time carry on a successful competition in the world markets. This enormous increase in intense industrial productivity, however, necessarily leads to the consideration of a problem of first magnitude—the problem of safety.

The Problem of Safety

In spite of the remarkable achievements of American industry—achievements which are the basis of unparalleled national welfare and a source of national pride—a study of the performance of the most representative and even of the best plants throughout the country indicates that great improvements can still be brought about; and most important of all, that, at the present stage of development, highest efficiency in production and operation will be attained only when the amount of waste shall be brought down to a minimum.

Of all industrial waste, human wastage is the most inexcusable from every point of view. The industrial and economic factors involved in human wastage, apart from the humanitarian aspects, make the question of plant accident performance a problem of first-class national importance. But before proceeding to a discussion of the basic aspects of safety, it may not be out of place to make a brief review of the development of the safety movement. (1)[3]

Development of the Safety Movement

The beginning of the safety movement as such may be said to date as far back as some nineteen years ago when the first workmen's compensation laws were passed. However, the first organized effort in accident prevention was made much earlier, viz., in 1867 in Alsace-Lorraine, and the idea began to spread rapidly in the most progressive European countries.

In this country the first effort to prevent accidents was undertaken on a large scale by the United States Steel Corporation in 1907. In 1910 the railroad companies adopted the slogan of "Safety the First Consideration" as their operating rule to reduce their appalling accident rate. On account of the great number of casualties in the iron and steel industries, a group of engineers connected with the latter arranged a conference in Milwaukee in 1911, followed by a second meeting in 1912, at which many representatives from other industries were present.

The organization of the National Safety Council was a result of these meetings. The National Safety Council is a rapidly growing organization, non-sectarian and non-commercial, having at

[2] Student, Polytechnic Institute of Brooklyn, at present graduating in Mechanical Engineering. Born in 1908, brought up and received both elementary- and high-school education in Moscow, Russia. Wanted to study engineering, but could not do so in Russia. Taught himself English, and arrived in the United States in September, 1927. Immediately upon arrival enrolled at the Polytechnic Institute of Brooklyn, where he was last year designated honor student. Interested in Student Branch of A.S.M.E.

[3] Numbers in parentheses refer to the Bibliography at the end of the paper.

present a membership of 4000 industrial concerns—the flower of industrial and railroad service—and is doing magnificent work in carrying on safety service and propaganda throughout the United States.

What Price Accidents

It is essential to a clearer realization of actual values involved in the material and human waste which accidents entail briefly to recount a few statistical data, although it must be mentioned that owing to the variability of the different factors it is impossible accurately to estimate the enormous economic loss caused by industrial accidents.

To take, for example, the year 1929, as a rather typical year, the mortality statistics of the United States Bureau of Census show that 23,000 men were killed during that year in industry. If each death be taken as representing a loss of only $5000, this source alone accounts for a loss of $115,000,000. (2)

According to Mr. Beardsley, (3) on the basis of data obtained from the industrial centers of the country, 50 out of every 500 men who are engaged in industrial work[4] are eventually hurt. Of these 50, 3 are seriously hurt, 1 dies, and some of the others are permanently injured. It has been estimated that, on the average, approximately 3,000,000 men are injured in industry every year, and that in terms of wages industrial accidents for but one year resulted in a loss of $827,000,000, (7) the burden falling not only on the workmen but on society in general.

The foregoing survey does not tell one-half the story. The mind is fairly staggered when one begins to consider the losses due to the following:

1 The disorganization resulting from additional labor turnover
2 Increase in damaged machinery and spoiled material because of the replacement of the killed and injured by new men
3 Loss of time connected with each accident
4 The reaction of accidents on the morale and psychology of the workers, foremen, and company officials
5 A yearly loss of half a billion dollars due to fires alone
6 Occupational diseases resulting from unsanitary or otherwise improper working conditions.

These facts become still more striking when it is realized that the major percentage of accidents are preventable. This has been established definitely beyond question and is proved by the vast amount of information now available.

However, it would seem that as far as the employers of labor are concerned an emotional, ethical, or moral approach to the problem is inadequate; it does not suffice to picture the wrecked homes and lives, ruined hopes and ambitions, the suffering and the misery and the sorrow which grimly follow in the trail of accidents. That is, it is impracticable to set the "purely human" against the "money" values. From this standpoint the following thesis assumes a profoundly significant importance: *The safe factory is the most productive and the most efficient factory.*

Relation of Safety and Efficiency

At the request and with the financial aid of the National Bureau of Casualty and Surety Underwriters, the American Engineering Council undertook two years ago a study of the relation between industrial safety and efficiency of production. The results of this investigation are embodied in a most thoroughly exhaustive and singularly well-organized report. (4) Before stating the chief conclusion at which the authors arrived, it may be of interest briefly to outline the work accomplished, to give the reader an idea of the unique thoroughness with which the research had been conducted.

The investigation was nation-wide in scope and covered the following industrial groups: Cement, coal, mining, coke, electric railways, mineral mining, quarries, steam railways, chemicals, electric light and power, gas, iron and steel, machine building and metal working, paper and pulp, telephone and telegraph, textile, woodworking, and a large miscellaneous unclassified group.

There is a wide range in the size of the companies included, varying from 8 to 82,000 employees. Through the field investigation information was obtained from 1145 individual plants located in 40 different states. Investigation centers were established in 15 industrial cities, and definite territory was assigned to each field engineer, with local committees composed of industrialists, engineers, and safety men in many localities.

The vast wealth of detailed statistical information obtained, as well as the thorough analyses of the levels of plant performance, brought the authors of the report to the following outstanding conclusion:

"There is a close relationship between safety and production—a relationship so pronounced and consistent throughout as to indicate a fundamental of management, which may be stated as follows: Maximum productivity is dependent upon the reduction of accidents to an irreducible minimum. The data for the 13,898 plants consistently show that those plants and industries which have the highest production performance also have the lowest accidents rates, which fact sustains the fundamental stated. This fundamental clearly indicates that if the management desires maximum productivity it must initiate, direct, and control ways and means of keeping accident frequency and severity rates at an irreducible minimum."

In order to enable one to have a better appreciation of the possibilities of the safety movement and of its attractiveness and economies, particularly with reference to the foregoing fundamentals, it may be timely to introduce a few examples.

Illustrative Examples

1 The following experience of the Du Pont company is very instructive:

During the war the Du Pont company built a smokeless-powder plant and a shell-loading plant for the United States Government. On the basis of their previous accident experience, accidents on the smokeless-powder plant job would have cost them at least $452,752. For economic as well as humanitarian reasons the Du Pont company decided to carry out a program of intensive safety work. The total cost of safety work plus compensation and medical expenses amounted only to $116,000—i.e., the company had a net saving of $336,652. The insurance rate on the shell-loading plant was $103,545. Thanks to efficient safety work, the safety and accident expenditures amounted oniy to $16,233—i.e., on this job alone safety work resulted in a net saving of $87,312. (5)

2 An interesting illustration of the psychological effect of safety work on the workmen's efficiency is reported by the California Industrial Accident Commission: (4)

"At the Moccasin power plant of the Hetch Hetchy project a surge chamber 40 ft. in diameter by 160 ft. deep was being constructed of concrete. After the concrete had reached a height of 80 ft., it was decided to stretch a life-net between the walls of the chamber to serve the double purpose of saving the life of any workmen who might fall from the top and also to provide protection for the men below from falling timbers. While the net was installed solely with the idea of affording protection, it actually resulted in reducing the cost of the work, it is stated, due to the added sense of security afforded the workmen, which enabled them to speed up all operations in connection with the

[4] Figures are specific for the electrical utility industries.

concrete lining, with the result that the time required for completing a 5-ft. lift was reduced from 56 hours to 48 hours, an actual saving in labor cost of nearly 20 per cent."

3 In his recent book on industrial safety (6) Mr. L. A. De Blois says the following:

"Safety and efficiency are unquestionably linked together by what is best described as 'continuity of operation.' For continuity of machine operation—that is, useful operation—we must have continuity of feed and stock removal, as well as continuity of power supply. The joint effect on safety and production wrought by common sense changes in the methods of feed and stock removal is well illustrated in the operation of punch presses."

A case in the point is the Simmons company, related as follows:

"In 1919 when there were 700 presses operating in one department, 36 fingers were taken off in accidents. With a change in the methods of feed and stock removal the injuries decreased to 7 fingers during the first six months of 1920. In the four years following not a single finger was lost, and the production per press had increased on the average 60 to 65 per cent. Our experience has been that whenever we made a job safe we also increased the production from 15 to 150 per cent."

Here are two more illuminating examples cited by Mr. De Blois:

4 At the Newburgh plant of the Du Pont company accidents at the presses used for embossing Fabricoid, a leather substitute, led to a development of guards, and later to additional safety installations. Through the elimination of accidents, production per press was increased 80 per cent.

5 In the manufacture of dinitrobenzol by the dye works of the Du Pont company production has been increased 100 per cent in one year coincident with a reduction in the number of injuries (including poisoning gases) to 50 per cent.

6 In concluding the presentation of the illustrative material it may be of interest to cite Mr. Albert W. Whitney, (4) as follows:

"The question arises: 'Can they (accidents) be controlled? Perhaps, after all, with an increasing intensity of industry, an increasing hazard is inevitable?'

"The answer is a simple one, and not only conclusive, but suggestive of the solution in general; the answer is, namely, that individual cases exist, characterized also by high industrial efficiency, in which this control has been secured.

"The United States Steel Corporation in 13 years has decreased its accidents 86 per cent; the Union Pacific Railroad has a safety record for shop employees that is five times as favorable as the average of the other large railroad systems of the United States; the Clark Thread Company has a record of nearly 10,000,000 man-hours without an accident; one of the plants of the Du Pont company with 65 employees has a record of 11 years with only one accident, and that a relatively minor one."

A close consideration of the cases presented in the preceding, as well as the inherent nature of the subject, would lead one to contemplate the relation between engineers and industrial safety.

Relation Between Engineers and Industrial Safety

The foregoing examples indicate that the technique of safety organization involves essentially:

1 Planning and layout of plant, equipment, and operations with a view to maximum safety.

2 Inclusion of the mechanical and automatic safeguarding equipment in the original machine design and construction.

3 Location and elimination of hazards by superimposing and adjusting safeguards; i.e., fundamental changes in or redesign of operating practice, processes, and structures.

4 Substitution of industrial railways, conveyors, hoists, lifts, chutes, cranes, automatic feeds, and other machine devices for the human element.

5 A psychological approach to the workingmen, such as:

(a) Systematic education in safety
(b) Consideration of physical and mental fitness of operator for the particular job
(c) Placing the right man in the right place.

In the modern literature of the subject the first four points are referred to as "engineering revision," although the latter is ordinarily employed in the sense of item 3. Item 5 has been generally termed "human engineering."

In the early stages of the development of the organized safety movement, "human engineering" was particularly emphasized. But in the course of time experience has shown "engineering revision" to be of surpassing importance. Mr. Beardsley (3) is authority for the statement that, according to accident statistics,[5] the more highly trained men are the more seriously injured. It can thus be stated without any fear of contradiction that, thanks to his practical and theoretical training, the engineer is the man best equipped to tackle the problem of safety organization—a large, new, and interesting field, full of great possibilities.

Conclusions

On the basis of the foregoing discussion of the various aspects and possibilities of the safety movement, it may be well worth while to emphasize the following practical recommendations:

1 It is necessary that safety be made a primary executive interest and a managerial responsibility.

2 The states should adopt uniform safety codes and establish universal periodic health examinations.

3 The safeguarding equipment should be made an integral part of machine design by the manufacturers.

4 Engineering colleges should include safety as an important part of their curricula.

When society is freed from the inexcusable burden which industrial accidents impose upon it, the entire human life will be elevated to a higher level of comfort and happiness, and by an active leading participation in the industrial safety movement, engineers will add credit to the profession, and human life will be made still richer and deeper for the engineers' predominant influence upon it.

MAN-53-7

Symposium on the Stability of Employment in Industry

LONG BEFORE unemployment became the problem of the hour, the Management Division of The American Society of Mechanical Engineers had planned to have a Round Table conference on the subject upon Dec. 3, 1930, during the Annual Meeting, with the American Management Association cooperating. It was proposed to have brief outlines informally presented by numerous representatives of industry rather than a program entirely of formal papers. In order to secure the utmost freedom of discussion, it also was proposed to consider both these outlines and the impromptu discussions that might follow as confidential; that is, they were not to be printed without the consent of the speakers in every instance.

Mr. Ralph E. Flanders, Vice-President of the Society, presided and opened the meeting by recalling the challenge which Dr. Wesley C. Mitchell[1] had given engineers to face economic problems. Mr. Flanders stated that this meeting, although arranged far in advance of Dr. Mitchell's address, was nevertheless an acceptance of the challenge. He then called for the presentation of the three formal papers and the general discussion that should accompany them.

Manufacturing in Advance of Orders in Seasonal Industries

By EDWIN S. SMITH,[2] BOSTON, MASS.

The methods used by American business concerns to reduce seasonal slumps have formed the basis of study for the opinions of the author. Efforts to reduce seasonality may take the form of striving for a more uniform sales demand throughout the year, an attempt to get orders further in advance of the season, or a more level production curve. The experience of a number of manufacturers is related in the effort to show preferred methods in many lines.

THE data and opinions set forth in this paper are the result of a study by the author of methods used by American business concerns to reduce seasonal slumps. The study was made under the auspices of a committee of New England business men consisting of Henry S. Dennison, President, Dennison Manufacturing Company, Framingham, Mass.; John H. Fahey, Publisher, *Evening Post*, Worcester, Mass.; A. Lincoln Filene, Chairman of the Board of Directors, Wm. Filene's Sons Company, Boston, Mass.; Henry P. Kendall, President, Kendall Mills, Boston, Mass.; and J. Franklin McElwain, President, J. F. McElwain Company, Boston, Mass.

Effort to reduce seasonality may take the form of striving for a more uniform sales demand throughout the year, an attempt to get orders further in advance of the season, or a more level production curve, or all three. Numerous instances can be found in American business of these various types of procedure.

The author's belief is that the solution of the problem of seasonality by the first of these methods, which takes the form of filling in the valleys of a normal seasonal dip in sales, is the most difficult to achieve. Sometimes new uses can be developed for a product which will appeal in the off season. Again, by slight alteration a seasonal product may be made into a year-round seller. But the cases when this can be accomplished appear relatively rare. To stimulate sales in the off season by making a special advertising and sales drive may or may not result in new business at a profit. If the effort keeps down overhead and keeps up the morale of salesmen, such drives for off-season sales are no doubt often justified. In general, reluctance of the consumer to buy certain products at certain seasons represents a deep-rooted habit whose force the manufacturer is bound to respect.

There are many cases where a manufacturer has helped to fill the hollows of a seasonal sales curve by cultivating a foreign market in the Southern Hemisphere, which has seasons opposite our own. Seeking a diversified domestic market, both geographically and by trades, may afford opportunity for extending sales through the dull season.

To introduce into the line a new item which enjoys a busy season in the dull season of the company's regular product seems to offer to many manufacturers an attractive avenue out of the slough of seasonality. Several have followed this plan with success. However, if the new product requires a substantial departure in sales or production technique, it may prove a risky undertaking. Also it may grow at a faster rate than the regular line and so create a seasonal peak of its own.

A common method of trying to regularize seasonal production is to endeavor to get orders in earlier. The retailer's marked present preference for buying close to the season makes this a

Contributed by the Management Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

difficult policy to pursue. Even special discounts and datings many times will not tempt them. This is particularly true in industries where style plays an important part. Until the trend of fashion is known, the retailer prefers not to order. Chains, cooperative buying groups, and mail-order houses, which buy in large quantities, are obliged to indicate their requirements earlier in order to obtain prompt delivery. They are therefore a stabilizing influence on the flow of orders.

An inquiry among department stores revealed the fact that in almost every line the larger department store, at least, is placing orders with fewer manufacturers. Although up to the present this policy may not have resulted in more advance ordering, it seems that this should be its ultimate result. The more closely individual manufacturers and retailers work together, the more aware they become of each other's needs and the more confidence they acquire in each other's judgments. If the retailer has been taught by experience to have faith in the salability of a certain manufacturer's merchandise, he should be more willing to place orders with him before the direction of demand for the next season makes itself definitely felt. The simplification movement, by eliminating slow turning items, has for many kinds of merchandise made advance ordering by the retailer less risky.

The brief summary just given of some of the topics covered in this study indicates their complexity. In a brief paper delivered to an audience familiar with the details of management practice, the author believes that to isolate one phase of his study and treat it more comprehensively would be the most satisfactory procedure.

One phase of regularization can, in a short period of time, be discussed with much greater satisfaction than many. For purely selfish reasons also the author is anxious to get the reactions of a technical group on the particular subject picked for presentation, namely, manufacturing in advance of orders. Time does not permit treatment of the subject of budgeting production in a seasonal business, but budgeting quite properly precedes the manufacturing to stock.

The attempt to achieve level production despite a seasonal sales curve is perhaps more often made by manufacturing to stock than by any other method. Under present conditions of close-to-the-season ordering by wholesalers, manufacturing in advance of demand is virtually a necessity in most seasonal industries. Even though a concern may not deliberately set more level production as a goal desirable to achieve for its own sake, it must ordinarily do some manufacturing in advance of orders, so that it may have merchandise ready to deliver when active buying commences.

Instances of Advance Manufacturing

The May Oil Burner Corporation, whose business is distinctly seasonal, feels it necessary to build up a certain amount of stock in dull seasons to meet later delivery demands. However, it attempts to achieve level production for about eight months only in the year, two months going extremely high and two months about 25 per cent higher than normal. Finished stock is not in excess of 90 days' shipment in the dullest time of the year, or two weeks' shipments in the busiest. Employment is much steadier than production because overtime is resorted to in the peak months. This policy serves to cut down lay-offs in the dull months.

The Gruen Watchmakers Guild of Cincinnati sells as many watches in four months of the year as in the remaining eight, the peak seasons being at graduation and the Christmas holiday season. It employs about 2800 persons and states it has never let anyone go because of lack of work to do. During the eight months of lower sales it manufactures about twice the quantity of watches which it sells.[3]

[3] Radio talk by Dr. Francis H. Bird, University of Cincinnati. March 24, 1930.

The Crompton Company, manufacturer of velvets, plushes, etc., has a selling season which is largely concentrated in August, September, and October. As it takes two to four months to prepare the fabrics, it is obliged to undertake manufacturing in advance of orders. If, then, the season turns out unsatisfactorily, production is curtailed. This sometimes necessitates a carry-over of finished goods until the next season. "Obviously," the company states, "this requires large amounts of capital and considerable patience. So far we have found no better solution of the problem."

The Norton Company, Worcester, Mass., maker of grinding machines and wheels, manufactures to stock in accordance with sales forecasts balanced against variation in incoming orders. Stock is classified by items on the basis of turnover, and when stock is being accumulated, it is made up of items which are most active. This is of course the soundest method to pursue in any program of manufacturing to stock.

Keeping the Labor Supply Intact

Keeping the labor supply intact is a reason which frequently determines a policy of advance production in months of dull sale. This may be a sufficient motive, even though to let manufacture fluctuate with demand would be in other respects cheaper.

The refrigeration department of the General Electric Company has a sales curve which reaches a high peak in the warm weather. This company stated that it would be more economical to have its monthly production rate vary with sales, particularly as improvements by competitors may affect the sale of models which are manufactured in advance of demand. However, the machines used in the manufacture of refrigerators are built to very limited tolerances and require a high degree of precision. To make sure of keeping a properly trained working force, the company has felt it necessary to produce about the same quantity of refrigerators every month.

In a small community the need for maintaining a low employee turnover may be particularly acute since the labor supply cannot be readily replenished. The American Optical Company, Southbridge, Mass., has this problem. It feels obliged to do much advance manufacturing, although it finds this more and more difficult, as style appeal plays an increasingly large part in the sale of its products. It avoids this difficulty in part by carrying advance manufacture only up to the point of actual finishing. Concerns which are able to take this form of insurance against style change are in a favored position when they undertake to manufacture in anticipation of orders.

Factors Assisting Advance Manufacture

It is often possible for a manufacture of products which are fairly standardized to make up parts in advance, even though the final assembling of the product has to wait until specific orders are received from the customer. The Barrett-Cravens Company, manufacturer of lift trucks, portable floor cranes, portable elevators, etc., makes up in dull times various parts of the lift trucks and other products such as crossheads, platform tops, wheels, handles, and even frames.[4] The device of making repair parts for stock is employed by many concerns in an effort to get more level production.

The practice of standardization of parts and products and of simplification of lines is assisting many concerns to undertake advance manufacturing with less risk. The movement for limiting the variety of colors has assisted paint companies in knowing the proportions of certain colors that it is safe to manufacture in advance. The Sherwin-Williams Company finds that 30 per

[4] "Steadying Business: No. 2, The Metal Trades," published by the Policyholders Service Bureau of the Metropolitan Life Insurance Company.

cent of the demand for house paint is for white, with ivory, colonial yellow, and grays following. This enables that company to make up stock in advance and ship it to the warehouses.

Many concerns which do not dare to take the risk of manufacturing in advance of the season on their style lines are in a position to fall back on certain staples which can be made year in and year out, during dull buying seasons, feeling reasonably assured that those articles will prove salable.

The Hickey-Freeman Company, men's clothing manufacturers, states that it is able to offer workers year-round employment even though the men's clothing business is notoriously seasonal. One means used to achieve this result is to manufacture for stock blue suits, tuxedos, and other staples.

The Stehl Silks Corporation, broad silk manufacturer, is in a business which is drastically affected by styles and is highly seasonal. Also the process of manufacture takes three months from the time of shipment of raw silk to the throwing plant until pieces are received back from the dyers. Under these circumstances there is nothing to do but forecast styles as well as may be and to build up inventories in the slack season, in order to make prompt deliveries later. There are certain staples, such as georgettes and crepe de chines, which can be woven "in grey" before decision is made as to the design or colors which will later be applied. This removes some of the risk of advance production.

An important part of a well-thought-out program for manufacturing to stock is the continual effort by the sales division to get customers to order stock items instead of clinging to the often trivial variations which in many lines characterize special orders. The Eaton, Crane & Pike Company reports that it continually strives to interest customers in stock items because this gives a better chance to plan production ahead. This company carries a large stock which does not move for several months, but it believes this policy warranted by its results of steadier production and employment.

The Dennison Manufacturing Company reports that by studying a number of special orders, stock items which meet the requirements of most of these orders can frequently be worked out. This not only permits manufacture in large lots at times which balance the production schedule, but helps to eliminate rush orders and makes immediate deliveries possible.

The Link-Belt Company, of Chicago, states that it is always looking for items which can be grouped and carried in stock. This has been done successfully with crane parts such as loaders, vibrating screens, speed reducers, etc.

The Carborundum Company, of Niagara Falls, N. Y., maker of abrasives and refractory materials, reports a larger percentage of finished products as manufactured to stock and that more and more special orders are from time to time changed over into stock items. The concern, which has only a few customers whose wants are well known, may even in an industry much affected by style, successfully anticipate future orders in its desire to produce on a more level basis.

Because the Lumb Knitting Company, of Pawtucket, R. I., women's rayon underwear manufacturer, has only four customers, and its connection with each of those customers is one of long standing, it has made it its business to understand its customer's needs with such thoroughness that it has often successfully anticipated what quantities of certain items will be ordered, before the customer himself has ventured to enjoy any such confidence.

"In-Stock" Departments Necessitate Advance Manufacture

Manufacturers who have changed their distribution from jobbing channels to dealing direct with retailers, necessarily carry a larger stock. Their goods, which in pre-war days would have been shipped out in large quantities at certain seasons of the year in response to heavy ordering by wholesalers, are now more likely to be accumulated gradually with an eye not only to the customers' needs, but to the economy of level operation. Under an intelligent policy of inventory control, many manufacturers have found that the warehousing and jobbing functions they have been obliged to assume have had a silver lining in their effect on their production program.

Hand-to-mouth buying, with its emphasis on prompt delivery, has forced many manufacturers to develop elaborate "in-stock" departments. These are to be found today in almost every line of business. By means of these stock departments, the customer can re-order constantly during the season in small quantities. The need to maintain such departments has forced many manufacturers into a program of manufacturing in advance of orders.

E. T. Wright & Co., Inc., Rockland, Mass., maker of Arch-Preserver shoes, reports that it has increased the business done on stock shoes until this represents approximately 75 per cent of output. As it is necessary to anticipate busy stock-shipping months the company finds that its stock-manufacturing program "has helped amazingly in ironing out the seasonal valleys."

An extreme instance of manufacturing to stock is furnished by the United States Cotton Company, of Fall River, Mass., makers of Cape Cod shirts. The men's shirt business is highly seasonal. Thirty per cent of the year's business of this company is done in the month of December. Seeking to attract the department-store trade, it aims to keep a stock of shirts at all times sufficient to cover the demand for immediate delivery. It has no orders in advance and does not seek to get them. Naturally it cannot achieve entirely level production, but by specializing in a standard broadcloth shirt in a limited range of colors, it is able to manufacture in advance of demand with a minimum risk.

Building up in-stock departments has of course necessitated enlarging warehouse facilities. The existence of these facilities has undoubtedly made it possible for many concerns to manufacture for stock which they could not previously have done because of lack of storage space. Bird & Son has steadily increased its warehouse space in the last ten years in more than direct proportion to increased business, for the purpose of maintaining more nearly level production. As a result of this policy this company reports that no production department faces a complete shutdown from a lack of orders or storage space.

Research an Aid to Manufacturing in Advance

Many times when a manufacturer desires to spread his production more evenly, he has to undertake research to make it possible to store his product without danger of deterioration.

The New England Confectionery Company manufactures some 500 varieties of candies, some of which can be stored and others not. At one extreme are fudges which deteriorate rapidly, but lozenges at the other extreme can be stored for years. In between are various lines with different keeping qualities under storage conditions. Chocolates can be stored in properly conditioned rooms from two to six months. As a matter of fact certain candies are improved by storage.

The Procter & Gamble Company, soap manufacturer, acquired some cotton-seed mills which at the time were running only four months a year. This part-time operation was characteristic of the industry. The company promptly proceeded to equip every one of the 15 mills which were taken over with large storage tanks to store seed, and through research found a way to keep the seed from molding or heating. It now runs three of the mills 11 months of the year and could run the others also if there were enough seed in the locality.[5]

[5] From article in *Printers' Ink*, Apr. 17, 1930, "Steady Work—Management's Job," by R. R. Deupree, vice-president, Procter & Gamble Co.

Special Arrangements With Suppliers to Facilitate Advance Manufacturing

Carrying high-priced products in stock is expensive, and this cost deters manufacturers in many lines from advanced manufacturing. Sometimes the cost of manufacturing relatively expensive products for stock can be reduced by favorable arrangements with parts manufacturers. The Silent Automatic Corporation, maker of oil heaters, manufactures on an almost equal monthly schedule throughout the year despite the fact that 60 per cent of its business is obtained during August, September, and October. In order to produce in such large volume in excess of sales, this company took advantage of the fact that the motor manufacturers and control manufacturers from whom it bought had dull seasons at the same time as the Silent Automatic Corporation. Arrangements were made with these suppliers to furnish equipment on a basis of equal monthly shipments, the material not to be paid for until sales had been made by the Silent Automatic Corporation to its dealers or branches.

The Meyercord Company, maker of decalcomania transfers, has made an interesting arrangement with certain veneer manufacturers which permits the Meyercord Company to get into production early and to advance its delivery date at very little expense to itself. During October and November it permits the veneer manufacturers to ship anywhere from 40 to 70 carloads of veneers that are standing in their warehouses, arranging to settle for these veneers as they are used, the veneer companies paying the insurance; in other words, the Meyercord Company offers the veneer companies free warehouse space at certain seasons, but as their own warehouses are fairly depleted of finished products at such times, this arrangement can be made at no economic sacrifice. The veneer manufacturer is also able to clear his warehouses and start production earlier, an arrangement for which he is quite willing to receive deferred payment on the veneers which he has shipped out.

There are probably many instances of seasonal business in which the maker of the finished goods could use his warehouses for the storage of raw materials on which he might draw as needed to the mutual advantage of himself and his raw-material supplier. This type of arrangement offers a method by which production in advance of demand can be undertaken at considerably less expense than when raw materials are bought and paid for in advance of use.

How Food Producers Have Extended Production

Industries which prepare fresh food products for immediate sale, or which can and preserve these commodities, are governed in their productions by current supplies, and these supplies vary with the season.

Concerns in these industries frequently try to meet the problem of achieving more level production by attempts to spread the growing season of crops or the season in which animals are ready for slaughter. With canners manufacture for stock is automatically resorted to because the selling season does not correspond with the production season.

In addition to spreading the season in which supplies are received, meat packers are hoping to achieve more even sales by introduction of frosted meats which can be held in stock.

Canners in general are obliged to manufacture their products at a time when the quality of the main ingredients is at the best. The Campbell Soup Company was regularly faced with a large production load in the early part of the tomato season. However, through its research department it was able in this instance to harmonize the operations of nature with its own needs. It selected varieties of tomatoes which ripened at a later date and persuaded farmers to grow them, thus extending its tomato-packing season.

Through the activities of its laboratory, field-production department, and seed department, the California Packing Corporation (Del Monte products) is constantly endeavoring to secure new strains to extend the packing season. The California canners have interested the Federal Government in trying to develop new varieties of fruit to fill in the intervals when present fruit crops are scarce.

Difficulties in the Way of Manufacturing in Advance of Orders

Despite the most intelligent efforts of management, through standardization, simplification, anticipation of styles, etc., there are bound to be many cases in which a policy of manufacturing for stock, at least on an extensive basis, will be too risky and too costly to undertake.

Lack of certainty of demand for standardized product is a difficulty in the way of advance manufacture which confronts even manufacturers of producers' goods into which style, in the sense ordinarily conceived, does not enter. Due to improved design, the products of the industry which they serve may be changing constantly. Naturally their own products must keep pace.

The Black & Decker Manufacturing Company, maker of portable tools which are used in the automotive and aviation industries, is obliged to alter its product in accordance with mechanical and design changes in various makes of automobiles and airplanes. This situation would make it very risky for it to attempt a great degree of manufacturing in advance of orders. Moreover, style enters even into the tool industry. This company has found it necessary constantly to improve the design and accuracy of its tools in order to hold the interest of garage mechanics who are accustomed to changes in the products on which they work and the implements which are used.

The competitive situation is constantly engaged in making everyone impatient with products to which he might otherwise become accustomed. As long as this force is at work, few manufacturers without much justified trepidation can count on sufficient stability of demand to undertake manufacture in advance of orders.

The Edgemoor Iron Company attempted to manufacture in advance the principal parts of a number of different sized boilers. Changes in the design and construction of boilers made it impossible to find ready sales for this product, much of which had to be carried so long that any saving in manufacturing costs was offset in interest charges.

Even when the risk of a change in demand is not a factor which need cause the manufacturer particular concern, the expenses connected with holding stock in anticipation of orders may be greater than he feels it wise to meet.

The Edward G. Budd Manufacturing Company, of Philadelphia, is a large manufacturer of automobile bodies. Even if it could anticipate with safety, which it cannot, the type of bodies which the automobile companies are likely to demand in any season, it would not manufacture in advance because of the heavy storage expense. This same consideration is distinctly operative in the policy of unwillingness of automobile companies to manufacture for stock.

The value represented in stored goods is a burden which most manufacturers will avoid unless there are powerful considerations impelling them to undertake manufacture in advance of sale. Even though a manufacturer of heavy products concludes that he can save storage space by manufacturing parts and assembling them later, he has to bear a considerable cost in putting the material into storage and getting it out again, a cost which must be weighed in considering the desirability of manufacturing to stock.

Style Fluctuation Hinders Advance Manufacturing

In a vast range of consumers' goods, the probability of change in style or mechanical improvement has become so great that many manufacturers refuse to accept the responsibility of advance production, preferring the expense of expanding their plant and working forces to a point sufficient to handle peak orders.

The women's garment industry, both outer wear and inner wear, goes through decided shifts in color, material, and design from one season to the other, and often during the season, so that with the exception of some reasonably staple items few manufacturers in this industry can afford to take the risk of advance production.

Manufacturers of women's hosiery, like shoe manufacturers and underwear manufacturers, are obliged to carry large stocks for immediate shipment, which is risky because of changes in the demand for colors. The stocking manufacturers have, however, an advantage which the dress manufacturer does not possess in that they can manufacture stockings in the undyed state, dyeing them as the season advances and the trend of demand is disclosed. Also stockings dyed the wrong color can be redyed, but naturally this is an expense to be avoided if possible.

The jewelry business is definitely seasonal, with a high peak in December. It has always been a business which depended very much on the introduction of novelties, and with the coming of costume jewelry this tendency has increased. The R. F. Simmons Company, in Attleboro, Mass., has as a chief product men's watch chains, which are probably as near a staple article as is being produced by the jewelry industry. Nevertheless, operating schedules in this company are cut from one-fourth to one-third from March 1 to September 1, since the risk of advance manufacture is held to be altogether too great.

The radio industry is at present passing through a stage where advance manufacturing is definitely dangerous. At least this is the opinion of many prominent radio manufacturers. The selling season is very definitely concentrated in the winter months, and the manufacturer who attempts to build up stock out of season is likely to find that mechanical improvements in the sets of his competitors will very probably make his own stock unsalable at profitable prices.

The Hoover Company, maker of vacuum cleaners, points out as a difficulty of advance manufacturing that when new models are brought out the accumulation of old models held in stock has to be worked off on unfavorable terms. The automobile and radio companies, which are frequently forced into bringing out new models because of competitive offerings, are loath to accumulate large stocks for similar reasons.

The possibility of price decline is another factor which militates against holding of inventories. This may be true in certain lines even when stock is held for only a couple of months.

Fear of Deterioration as a Deterrent

Manufacturers of food products, with the exception of canners, often prefer not to manufacture for stock because of fear of deterioration. Candy manufacturers, through refrigeration and other devices, have overcome this handicap for certain of their products, but other types of candy cannot be successfully stored. The Coca Cola Company does not manufacture greatly in advance of demand, feeling that freshly bottled syrup is essential to the right flavor for its beverage. It encourages dealers to keep on hand only a 30 to 60 days' supply of Coca Cola. Canada Dry Ginger Ale, Inc., has experimented with keeping production on an even plane, but found it unsatisfactory because of the difficulties of handling heavy cases in large quantities for storage, and the fact that the product goes out again with great variance in age.

Dangers of Overproduction

Advance manufacturing always carries with it the danger of overproduction. This may be true even when the merchandise is entirely in line with consumer demand. When a seasonal business finds itself as the season progresses with heavier stocks than it can hope easily to dispose of, it feels forced to unload these goods at unfavorable terms rather than to undergo the risk and expense of holding them until the next season. That is why the Stehli Silks Corporation, for instance, which is obliged to manufacture in advance of demand, believes that the ideal situation under present conditions of hand-to-mouth buying is to carry sufficient stock to make prompt deliveries, but never to have out-of-demand merchandise on the shelves or to build up inventories in the dull period to a point where dumping and price cutting are necessitated in the busy season. Experience has demonstrated to this company that maximum inventory should never be more than two and a half times the average month's sales.

The most serious result to be apprehended from manufacturing to stock is that the building up of inventories by a sufficient number of concerns may reach a point which constitutes overproduction for the entire industry. This inevitably hastens the coming of a serious depression. Such a state of affairs is particularly likely to happen if piling up inventories in anticipation of seasonal business corresponds with a situation of general overproduction throughout the country whose presence has not yet made itself distinctly felt. That is what occurred in the radio industry, which in the fall and winter of 1929 and 1930 definitely overproduced and was obliged to go through a period of selling merchandise at distress prices. Such an unwise building up of inventories is of course reflected back into the business of the suppliers of the manufacturers who are overproducing. It is for this reason that the R.C.A.-Victor Corporation insists that all its suppliers accept R.C.A. orders for material with the distinct understanding that it cannot build up inventories.

In any seasonal industry an inventory policy that is directed toward the anticipated sales of a normal season might well prove a boomerang if the whole business world abruptly enters on a period of declining volume before this season arrives. To say this is not to say that a policy of building up inventories out of season is unsound. It becomes unsound only if the concern pursuing this course fails to check its inventory expansion constantly in reference to the present and probable future trend of sales in its own and other industries.

In its effect on stability of production and employment, lack of control of inventories by prospect of profitable sales is in the long run disastrous. Temporary employment and fuller use of productive facilities are obtained at the price of long periods of idleness for both capital and workers when business failures or prolonged shutdowns take their inevitable toll. Situations of this sort, occurring either in a highly seasonal industry or one with a more stable sales curve, are of course completely removed from the legitimate production in advance of demand, which is based on careful calculation of profitable orders to be expected when the buying season is under way.

Figuring the Costs of Advance Manufacture

A decision to manufacture for stock may come from any of the motives listed, such as the necessity for prompt delivery when the busy season opens and the desire to keep the labor force intact. Probably not many companies work out an exact comparison of what would be the difference in cost between a policy of manufacturing for stock and holding inventories, including interest and insurance, and a policy of resorting to overtime at peak periods or expanding plant space and adding to equipment in order to take care of the seasonal load.

Unforeseeable changes in price, money rates, or wage rates might well affect the validity of judgments as to the cost of manufacturing to stock or not manufacturing to stock. Nevertheless an attempt to figure these costs is warranted in view of the fact that stock is ordinarily held for a short time only, and therefore changes in price, etc., can often be anticipated.

In certain companies reporting in the study which the author has been conducting a policy of manufacturing to stock has been adopted only after careful consideration of its effect on costs.

The Ritter Dental Manufacturing Company made a study which indicated the definite seasonal character of its business. It then determined the additional value in inventory required to manufacture on a level basis. The result of the calculations showed that the cost of carrying additional inventory, both in storage expense and interest on investment, was more than offset by the cost of the additional investment which would be required in machinery and buildings to manufacture according to seasonal trend.

The Gorham Manufacturing Company of Providence, R. I., maker of silverware, have definite sales peaks in April, May, and June and in October and November. These are the popular months for weddings, and 70 per cent of the business of this company is in wedding silver. Its merchandise is fairly staple; it is meant to last for generations and therefore changes in style are made conservatively. This policy is also dictated by the fact that reorders for silver in patterns originally bought are an important part of its business. Before a change in management in this company took place some years ago production was carried on very much in accord with the sales curve. The new management found upon investigation that interest on merchandise held in stock was less than the overtime paid in old days when manufacturing was according to orders, to say nothing of the factor of impaired efficiency of workers who were subject to overtime schedules. The Gorham Company therefore deliberately divided planned annual production by 50 weeks, and has proceeded to manufacture on practically a level basis since then.

The experience of the Gorham Manufacturing Company at the beginning of the recent depression is an interesting illustration of the fact that a soundly financed company which has adopted a level production program need not necessarily fear that an accumulation of inventory will prove seriously embarrassing. The company, at the end of its fiscal year, Jan. 31, 1930, found itself with a larger inventory on hand than was desirable in view of the business depression. It proceeded to scale down anticipated sales for the year. As the product is not subject to rapid style obsolescence, the only embarrassment in connection with the inventory was the amount of capital invested. In laying out schedules for 1930, it took into consideration the inventory overage and computed the schedule of weekly production, having in mind both the additional inventory and the anticipated sales.

Results of Manufacturing to Stock

A policy of manufacturing for stock does not necessarily imply that level production is thereby achieved. The results of manufacturing to stock may range all the way from practically uniform production month after month to merely a small degree of anticipation of peak-season orders as a result of getting into production a few weeks or a few days earlier. However, there are probably numerous companies besides the Gorham Company which attempt, if they do not achieve, actual division of the production year into equal monthly or weekly quotas. The Procter & Gamble Company estimates the business it is going to do over a 12 months' period and divides it by 49 weeks. This company guarantees employment of 48 weeks to any worker who has been employed six months or more. The production schedule gives one week's leeway. The soap end of the business is not highly seasonal; the product is reasonably standard and can be stored without deterioration. Naturally these factors help to make a level production policy practical.

The White Sewing Machine Corporation points to the favorable result on employment of its manufacturing to stock policy as seen in the year 1929, when the month of smallest sales was 56 per cent of the peak, the month of smallest production 83 per cent of the largest, and the number of employees in the minimum month 92 per cent of the maximum month.

Even more significant testimony as to the spreading of production by means of manufacture for stock comes from the Wickwire-Spencer Steel Company. It attempted to manufacture window screens and poultry-yard screens in nearly equal monthly quantities, with the result that in this line of the business the ratio of production in the smallest month to the largest would be approximately 80 to 100, whereas in sales it would be only 18 to 100.

Summary

Some production in advance of the seasonal rush has become almost necessary in the present era of close to the season buying; otherwise deliveries cannot be made on time, or business will be lost because the capacity of the plant is not equal to the extreme demand that is made on it.

A reason frequently given for advance manufacturing is the desire to prevent skilled workers drifting away when the work is slack. In a seasonal industry a plant must either be large enough to take care of a heavy peak load or the load must be reduced by advance manufacture, thus making possible a fuller utilization of the capacities of a plant that is also smaller. These are two powerful arguments in favor of the economy of manufacturing in advance of orders.

There are many considerations that operate against manufacturing in advance of the season. When the product is bulky and costly, the carrying charges of holding inventories may be greater than the losses due to irregularity of production. A risk to be greatly feared is that a change in style or a mechanical improvement introduced by a competitor may render one's own product obsolete and salable only at a loss of profit.

Many products cannot be held in stock because they deteriorate. Certain kinds of food product are an example.

A concern in a staple industry runs the least danger when it undertakes advance manufacture. Sometimes a company making a style product is in a position to carry advance manufacture to a certain stage, leaving the finishing touches to be added when the season's style trend has made itself known. In most lines there are some items of staple merchandise which can be made up in advance of the season. Simplifying the line so as to eliminate slow selling items reduces the risk of advance manufacturing. Converting special orders into stock items is one device frequently employed that makes manufacturing to stock more practical.

Many concerns now maintain in-stock departments so that they may promptly fill customers' reorders. The additional storage space afforded by these in-stock departments makes possible advance manufacturing. Furthermore, the need to have an ample supply of goods to meet the retailers' current demands, even in the dull season, makes necessary a program of building up of stock inventories.

In a seasonal business inventories cannot be carried over until the next year without incurring heavy expense. Inventories which have been piled up in excess of the seasonal demand which finally makes itself felt frequently have to be "dumped" at a loss when the season is ending. When many concerns in the industry pile up inventories in a dull season, and general business takes a turn for the worse, the whole industry can easily find itself in a state of serious overproduction. On the other hand, if a factory produces a commodity that is not subject to deterioration or to

style obsolescence and that enjoys a unique reputation by which it is virtually insured of ultimate demand, it stands in little danger from overproducing beyond current demand. The only penalty it must pay if there is a serious business slump is the expense of holding inventories unduly long.

In evaluating the policy of manufacturing in advance of orders as a means of regularizing seasonal production, it must never be forgotten that the term is entirely relative. In the instance given a little piling up of inventory may be a highly desirable move, but an excessive piling up of inventory may be disastrous.

Unemployment—Causes, Palliatives, and Preventives

By DR. ROYAL MEEKER,[6] NEW HAVEN, CONN.

The causes of unemployment are manifold, but come under the single head of maladjustment between production and consumption. The chief contributing causes are: Lack of planning of production to meet and not to exceed consumption requirements. Faulty distribution and utilization of the national income, causing alternating periods of over-saving and over-investment in production or intermediate goods, accompanied by under-spending and under-consumption of immediate or final consumption goods, followed by over-spending and under-saving. Wide variations in the general price level, which mean changes in the purchasing power of money. Unforeseen calamities, including marked overproduction of some commodities, as well as destruction of lives and goods by earthquakes, floods, storms, droughts, famines, etc. Technological improvements due to new machines, methods, management, and organization.

Until recently little was known about the underlying causes of unemployment, and that little was known by very few. Hence the methods of treating this social-industrial disease, or accident, are for the most part merely palliatives, not cures or preventives. The palliatives which are most invoked to help us out of depression are: Soup and bread lines; odd jobs; "buy it now" slogan; wage maintenance; public works; regularization of individual plants; unemployment reserves in individual plants. The only cure for unemployment is employment. There are, however, three major policies which may be inaugurated at once for the amelioration and prevention of unemployment: Planning a consumption-production program in all industries for several years in the future. Stabilizing the general price level, through credit and monetary control. Providing carefully planned, all-inclusive unemployment insurance. To make a start on any of the measures proposed requires a degree of knowledge, of cooperative spirit, and of authority which are at present largely lacking. But the evil of continually recurring unemployment demands bold and drastic action.

IT IS true that but little progress has been made in the direction of creating systematic means for either preventing unemployment or caring for the unemployed. Our backwardness in this, the most important aspect of present-day life, comes from our overemphasized individualism and our failure to understand the nature and the causes of most unemployment.

Unemployment, seasonal, cyclical, or continuing, is the most serious defect in the present-day economic organization. The job comes first. Before the intricate and innumerable problems of wage rates, hours, division of labor, rate of production, conditions of labor, etc., can come into existence, there must be jobs and workers doing these jobs.

Unemployment means involuntary idleness from whatever cause, and includes besides the jobless all those who for any reason are employed less than full time. The unemployed includes, then, all jobless workers, all part-time and irregular workers, and all workers who for any reason are not fully employed while actually on the job—those unemployed on the job, so to speak. Unemployment concerns only those able and willing to work. It has nothing to do with the chronically unemployable and those who do not or will not work.

Causes of Unemployment

A large number of names have been used to explain unemployment, the most hackneyed being, "overproduction," "underconsumption," "underproduction," "changes in the price level," and "technological improvements." All these causes can be included under one head—namely, a lack of balance between production and consumption. Five causes contribute to this condition:

1 Lack of planning of production to meet and not to exceed consumption requirements
2 Faulty distribution and utilization of the national income, causing alternating periods of over-saving and over-investment in production or intermediate goods, accompanied by under-spending and under-consumption of immediate or final consumption goods, followed by over-spending and under-saving
3 Wide variations in the general price level, which means changes in the purchasing power of money
4 Unforeseen calamities, including marked overproduction of some commodities, as well as destruction of lives and

[6] Associate in Economic Research of Prof. Irving Fisher. Dr. Meeker was United States Commissioner of Labor Statistics from 1913 to 1920, when he took charge of the Division of Research of the International Labor Office. In 1923 he headed the Department of Labor and Industry of Pennsylvania. In 1924 he went to China on the Commission of Social Research in China. Since his return in 1925, he has taught for a year and a half at Carleton College, Northfield, Minn., and is now engaged in economic research.

Contributed by the Management Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

goods by earthquakes, floods, storms, droughts, famines, etc.

5 Technological improvements due to new machines, methods, management, and organization.

Until recently very little was known about the underlying causes of unemployment, and that little was known by very few. Hence the methods of treating this social-industrial disease, or accident, are for the most part merely palliatives, not cures or preventives.

Palliatives for Unemployment

The first and favorite palliative is the time-honored and dishonorable institution of the soup kitchen and the bread line. Every thoughtful American must feel angry and ashamed that, after passing through ten major business crises and some two dozen less severe business slumps during the past century and a half, we have no effective plan to deal with these emergencies, but still rely mainly upon voluntary haphazard doles to keep the victims of calamity from starving and freezing. The one unanswerable argument in favor of these doles is the fact that even the hard bitter bread and thin soup of charity do keep men from dying of starvation. The Roman emperors did as much. They dispensed free bread and circuses to the jobless proletariat of ancient Rome; we dispense free bread and soup. Whether or not we have improved upon the Roman method seems to depend chiefly upon the relative merits of the free Roman circus and free American soup!

So long as present conditions prevail in America, both the unemployed employee and the unemploying employer will continue to be the unwilling or the unwitting recipients of our doles of bread and soup. The employer whose discharged workers are kept by public or private charity during depressions receives alms indirectly but just as truly as do those who eat free bread, drink free soup, and sleep in free "flop houses." The great American dole is a very poor palliative, indeed, and it is our shame that it still remains our main reliance in every industrial depression.

Next, there is the odd-job palliative. This has less demerit than free bread and soup, but it has not very much merit. Reconditioning and rebuilding plants are not odd jobs. The odd job is merely one means of keeping workers from starvation or complete pauperization during an industrial depression. Again, so long as industrial and political leaders do not tackle the causes of unemployment, the odd job with all its inadequacies will continue as a method of dealing with unemployment.

Within the past few months the "buy it now" palliative has emerged. Merchants have discovered the power of "buying power" and are urging consumers to buy now whether or not they really need things or can pay for them. This palliative at least recognizes the need for buyers to absorb surplus goods, but its merit is slight indeed. The great danger is that large numbers of people may be persuaded to acquire things more or less useless by promising payments which they can never meet.

Wage maintenance is another palliative. This palliative has decidedly limited applicability. The employer cannot pay wages unless he has money with which to pay. Employers who maintain rates and employment out of surpluses accumulated during prosperous years are really practicing a form of unemployment insurance. This form of spreading industrial earnings in fat years over the lean years may be good or bad according to the plan used and the conditions. Most employers have no surpluses left when the lean years come and can maintain wage rates in the face of dwindling income only by cutting down labor costs through substituting machines and methods for men and by discharging, laying off, or giving partial employment to workers. An employer may maintain the rates, but he cannot maintain the earnings of his employees. Buying power of workers is cut down as much or more than it would be by allowing wage rates to decline along with other prices. The sole merit of this practice, if it be a merit, is in keeping a high wage standard against the time of business revival.

The palliative of public works has certain merits, but its function has been greatly exaggerated, not to say misrepresented. Its applicability is very limited. Money or credit taken by taxation or by loans from the people for public works leaves just that much less for private industry. It is not asserted that public works are no good. It is possible to work out a program of public construction extending over 10 or 20 years, although no such program has ever been planned anywhere. Such a program might be speeded up to tide over a severe emergency situation, but at best such work can be helpful for only a very short time. Private initiative and enterprise has in times past been less tardy and more effective than public efforts to aid recovery. However, hearty support should be given to the present public-works program as an emergency measure.

Regularization of Industry

The regularization plans of private corporations and plants deserve hearty commendation and their extension to other plants and industries should be encouraged. They are most interesting and valuable, but they are as yet too limited in scope to help much toward the solution of the major problems of unemployment. No single employer, or group of employers in one industry, or even in several related industries, can effectively regularize production and employment in the one plant or the group of plants included under the plan. To be effective regularization must include all industries in the country and eventually in the world. Encouraging beginnings have been made on a national scale in this country by employer associations similar to the Citrus Fruit Growers Association. International cooperation has been attempted by the several international cartels like the Steel Cartel, the Copper Syndicate, and the proposed Sugar Agreement. The limitations and weaknesses of the existing employer agreements and associations, international as well as national, are too patent to require comment. Before any considerable progress can be made in this country toward extending and making effective an industrial regularization plan, the anti-trust laws must be drastically reconstructed.

The limitations which apply to the individual plant and to groups of plants apply to cities and communities. All these plans by individual employers, by employer groups, by industries, and by communities to regularize production are all to the good. They show that public-spirited employers and public officials are on the right track in tackling the chief cause of unemployment. These plans call for hearty commendation and support from all who desire to attack the causes of unemployment. These efforts are classed at present among the palliatives because of their limited scope and extent.

Unemployment funds set up by individual employers and groups of employers to tide over periods of depressions are described in the report of the Industrial Relations Counselors. But these unemployment funds are quite inadequate to solve unemployment. They are likely to go on the rocks during serious depression because the regularizing of employment is too big for a few individual employers or even groups of employers to accomplish. The plan deserves the heartiest commendation, however, as a first application on a limited scale of the insurance principle to the care, cure, and prevention of unemployment.

Preventives of Unemployment

The only cure for unemployment is employment. This sounds like saying the cure for illness is health; the way to be good is to avoid doing wrong.

There are, however, three major policies which may be inaugurated at once for the amelioration and prevention of unemployment:

1 Planning a consumption-production program in all industries for several years in the future so as to minimize or eliminate overproduction or underconsumption. This should include a more equitable distribution of the products of industry; that is, the national money income
2 Stabilizing the general price level; that is, the buying power of money
3 Providing carefully planned, all-inclusive unemployment insurance to prevent unemployment, as well as to care for the unemployed.

To make a start on any of the measures proposed requires a degree of knowledge, of cooperative spirit, and of authority which are at present largely lacking. If the main framework of the existing economic order is to be preserved, these deficiences must be supplied. If it is difficult to make a beginning, it is even more difficult to carry through to a successful finish. But the evil of continually recurring unemployment demands bold and drastic action. Nothing worth doing is easy.

A Planned Consumption-Production Program

The measure of first importance is naturally the most difficult of all. All that can be attempted here is to emphasize the necessity of directing and controlling our work toward the end of gratifying our wants most effectively. The working out of the complete program will require years of careful research and experimentation.

A beginning, however small, has been made in the planning of production for consumption. These small beginnings should be supported and expanded as rapidly as possible to include all industries throughout the nation, and eventually the nations trading with us. This program is of tremendous difficulty and magnitude, but it is indispensable to the realization of regularization in business and employment. It calls for all the genius of organization and statesmanship among our industrial, financial, and political leaders. It demands the fullest understanding between employers' and employees' organizations, the public, and their representatives. The very difficulties in the way should stimulate our leaders to overcome them.

Stabilization of Money

The reasonable stabilization of the price level is indispensable to the reasonable stabilization of business. Here again there must be clear understanding and complete cooperation between private financial organizations and the public agencies. More progress has been made in theory and in practical application in this field than in either of the others. Numerous books and numberless articles have been written on the subject of stabilizing the price level. While it cannot be proved statistically that price fluctuations precede and cause business fluctuations, nevertheless price changes do affect business profoundly. A consumption-production program would be very difficult or impossible to carry into effect without reasonably stable prices. A good beginning in monetary control has been made by the Federal Reserve System, but it is only a beginning, and there is serious danger that the feeble efforts already made may be repudiated by Congress unless business men act vigorously to support and strengthen the system. The completion of the task will be difficult, but it can and must be done, if socialistic and communistic experiments are to be avoided.

Unemployment Insurance, Preventive and Cure

Unemployment insurance should be enacted primarily to prevent unemployment and to take care of the unemployed. To avoid confusion fundamental terms must be made clear.

First, unemployment insurance is a means of distributing the losses due to business crises and depressions among all buyers of commodities, instead of letting them fall with smashing force upon unlucky individual employers and employees as at present.

Second, the fundamental principle of insurance is the distribution of losses among a large body of risk takers. Losses so distributed would cost the employers and insurance carriers nothing, and the consumers who ultimately would pay the bill could detect no difference in prices, so slight would be the portion of expense falling on any one commodity.

Third, the notion that the whole cost of unemployment insurance will be an *added cost* upon production is absurd. This theory, which seems to be accepted by most employers without question, assumes that unemployment now costs nothing because no system exists to care for the unemployed. A national employers' organization has published a statement declaring that unemployment insurance would cost each year from $195,000,000 to $334,000,000. Possibly the costs would total those sums if *unemployment were not reduced.* The total cost of insurance is of no importance. The difference between the cost of unemployment under the insurance plan and under no plan at all is of vital importance. We must quit deluding ourselves with the foolish fancy that unemployment does not cost us anything so long as we do not recognize it. Make no mistake! We are paying for unemployment and paying through the nose—in taxes for maintaining our extravagant poorhouses, our ever-present street beggars, our sporadic and prodigal outbursts of charity to keep the unemployed from starving and freezing, the colossal costs of inefficiency and ca'canny directly ascribable to unemployment and the fear of losing the job. Even if unemployment insurance should add $500,000,000 to the price of all commodities, the whole nation, including employers, would be the gainers. The total drain upon the national income would be substantially less than at present, but the greatest gain would be in the improved morale of workers freed from the fear of being thrown out of a job.

Fourth, the unemployed eligible for insurance would consist of those alone who lose their jobs through business hazards and not through the workers' own fault. Unemployment is really an industrial accident or disease. In fact, it is the only truly industrial disability. One can fall ill or fall and break a leg at home as easily as at work. One is more likely to get killed or maimed by an auto on the highway than by an operation on the job. But the only way one can become unemployed is to lose his job. Unemployment is just as insurable as illness or traumatic disability.

Unemployment insurance is not intended to pay workers for not working. Its most important effect is prevention. Unemployment insurance will unquestionably act like workmen's accident compensation insurance to prevent the disability insured against.

The Complete Program of Prevention

It is no cause for regret that this country has not thus far resorted to unemployment insurance as a cure-all for unemployment. Insurance should be utilized only as one part of a completely rounded program to combat booms accompanied by hectic over-employment followed by depressions with under-employment and unemployment.

Employment assurance is being advocated by many American employers as an alternative superior to *unemployment insurance* which has been so widely adopted in Europe. It may be said that *job assurance* is but another name for *job insurance.* There is much truth in this statement, but regularization of employment may be practiced without unemployment insurance, and

unemployment insurance may be applied so as to have little or no effect in smoothing out booms and depressions.

Employment assurance and unemployment insurance are the two halves of a complete employment program. Either one alone will fail to take care of fluctuations in business and employment. Both together will achieve a much desired stabilization—economic, social, and political.

When consumption-production is equalized, the value of money stabilized, and unemployment minimized by putting the costs where they belong, we may reasonably expect unemployment to be so reduced that the actual payments by insurance carriers to the unemployed will be much less than the lowest estimate of costs made by the National Association of Manufacturers.

When employers and the rest of the public realize fully that unemployment is what President Hoover has described it to be, the greatest waste in industry, and that every partly or wholly unemployed person must be supported out of the national income produced by those employed in industry, they will take the necessary preventive measures against this greatest evil in the modern economic system.

Employment Stabilization in the Procter & Gamble Company

By HARVEY C. KNOWLES,[7] IVORYDALE, OHIO

The history of one company in stabilizing employment is detailed. Having but three presidents over a period of 93 years, a definite family policy has been carried out, resulting in a plan that virtually guarantees an employee that he shall have work for 48 weeks during the year; that he shall have a share in the profits; that in case of sickness he shall receive two-thirds of his pay for a year and a pension in case of disability; that he may participate in a home-buying plan.

EMPLOYMENT STABILIZATION is a subject much discussed, and there have been thousands of pages written about it. Methods and systems without number have been studied and tried out. It has received the sincere and detailed thought of educated men. Plans, most of which are quite complicated, have been worked out by the score. The method used by us, we believe, is complete and yet very simple. This is all it is: "We guarantee you full pay for full-time work for not less than 48 weeks."

This guarantee of regular employment reads as follows:

To employees located at Ivorydale, Ohio, factory, and participating in the Procter & Gamble profit sharing plan, the company hereby guarantees full pay for full-time work for not less than 48 weeks in each calendar year, less only time lost by reason of the customary holiday closings, or through fire, flood, strike, or other extreme emergency, and subject to the following provisions:

(*a*) When an employee enters the profit sharing plan after January 1 of any calendar year, the company guarantees to him under the terms and provisions outlined herein, full pay for such of the 48 weeks as may remain in that calendar year.

(*b*) The company reserves the right under this guarantee to transfer any employee to work other than that at which he is regularly employed, and to compensate him for same in accordance with the following terms and provisions:

(1) If the transfer is the result of a full or partial shutdown, or a temporary cessation of work in the department in which he is regularly employed, or as emergency in the department to which he is transferred, it shall be regarded as temporary, and the employee shall receive, during such period of transfer, his regular wage rate per hour.

(2) If the cause of the transfer is the permanent termination of the particular department or the particular job where he has been employed, or where the transfer is in the nature of a demotion for any cause, it shall be officially recorded as a permanent transfer, and the employee shall receive the wage rate which prevails for the work to which he has been transferred.

(*c*) The company reserves the right to discharge any employee at any time and for any cause, and further reserves the right to terminate or modify this guarantee in whole or in part at any time after serving six months' notice to that effect.

By this guarantee the employee is assured of regular work and regular pay, and he will also receive quarterly profit sharing dividends on his wages. In addition, he is accumulating with but little effort on his part an investment from which he will receive the regular dividends paid on the Procter & Gamble Company's common stock.

The whole plan of the Procter & Gamble Company has a background covering a couple of generations. From 1837 to 1930 the company has had only three presidents—grandfather, father, and son in 93 years.

Mr. William Cooper Procter four years out of college, when he was 25, went to his father with the thought that it was right for the factory workers to gain some part of the company's earnings. Such a plan was put into effect, and in 1887 Procter & Gamble employees drew profit-sharing dividends, paid in cash. As near as can be told today, the ideas and ideals forming in the young Mr. Procter's mind at that time were something like this:

You have a better and stronger company; you have better citizens in your factory if ways and means are worked out to make it possible for your employees to become part of the company and to become independent and free from worry. There is no thought of dealing in the home affairs; there is no thought of charity; there is, though, a way to meet the conditions feared by labor.

Someone has summed up the needs of the working man as follows:

He must be taken care of when an accident happens.

He must be taken care of when sick from any reason.

He must have a way of purchasing a home—a way of being sure to be able to pay for that home.

He must have a method to build up an independence so that there is no fear of old age.

Mr. Procter has worked out plans in the last forty-odd years that take care of all of these points. These points can be covered as follows:

Accidents. This has been recognized by the states and is well taken care of.

Sickness. Our present plan takes care of a man who is sick from other than industrial accidents, by paying him 66⅔ per cent of his salary over 12 months, and then providing a dis-

[7] General Superintendent, Procter & Gamble Company.

Contributed by the Management Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors and not those of the Society.

ability pension in case of continued sickness. The fund for this plan is built up by the employee contributing $10 per $1000 of payroll, and the Procter & Gamble Company contributing $20 per $1000 of payroll. This plan has been in effect long enough now so that several actuary studies have been made and we feel it is quite sound.

Home Buying. The company has a home-building plan by which money is advanced on homes selected by employees. The assurance of paying for the home comes through good wages and steady work, together with profit sharing. Our profit-sharing plan is as follows:

An employee must be in the service of the company for six months before being eligible for profit sharing. There are numerous reasons for this. First, there are a certain number who are always moving from one job to another. Second, we want the employee to be sure that he likes us, and we want to be sure that we like him. After this six-month period, and upon recommendation of his foreman, a number of shares of the Procter & Gamble Company stock is bought in the open market, the value of which comes closest to the employee's yearly salary. We guarantee this price against decline on the first block of stock. The employee must pay in 5 per cent toward the redemption of the stock, and the company pays in 12½ per cent. Interest of 4 per cent is charged on the unpaid balance, and dividends are credited. This means that the employee will get his stock in about six years. If he leaves prior to a five-year period he gets back the money he paid in, plus 6 per cent interest. Under this plan there are several men who today have over $100,000 worth of Procter & Gamble stock and who have never earned over $35 per week. As a part of profit sharing, the employee comes under the guarantee of employment plan.

It is our belief that what people want is to become independent through their own efforts and not have to rely on charity in old age. Under the plan a man may retire from 50 years of age on, with an income somewhat larger than his wages. He builds his own security.

The method used in establishing the guarantee of a full-time job for 48 weeks was worked out about as follows:

Shortly after the war, Mr. Procter said: "Are we not missing the biggest point in our manufacturing program when production is not controlled to flow evenly? The consumer uses our products at an even rate; the grocery store sells to them at an even rate; why should not our business be operated at an even rate?" The first work was for the sales department to estimate the business of the next five years.

Each salesman covers a population of approximately 200,000, or 50,000 families. He knows what he has sold in that section, and he estimates what he can do in the way of bettering his condition in the future. We have then a real estimate made up by the men who sell the goods. This five-year estimate was then gone over with the manufacturing department. The salesman takes the first responsibility, and before the schedule is put into effect every person in the company takes his responsibility in seeing that this guarantee of employment is carried out. The plant went into effect August, 1923. As a matter of interest, the 1926 production schedule was within 0.12 per cent of that schedule made out in 1922 for 1926, and the only variation was in slightly larger sales than estimated.

Our present method is about the same. Each fall of the year the sales department estimates the coming year. If our equipment is close on certain brands, we will ask them for a three- or five-year estimate, but the year schedule stands for the next calendar year. We guarantee 48 weeks; we divide the schedule by 49 weeks, and our experience has been that we give about 50 weeks. There are seven recognized holidays throughout the year, so that a little over a week is lost that way. The month is worked out by dividing the week by 5½ and multiplying by the number of working days in the month. When this yearly schedule has been agreed to by the sales manager and the manufacturing department, it is approved by the administrative committee of the company and becomes fixed.

It is agreed that on major brands the sales department will hold their monthly schedule within 10 per cent; this is only by brands, and the total of the factory must remain the same. Here are a few figures on how this has worked out:

On one brand of goods the schedule was 1,463,000; the goods produced was 1,447,000. On another brand the schedule was 389,000; we produced 399,000. On another brand the schedule was 349,000; we produced 343,000. On a whole group of products there was a schedule of 12,096,000 for the year, and we produced 12,173,000, or six-tenths of 1 per cent over the schedule. Now this is not at all easy to do. It means that every one in the organization must accept his responsibility.

When conditions such as for the last twelve months have called for increases in some particular brands and decreases in others, the matter is talked over between the sales and the manufacturing departments, carrying it right down to the distribution of labor.

This guarantee of employment has cost us a little money at times. Due to the lack of buying last spring, it was necessary to stock quite a lot of soap. On the other hand, it has had many fine sides in addition to providing steady employment. For instance, when we built our Baltimore plant, which started operations in July, and when we planned the Long Beach, Calif., plant, which will start next July, we not only have a well-thought-out schedule for these plants, but we plan our manufacturing on the basis of the plants producing 50 weeks a year, and the equipment is not much more than that. Prior to starting up the Baltimore plant, for a period of three years it is doubtful if we had a capacity of 10 per cent in excess of our average production. It has meant that all the equipment is going and all building space is used; both are naturally maintained because of the necessity of keeping them in operation, and everyone knows that the way to have good equipment is to run it.

We have not yet applied guarantee employment to the cottonseed mills, but we have been able to double the time of operation of the mills and make it perfectly possible to run the year around, if the seed could be bought. Mr. Procter took active charge of the mills four years ago, and it was not very long before tanks had been erected for storage and ways and means for preserving cotton seed had been perfected.

We do not know how this guarantee would apply to other businesses, but we do know that there are many ends of our business that ten years ago we would have said were impossible to stabilize. Today it seems quite logical. There are many instances where certain by-products are seasonable, and we have trouble disposing of them evenly, but we have made arrangements to fill in with another product during that time.

The number of people affected by the profit-sharing plan will be of interest. To be eligible one must have been with the company six months and be either an hourly worker or a weekly one getting $2000 a year or less. Of those eligible over 95 per cent are profit sharers and come under the guarantee.

The main thought is this: Ten years ago our business was quite seasonable. There were periods when we would do almost twice as much business as other periods. Every one naturally fell into his or her responsibility and has helped work out a definite plan.

If we have not obtained the best type of plan, we have at least found out that when one has set a goal ahead that is right and is determined and willing to put in the time and effort, it just becomes natural to find a solution.

Discussion on Stabilization of Employment

REPORTED BY CHARLES W. LYTLE,[8] NEW YORK, N. Y.

IN inaugurating the discussion, Chairman Ralph E. Flanders presented Dr. Lillian M. Gilbreth,[9] who spoke from her experience as the women's representative on Mr. Hoover's Unemployment Committee. Mrs. Gilbreth first told something of the personnel of the committee. She then pointed out that those present represented types who still held positions and that there was much they could do to support the work of the regular committee. While she praised the measures for long-run stabilization, she also stressed the importance of immediate relief measures. One of Col. Arthur M. Woods' first slogans, she said, was "Spruce up your home." Finally, she stressed the importance of maintaining American standards of living and present wage rates, saying: "I think, from the President all the way down to the committee, we all feel that reduction in wages and in living standards would be absolutely fatal."

The general discussion centered largely around Mr. Knowles' paper and continued at a high pitch of interest. The Chairman commented on the great responsibility of a management which undertook such a program and asked Mr. Knowles if the salesmen did not feel like quitting when they received their quotas. Mr. Knowles answered that, on the contrary, every one knew just what he was expected to do and that there was a clearer understanding of responsibility all the way through. In answering questions regarding the security of markets for the soap business, Mr. Knowles pointed out that the general run of soap constituted only half of the business and that the making of fats such as Crisco constituted the other half. The first half had recently fallen off 10 to 15 per cent, but as a whole the business for the present year would be a little larger than for the last year. A factor which had facilitated sales was replacement of a certain amount of the jobbing business by chain stores.

To illustrate that the soap business has not always been as stable as at present, Mr. Knowles cited the cotton-seed end of the business. Ten years ago 90 per cent of the cotton seed used was crushed by the middle of January. Mills then shut down for the rest of the year. The reason for this was that they did not know how to carry cotton seed over without its deterioration. At present Procter & Gamble has three cotton-seed mills operating all the year round, crushing a total of 157,000 tons per year, their other mills operating up to April 15. Even here it is expected to bring about greater stabilization. Referring to the fact that some money had been lost in order to work out the ideal, Mr. Knowles asked, "Is it not logical and necessary to lose money in advertising and experimenting when you have faith that your plans are right?" M. F. Simmons[10] pointed out that there was naturally a seasonal factor in the marketing of the electric lamp globes, but that his company had already announced a guaranteed employment plan in all lamp divisions and hoped to do the same in the turbine divisions.

The Chairman called attention to the fact that the Procter & Gamble Company and the General Electric Company represent two radically different types of management and yet they seemed to be in substantial agreement. "This ought to give some of the rest of us a little more courage."

Mr. Knowles continued by saying that their sales department was bound not to increase the yearly schedule until such schedule could be maintained. This puts a premium on making the sales continuous and does not allow coverage of poor sales by a temporary excess. Some one asking if Procter & Gamble made their purchases of equipment steadily, the answer was that purchases were reasonably steady. In fact, this is facilitated by the knowledge of how much volume is to be produced in advance.

Another machine-shop man recalled that years ago F. W. Taylor demonstrated certain principles in the machine industry which were reluctantly received by other industries on the grounds that they were not applicable. He then raised the question if such other industries were not now demonstrating new principles which in turn were being reluctantly received by the machine industries for identically the same reason.

The Chairman then called upon L. W. Wallace.[11] The latter expressed the opinion that Dr. Meeker had painted a picture which was entirely too pessimistic. "I think that individual industries and leaders of industry must begin to educate themselves and try out various methods in their own plants." He quoted the motto applied to the engineer at the 50th Anniversary of the A.S.M.E., "What is not yet, may be." "What leaders of industry need today is to carry that sentiment in their minds constantly." To the machine-tool people, he said, "May I suggest that you go back to your respective plants and keep engraved upon your hearts that statement. If you will start to work with that as a foundation, I believe you will be much surprised to find how quickly you can do something equivalent to what has been done by Procter & Gamble, Dennison Manufacturing Company, and others. Until we adopt that kind of a program we will confront crises similar to this 10, 15, and even 30 years hence. The encouraging thing is that people are beginning to think and act in a new direction. They are building a program which will eventually even out the peaks and valleys of the business cycle."

Referring to what the engineering profession could do in the present crisis, Mr. Wallace continued: "I realize that there is no group in the United States that can be more depended upon in the call to solve national emergency problems than the engineering profession." Here he explained the plan of Colonel Woods to make a canvass throughout local sections for the purpose of ascertaining what industry has done to stabilize employment.

Again taking issue with Dr. Meeker, he objected to the inclusion of public works as a panacea. He said: "Intermittently since 1882, the engineering profession, in cooperation with other organizations, has advocated a Federal Department of Public Works. Such a step would bring about great economy of operation." In the several bills before Congress, a planning board is proposed, the function of which would be to lay out long-time plans for public-works activities for the Federal Government. These plans would be projected forward from 10 to 15 years and comprise designs and estimates making possible scientifically accurate appropriations.

"It is proposed to set aside reserves so that funds will be available and plans ready when needed for execution. Had there been such a set-up in the Federal Government, it would have been unnecessary for the President to form a Cabinet committee or for Colonel Woods to organize the public-works section of his committee."

In conclusion he expressed the belief that the findings of Colonel Wood's committee would inspire many activities which would tend to lessen the frequency and severity of depressions.

The Chairman then asked R. E. W. Harrison[12] to describe the activities which Cincinnati has had under way for several years. Mr. Harrison paid tribute to the public-spirited employers in that city and to the City Manager, and also gave credit to Fred K. Hoehler, Director of Public Welfare. Mr. Harrison pointed out that the Cincinnati movement was started at a time of maximum prosperity, purely on the grounds of preparedness for recessions which were fully expected. He said that although Cincinnati was best known for its machine-tool industry, there was a wide diversity of industry. He agreed that it was good business for the employer to retain the skilled working force and to keep labor turnover at a minimum. Mr. Harrison then read a discussion by Mr. Fred K. Hoehler.[13]

The Chairman then introduced William J. Pedrick,[14] representing former Governor Alfred Smith, of the Committee on Employment Relief for New York City. Mr. Pedrick assured of the committee's cooperation.

The Chairman brought up the subject of maintaining wage rates. He had no hesitancy in saying that he was one of a large number of manufacturers who felt that it was advisable to maintain rates simply from the standpoint of maintaining the rate of consumption. He then asked Dr. Meeker to lead the discussion. Dr. Meeker outlined the economist's point of view on this question somewhat as follows:

In particular establishments, reserves may have been accumulated which can be used to contributed toward wage-rate maintenance, regardless of bad times. Throughout industry as a whole, he did not think such maintenance desirable. According to him it would mean that those employers who lacked sufficient reserves would, when faced with price reduction, be obliged to cut the labor cost of production. An attempt to maintain wage rates would intensify the substitution of machines for men and perhaps necessitate shutting down of the plant part or all of the time. In fact, he gave the opinion that the purchasing power of workers throughout the country is lower today than if wage rates had taken the older course downward. He believed that if this had happened there would now be much more employment and that the purchasing power of employees would be higher.

W. W. Nichols[15] dissented from this point of view and told about the findings of Whiting Williams,[16] who had repeatedly worked as an unskilled laborer in order to ascertain just what was on the worker's mind and had now completed another of these adventures at the request of Mr. Hoover. One of Mr. Williams' observations was that he could not at first understand the apparent serenity that prevailed throughout the country and that the laboring class suffered so much unemployment calmly. For instance, there were not the crowds at factory gates as in former depressions. In answer to this he found that there was an appreciation on the part of the employee of the necessity of the layoff and a belief that it would be only temporary. The employee seemed to retain his interest in his former job, with full expectation of getting it back shortly. He had, as Mr. Williams expressed it, "a vested interest in his job" that he had never felt before. Mr. Nichols said that it is this state of mind that has prevented for the first time the appearance of strikes and great unrest. In other words, there is an acceptance by the laboring element of the conditions that prevail and a feeling that both employer and employee are in the same boat. "When the change does come, both will benefit thereby."

Referring to Dr. Meeker's interpretation, Mr. Nichols said: "I want to refute the remarks that Dr. Meeker makes about reduction of wage rates. Recently I attended a meeting of a most representative group of industrial employers, at which this subject was thrashed out. While there was some difference of opinion at the beginning of the discussion, at the close there was no question as to the concensus of opinion in favor of maintaining wage rates. These men had all had long experience in dealing with such difficulties. They felt generally that they must recognize the psychological attitude of labor which interprets a reduction in rates as a thing to be resented. This naturally involves a loss of confidence. The worker today is willing to accept a reduction of hours, but the moment that a reduction of rates is proposed the opposition is strong."

Dr. Meeker insisted that economically the destination was the same. He maintained that it mattered little to the employee what the rate was if the total earning per week was less. In fact, it was his experience that workers were quite willing to accept cuts in rates on the ground that "a half loaf is better than no loaf."

Walter F. Dixon, General Manager of the Singer Manufacturing Company, said that his company had a 75-year record for keeping a reasonably steady gait in good times and bad. "We had reason to realize early that the backbone of the company, the manufacturing plants, was made up of the skilled, loyal, faithful employees. Our product is one requiring a high grade of material, but even more than that, extremely accurate, minutely measured work. One could get some idea of what the work amounts to in our product if it is told that the cost of material in one of our sewing machines is about 13 per cent of the entire cost; that is to say, between 13 per cent and 100 per cent is laid out for labor and overhead charges. As to the plan of the Procter & Gamble Co., with the legal promise they have made to all of their employees within the last two years guaranteeing them constant employment for fifty weeks of the year, we have never considered any legal agreement, probably because we thought the time might come and possibly would come when we would be unable to fulfil our legal promise to the employees; but we have had a feeling which has grown up in the course of years that a man who wants to work with us and has been an employee for any length of time is guaranteed employment, although full or part time we do not say. During the last year of depression we felt the effect of it a little later than every one else, and similarly we pick up a little after every one else. Fortunately for us, whether things are good or not, people have to wear clothing and most of them shirts and things of that sort, so that commencing a little sooner, when we began to feel the full effects of depression, we put our shop, instead of on a five-day nine-hour per day basis, on a four-day eight-hour basis; that is to say, we started working thirty-two hours a week instead of forty-five hours. We did not, however, decrease the piecework rates or the time rates paid to those that are not on piecework. We believe the psychical effect of not reducing rates but reducing time is a very important one; that the employee will look forward to the time when things will be better with no occasion of having to fight the rates back to what they were. They know that when things improve and the factory goes on longer hours their incomes will be greater because their daily rates have not been decreased. Of course every office manager having several thousand people under his jurisdiction hears all sorts of reports as to how things are being taken in the shops. We do not have detectives to report on what the men are saying, but many of the men voluntarily report either to me or the superintendent what the general feeling about business is. I can say

that the feeling is distinctly good at this time. We employ about 14 per cent of our total employees in mills, and the company is probably doing the best it can for them.

"We make all forms of machines. We make the ordinary family machine and we manufacture the so-called factory machine, which is very much more complicated and costs a great deal more to build. We call our simplest type of family machine, 'Unity.' One complicated machine may be equal to six of the Unity machines, so in watching our stock very closely, if we find that the Unity machines are piling up a little too fast, we switch the men over to the complicated machines. Of the various terms to represent this present condition, I do not know whether it is overproduction or underconsumption, but I do think that those of us who have done export business agree that in the conditions in China and the conditions in Russia, it has been underconsumption in the one case, due to chaotic conditions existing in the country, and in the other case conditions of a distinctly different kind. Of course it is a question which each manufacturer must settle for himself as to what extent we are justified in sending over American engineers and American experts of every description, including our agriculturists, in order to assist them in bringing about ultimate competition with ourselves and every other civilized country."

The Chairman introduced John A. Garvey,[13] who outlined the policy of Dennison Manufacturing Company on employment.

At this point the Chairman called on Harrington Emerson[17] to express his views. Mr. Emerson told something of his experiences abroad during the last four years, in which he visited many foreign countries, including Austria, Russia, China, and Japan.

John M. Carmody[18] pointed out that industry as a whole possessed too much obsolete machinery. "In some cases our inventories were heavier last June than they were a year ago in February or October. During the past two years I have visited perhaps 800 plants. I have said to them that we ought to take up this question of obsolescence. I think that question affects not only the great machine industry, but every great industrial manufacturer in this country, and there ought to be a concerted drive toward the elimination of obsolete plants."

Dr. Max Toltz[19] asked Dr. Meeker to explain how the various groups, such as economists, engineers, and politicians, could cooperate toward the relief of unemployment. Dr. Meeker replied that we are all politicians, and furthermore we are all either employees or employers. "It is up to us to solve that extremely difficult problem of keeping a balance between production and consumption. It is not confined to national wants. Unemployment is an industrial accident or disease. In fact, it is the only industrial accident or disease. You can fall and be injured; that is an individual affair. You can have any kind of disease or you can suffer any kind of accident at home as well as at work, but you cannot be unemployed without losing your job; that is an industrial affair. It is the only true industrial accident there is, and it is the only form of industrial accident that we do not insure."

James Winston[20] expressed the opinion that there were as many cures for unemployment as speakers and that the cures conflicted in many respects. He said that an unemployed person is primarily interested in money to supply his needs, and secondarily in a job. He believes that this more fundamental concept might throw light on the varying points of view. He said:

"Some time ago it was reported in the press that the governor of a state ordered certain road work to be done with pick and shovel to the exclusion of machinery. It was claimed that by doing the job by hand 50 men would be employed 60 days as against 15 days if the job should be done with the aid of machinery, making a payroll of $15,000 as against $3750 otherwise.

"If the state wanted to spend $15,000 for that job, why did it not use its road machinery, complete the work in 15 days, and pay the 50 men $300 apiece and let these men do whatever they wished (or do nothing if they preferred) for the remaining 45 days? I cannot see that either the state, the men, or any one else benefited by keeping 50 men 60 days on a 15-day job. On the other hand, I do see some very harmful results from this practice.

"My reasoning is in a mathematical or technical line. On the other hand, I have heard prominent business men, bankers, and statesmen, using the common method of reasoning, prescribe for the same ill a high tariff, a low tariff, high wages, low wages, spending, saving, recognition of Russia, non-recognition of Russia, mergers, non-mergers, etc."

Mason A. Stone[21] raised the question of what makes business grow better eventually. He said that there is a belief that the stock market anticipates the condition of industry, but that he had not found it so. "Last winter I canvassed the town to see what was being done in the building industry and was met with the single reply, 'We can't get any money.' That brings up the subject of credit. The reason that they could not get money was that the bankers did not think it time to build. I think that with the price of materials now decreasing we will probably see the bankers loosen up and construction increase. Thus we will find a demand for raw materials, and without exactly knowing how it all happens, we will find ourselves looking for the swing upward. The stock market will then take note of the situation, and we will be ready for another crash in about seven years."

John A. Garvey.[22] The contribution of the Dennison Manufacturing Company to the subject under discussion will be a description of a practical experiment in unemployment prevention and relief. It is more than 20 years since the company began work on a program to reduce unemployment to its lowest possible terms. Preventing unemployment, even in one small company, is a man-sized job. It meant breaking down buyers' habits and selling prejudices. It meant instilling factory management with a new point of view as to the responsibility for keeping employees busy. Above all things we have found that it is not a job that stays done.

Sometimes in discussion of our unemployment plan we have been greeted with a remark: "Oh, Dennison business is different. You can do things with your line that we cannot do with ours." This is to some extent true, but the reason that Dennison business is different is because it has been made so. Although the product is a varied one, some of the main lines were highly seasonal in character, and in the early 1900's there were few businesses that had more seasonal unemployment than the Dennison box business. Most of the boxes and paper cases were supplied to the jewelry trade to be used with Christmas gifts. It was the custom for salesmen to go out in the early summer and sell the box lines for delivery in November and December. As a result the box shop was extremely busy from July until December, and then business fell off sharply.

When the plan of selling the box line in January rather than in June was first proposed, it was met by a stubborn opposition. Nevertheless, the experiment was tried out in one of the sales

districts, and much to the surprise of most of our box salesmen it succeeded very well.

Within a few years our selling had been swung ahead from June until the early months of the year. The advantage to the factory in regularizing employment is obvious, for schedules could be laid out at the beginning of the year to produce with a stabilized force ten out of twelve months of the year. During the other two months stock could be manufactured to fill in the valley.

To cite an example from one of our other lines, consider our Christmas novelty merchandise. This line of seals, cards, tags, etc., requires expensive machinery and high-class workmen. We found it impossible to keep men and machines busy during the year on Christmas goods, and therefore evolved the plan of popularizing goods of the same type for other holidays in the year. This has been done for St. Patrick's Day, Easter, Hallowe'en, etc. And so to a far greater extent than before we have been able to regularize our production on this type of merchandise.

Our business is not vitally different from any other, and it requires long-range planning as well as considerable energy to get away from seasonal depressions. The program instituted for keeping cyclical unemployment at a minimum differs but little from what now seems to be more or less standard practice.

We guard against overexpansion of facilities and building during peak times. We do not launch new items when business is at the top, but we wait until it begins to fall off, and then use these items as a stimulus for additional business. We keep our advertising expenditure low during rush periods, and increase expenditures when the depression seems to be coming on. We try to keep inventories small during the expansion and build them up during depressions. We centralize the control of hiring to be sure that extra people are not taken on at a time when business is about to fall off. We try to train our employees to be versatile so that they may be shifted from one job to another. All these principles have been worked out little by little over a course of years and have been accepted by our management as being sound.

So much for prevention. But our directors went one step further. They knew that in spite of all these provisions some unemployment would probably come at intervals, and therefore they put aside a fund which would be used for the relief of unemployment. This fund of $150,000 was accumulated during the boom days of 1916–1920, and it was in 1920, after more than ten years of experience in building up a prevention program, that the relief plan was started.

In conference with the employee representatives a plan was devised which provides that all employees of more than six months' service who are temporarily laid off for lack of work will receive 50 per cent of their wages if they have no dependents and 70 per cent if they have dependents. The plan provides that, as soon as there is lack of work, employees who are below the standard requirements will be dropped first, unless there is special reason for keeping them on the payroll; that employees with less than six months' service shall go next; and then as far as possible transfers shall be made from those departments where layoffs are necessary to departments where business may be better. The difference between what employees are actually worth in the department to which they are transferred and the wages which they have been receiving is made up out of the fund. In other words, layoffs are the last step to take after all other steps fail.

Our first test of this plan came in 1921, and we were able to keep practically the entire force at work, and the total expenditure from the fund was only slightly over $20,000. We had a number of new items to throw on the market, and these happened to take very well, backed up by an advertising expenditure which was very much greater than we had used in previous years.

It would be well if it could be said that the same situation exists this year, but unfortunately it is not so. The reasons for this are varied. During the period since 1925 we have had, in common with other manufacturers, a hard fight to retain our markets. During this five-year period, which has been decidedly a buyers' market, we have not been in a position to hold back any new items for the day of severe depression; we have had to launch them as soon as they were ready in order to keep up our usual sales. We were unable to set aside large amounts from our advertising budget. On the contrary we have had to increase our advertising considerably year after year to give our sales folk the backing which they needed. Although inventories have been kept down, this year is no time to increase them, because the style element, even in our varied merchandise, has become important, and paper boxes and novelties of all sorts change styles much more rapidly than was the case 10 or 15 years ago. To be left with a large amount of novelties or boxes on our hands that are out of style would mean a very large loss. Moreover, continual pressure for cost reduction has meant continual work on better methods in order to reduce direct labor and overhead. Installation of machines and facilities for getting out production without the necessity of hand labor has been, as the world well knows, an added force which makes the recent depression a more difficult one than perhaps any other in this generation. The Dennison company has been no different from other companies in feeling the force of this development.

Yet in spite of these factors our experience has not been unsatisfactory taken all in all.

The total number dropped from our employee group since last January is less than 15 per cent of our total force, and this includes the six-month employees who do not fall under our unemployment benefit fund. We have kept most of our factory working on the 44-hour week, although certain departments have been shut down Saturday mornings occasionally.

Expenditures from the unemployment fund for layoffs and transfers have been very much higher than in any other year and will total before the first of 1931 more than $50,000. While this sum is a fairly large one taken by itself, considered in the light of our total yearly payroll it amounts to only 2 per cent, which is much less than many companies spend for projects far less worth while, both to the company and to their employees, than our unemployment fund could possibly be considered to be.

That point should be emphasized to business management—that while an unemployment fund may be a benefit to the employees, it is often of more benefit to management. This statement may not be taken seriously by many managers, and yet our experience of ten years with the fund has taught us that it is true.

It may be thought that the importance of relief rather than of prevention is being unduly stressed, particularly on a program which is devoted to the matter of prevention. Yet the relief side bears the same relation to the prevention of unemployment as the expenditure for fire-insurance premiums has to fire prevention. Years ago business men looked upon accidents as being very sad, and they extended their sympathy to cases where employees were injured or to the families where employees were killed. Yet they did very little about it until accident insurance was made necessary and they were obliged to pay either prevention expense or increased insurance premiums.

So it may be said that the spending of real money for unemployment relief has made the Dennison Manufacturing Company less theoretical about unemployment and more practical. There have been unquestionably fewer platitudes and more action since our fund began to operate. It is a spur to greater effort on the part of our salesmen, and we hear much less of that old story that the factory exists to produce what the sales organiza-

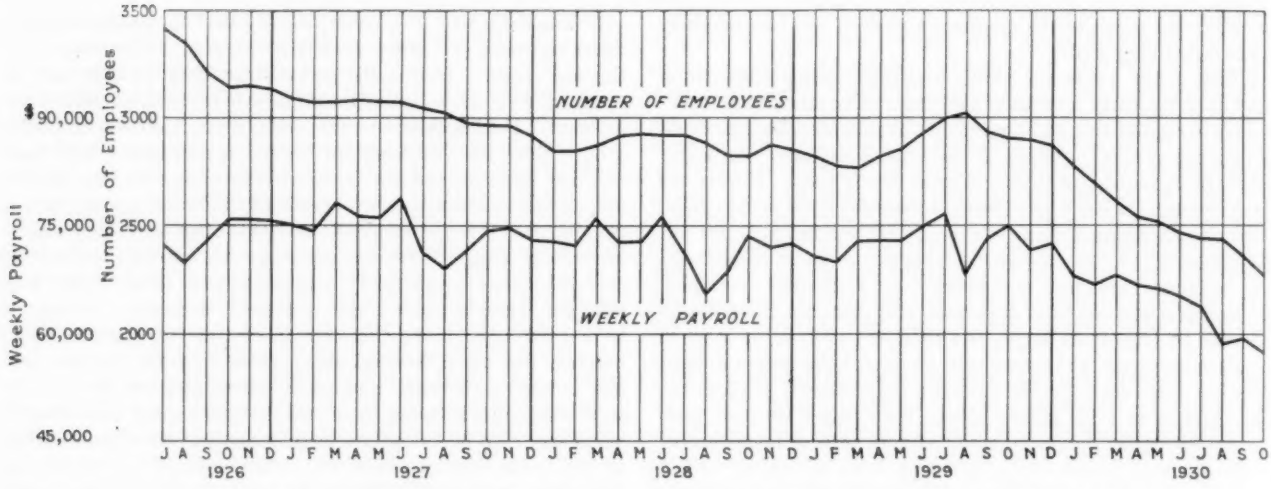

FIG. 1 CHART OF NUMBER OF EMPLOYEES AND AMOUNT OF PAYROLL IN DENNISON MFG. CO.

tion sells and not to give the sales organization orders as to what it shall sell.

At the same time the factory management is forced to take its share of responsibility, and the expenditures from the unemployment fund of each department are given plenty of publicity. As a result the factory management has become more farsighted; they are careful in regard to additions to their force in peak times; they are more apt to spend time training employees to become versatile on various jobs; they are more alive to changing conditions rather than keeping their nose well down to the grindstone and letting the rest of the world go by.

No longer does the sales management say about unemployment, "That is too bad, but really it is not our lookout." No longer does the factory management say, "Well, we are real sorry, but we cannot help it if there are no sales." Today both factory and the sales organization are drawn into close cooperation to prevent layoffs which can be humanly avoided.

And what about our employee group? It is safe to say that they have been more interested in our unemployment scheme in its various developments than in any other project that has been undertaken in our personnel program. In fact, one of our older employees who for many years served as chairman of our Employee Representative Committee said one day: "We can give up our lunch room and the clinic and the suggestion system and even the profit-sharing plan; all of them together are not as important as the unemployment plan. For if a man has a steady income, he can get along without all the other things, but if he has not a steady income, all the other things together cannot help him very much."

Our employees generally recognize the fact that our management is actively interested in this program of unemployment relief and prevention. They recognize the fact that here is one important subject where cooperation of employees and management is something more than a mere catchword. Through their Employees Committee we have brought them into active contact with the problem we have been facing to meet competition to provide steady work. Just as our management has learned a great deal from its experience with this subject, so the employees are receiving an education that it would be hard to give them in any other way. It would be too much to expect that they should forget their personal interests to safeguard our unemployment fund, and yet during the past year they have agreed to, and often have initiated, changes in the plan which we hardly would have expected only a few years ago. And so we face the continuance of our unemployment experiment with confidence that as the years go on we shall work out continually better practices. Although the difficult conditions of 1930 have made it impossible for us to achieve the same results that we were able to achieve in 1921, we have done better, we know, than we could otherwise have done if our plan for prevention and relief of unemployment was not in operation; and we feel even more certain as the result of our experiences this year that fundamentally the program that we have undertaken is both sound and worth while. The details of it will have to be changed, developments will have to be made, but the fundamentals, we are sure, are sound and workable.

E. F. DUBRUL.[23] The machine-tool industry, through the National Machine Tool Builders' Association, is continually taking stock of various conditions. In doing so we at times discover some things that may be of benefit to all other groups of machinery and equipment builders. Some of the latest investigations fail to confirm ideas that were widely prevalent during the last "new era" of stock booming, and also disprove other ideas concerning the widespread prevalence of "technological" unemployment, which is worrying so many people right now.

All can remember how the boomers used to say that last year's stock prices reflected the increasing prosperity of the country due to things such as these:

"Alacrity with which American business management adopted countless new improvements in existing implements of production."

"Strides in building new and more efficient machinery, demands for perfected types of productive instruments, a scientifically controlled industrial and commercial régime brought increasing profits to industry."

They explained the high prices of stocks as being a proportionate reflection of the widespread adoption of the newer productive instruments and methods. There is reason to think this to be a greatly exaggerated picture and one which gave stockholders, bankers, and directors a false sense of security.

That glowing picture seems greatly overpainted as concerns the metal-working industries as a whole.

The curve of stock values, as calculated by the Standard Statistics Company, tended upward enormously from early 1924 to the peak of August or September, 1929. The rise in values was out of all proportion to the increase in earnings of the companies. A glance at the curve of machine-tool orders shows it to have

[23] General Manager, National Machine Tool Builders Association, Cincinnati, Ohio. Assoc. A.S.M.E.

fluctuated at a low level for seven years from 1921 through 1927, and to begin its ballooning only in 1928.

Certainly this curve shows no great "alacrity" to adopt the new and more productive machines which had been designed during that time. Quite in line with these statistical facts were the complaints of the sales forces concerning the difficulty of getting users even to investigate the profit-making possibilities of these machines. So one may wonder why, during those seven years, management displayed so little "alacrity to adopt new methods."

The curve of machine-tool orders seems to indicate such alacrity only in 1928 and 1929. With the drop in the curve of orders to levels below 1927, we wonder where all this "alacrity" has now been stowed away, and how long it will remain under cover. Then, too, some other things make us doubt this "alacrity theory."

In 1926 the *American Machinist* made a survey of the ages of machine tools in service on January 1 of that year. This survey showed about 44 per cent to be over ten years of age.

This year the same paper made a similar survey which indicates that about 48 per cent or more of the machine tools in service on January 1 of 1930 are over ten years old. Apparently the "alacrity to adopt new methods" had been running so much "in reverse" in 1926 and 1927 that our boom orders of 1928 and 1929 were not enough to keep equipment as youthful as it was in 1926.

While some concerns did make a considerable advance over the manufacturing technique prevalent before the Great War it seems probable that the total advance was not as much as the enthusiastic stock-market boomers led the public to believe in the machine-shop field.

It is hard to believe that the managers of the 15,000 important machine-tool-using plants are greatly different, as a class, from the managers of plants that use other kinds of machinery.

So we suspect that there is not much basis for worry about the effects of "technological" unemployment. We suspect that large numbers of manufacturers do not realize how much their plants need modernizing to maintain and advance our present American standard of living.

We suspect that this condition may be due to lack of understanding of the problem of productivity on the part of bankers and financial men who control the expenditures of corporations of all kinds.

These surmises seem clear enough in the case of machine tools, but we have no similar surveys of other machine industries with which to compare our surmises. If these surmises are correct, it appears that there is a job ahead for the whole machinery industry in educating financial America still more concerning the financial benefits to be gained by installing more modern machinery of all kinds.

If the financial clamps were taken off, the machinery industries could do much to give more employment to a well-paid class of workmen, and thereby greatly increase purchasing power for consumers' goods.

GEORGE G. BERGER.[24] Much improvement can be effected and the severity of a depression considerably lessened by the application of the fundamental principles of scientific management. One of these principles is the principle of evaluating results accomplished and using the rating as a basis for wage payment for the purpose of stimulating improvement in these results. The principle of evaluation in terms of adequate standards has many proofs of its force as a stimulating agent. The scientific notation of physical properties of a product may be considered an evaluation on the basis of a standard. By its clarity, the evaluation stimulates the proper design of means to effect the end, the product produced. These evaluations in turn become the standards by which conditions are set for the worker's task. Payment on the basis of the worker's task stimulates productivity. Here we make important discoveries which have been proved by considerable time-study technique since Taylor's time. They are:

1 The human being is capable of doing much more work than he thinks he can do, and which becomes apparent only on stimulation.

2 There are fairly defined limits to the higher production rates which tend to make well-trained workers equal.

3 Wage payment based on productivity is the most effective means of stimulating improvement in productivity.

Now what I have really in mind is the evaluation of the results of the industrial administration, an evaluation in terms not of predicted standards with broad tolerances, but of natural standards set with the idea of maximum turnover of capital in mind. Such standards with one exception are to be secured only when the results to be evaluated are in. This idea of evaluating managerial results has come up before this society under the familiar heading of "the measurement of management." Consider what an effective evaluation or rating of the results of management leads to. First, it can be used to stimulate the personnel to secure improvement in results—that is, to increase competitive power, and work for the survival of the fittest in our economic structure. Second, as a basis for bonus payment, it serves to stimulate the administration executive to produce results which he may not think possible today. For although responsibility accompanies authority, responsibility is psychologically effected by stimulation, by gains accruing to the individual. Third, the balance sheet may be adjusted by the managerial constant to be derived from the ratings to give a conservative statement of what a concern is really worth, making for stability of investment values. These are all important factors in industrial and employment stability.

FRED K. HOEHLER.[25] During the depression of the early months of 1930, there were signs of an awakened public interest beyond anything experienced in former years, in the regularization of employment and the causes of unemployment. This same interest was created in Cincinnati as early as January, 1929, when that city, like many others, was enjoying a considerable amount of prosperity. The Permanent Committee on the Stabilization of Employment, consisting of twenty members, was appointed by the City Manager. The committee elected the City Manager, C. O. Sherrill, as its first chairman and his Director of Public Welfare was elected secretary, thus giving it official standing. The committee membership, representing banking, industry, education, social service, labor, and government, determined the purposes of the committee to be as follows:

(*a*) To study the problems of stabilizing employment

(*b*) To create machinery to handle an unemployment emergency should one arise.

The permanent committee began working through ten subcommittees, as follows: (1) State City Employment Service, (2) Continuous Employment, (3) Temporary Employment, (4) Public Works, (5) Cooperation With Private Social Agencies, (6) Budget and Finance, (7) State and National Cooperation, (8) Transients, (9) Fact Finding, (10) Publicity and Education.

The one great fact facing the committee was the absolute lack of reliable information on employment and unemployment. The very first step, therefore, was to secure and publish accurate and adequate information. There was in existence no one source from which such information could be obtained.

[24] Consulting Industrial Engineer, New York, N. Y. Jun. A.S.M.E.

[25] Director of Public Welfare, Cincinnati, Ohio.

The Subcommittee on Fact Finding utilized the best fact-finding agencies in the community and began work at once. In May, 1929, Cincinnati had its first complete census of unemployment. This was accomplished by using the machinery created by the Board of Education. This body is required by state law to secure an annual school attendance census by means of a house-to-house canvas. The board willingly gave its cooperation to the Fact Finding Committee, and enumerators were requested to ask a few extra questions. The results were later tabulated in the office of the Department of Public Welfare. The Fact Finding Committee then, with a fairly reliable census as a basis, developed current monthly figures on employment. It was this committee which saw the tendency toward an increase in unemployment in the summer of 1929, and so informed other subcommittees, which began to plan intelligently to meet a situation which was imminent.

One of the first tasks of the Committee on Stabilization of Employment was to strengthen the State City Employment Bureau. A subcommittee made a series of recommendations for improving records and methods of functioning. This committee inaugurated the monthly bulletin in Cincinnati and has encouraged employers to use the bureau continuously in supplying their labor needs. Regular and constant visits to industry by members of the staff were urged and insisted upon. The committee plans in more normal times to develop the bureau as a center for employment clearance and employment information.

The need for a strong Federal employment service, cooperating with state and local governments, similar to the Federal Provincial System of Canada, was stressed in the finding of the committee early in April of 1929.

The Subcommittee on Continuous Employment, which was headed by an economist and a former president of the University of Cincinnati, made a study of the concerns in Cincinnati to determine how many of the industries in that city made a conscious effort to stabilize employment. This committee realized that it must have available an adequate statistical and information service and a well-organized and efficient employment exchange to serve industry in its various employment problems. The work had barely begun when unemployment began to grow. The first essential, then, for this committee in dealing with an unemployment emergency was to spread whatever work might be available to as many employees as possible. The committee encouraged the introduction of methods such as the staggering of employment and using employees on a short-hour basis when production had to be decreased. Cooperation of the employers was very heartening and indicates the type of interest which will be given to this committee and its work as it continues throughout the years. Over 50 per cent of the employers reduced hours in order to provide work for the largest possible number of their men.

Largely through the activities of the permanent committee, the city, county, and state governmental units were active in speeding up public works. Public improvements which normally would have been deferred to another time were started during the last winter while labor was plentiful. Plans were formulated to start other improvements early in the spring. The city of Cincinnati and the various city, village, and county units surrounding that city have furnished more work for the unemployed during the past winter and spring than they have ever furnished before under similar conditions. This expenditure of public funds was not only well timed, but was according to a program well thought out in advance. Cincinnati and Hamilton County, Ohio, have for the last few years operated all public improvements on a five-year public-improvement program. Bonds are authorized after the Improvement Program Committee studies the projects, and the same committee then recommends and authorizes the expenditures of such bonds. This has virtually created a public-works reserve.

The Committee on Temporary Employment made a survey of possible jobs should an emergency arise, and set up a large committee of over 100 members geographically distributed. This committee functioned in locating jobs of a temporary nature. These jobs were sought in and about homes or in factories or business houses. In addition to the temporary jobs actually secured by the committee, its efforts helped to create a desire on the part of the public to be helpful, and many temporary jobs, not cleared through the committee, were given out direct to the unemployed.

After the various committees had secured all the work possible the residue of the unemployed were cared for through relief-giving methods. The Subcommittee on the Cooperation of Social Agencies was in charge of this phase of the work. Even here the policy of furnishing work, rather than relief, was followed out so far as possible.

A joint committee sponsored by the Public Welfare Department of the city and the Community Chest operated an industrial relief program, in conjunction with the State City Employment Service, more to furnish work than to provide straight relief.

The reason for securing this work at public and semi-public institutions was that the money which was used to pay for the work came out of tax funds and Community Chest funds. In the city and county we had work only in such institutions as the Hospital, County Home, and in the parks. Other public works were considered a legitimate charge on the regular funds and not as relief work.

The types of work provided by these institutions were cleaning, odd jobs of repair work, digging weeds, repairing camp projects, etc. The committee endeavored always to avoid conflict with regular labor organizations and skilled workers.

The wage paid for work supplied in the industrial plan program is only 40 cents an hour. This is considerably under the minimum wage paid by the city, which is 47 cents an hour, and by the Association of General Contractors, which is 50 cents an hour.

It is important, in this regard, to have the weight of the influence of the best employers of Cincinnati behind our effort so as to prevent a reduction of the hourly wage.

In referring the men to the jobs, preference was given to heads of families who are residents of this community.

In the early days of this experience, 44 hours a week were allowed each man. Because of the number of calls for this kind of assistance and the limited funds available, this was arbitrarily reduced to 24 hours a week as a minimum, with some cases allowed additional time because of special need. Where a man was on a 24-hour schedule, he worked for three consecutive days; i.e., Monday, Tuesday, and Wednesday, with Thursday, Friday, and Saturday free, during which time he could seek odd jobs to augment his earnings. There were two crews of men working; the first crew was paid off Thursday morning, and the second crew was paid off Saturday evening or Monday morning.

A card was used at the industrial relief headquarters for introducing a man for work to his employer. This card was later signed by the employer, who recorded the number of hours for which the man should be paid. At the end of a regular period the supervisor or the superintendent of the institution reports in letter form on the character of the work done and gives his opinion of each individual.

Men must not be allowed to use this as a solution of their unemployment problem. A great deal of vigilance is necessary in order to be assured that the man is not content with this work and will try to secure a permanent place. Where a man refused to take a regular job offered him, he was perhaps penalized by not being allowed industrial relief for a certain period.

The personnel required for this program is two capable social workers and one employment man or a man with employment experience who can follow up these workers and act as paymaster. The two social workers are used for interviewing the men and contacting social agencies.

This method was found to be not only more effective than relief-giving, but more economical. Over 3000 families were taken care of during the last winter by this committee.

The transient problem was handled directly by the Department of Public Welfare. Some of these men were found temporary employment in odd jobs; most of them were not looking for steady employment.

During the past winter nearly 10,000 homeless and transient men were provided with lodging, and nearly 200,000 meals were served. Each man who applied for assistance was given a work card, and by putting in a certain number of hours in the woodyard he could secure for himself lodging, meals, and some odd pieces of clothing. Through this work program the department was able to provide 40,000 bundles of wood to be distributed to families of the unemployed through social agencies. The deficit for the Transient Service Restaurant was carried on by a young woman in Cincinnati who has been working during the past winter with all activities of the Stabilization Committee.

Where it was necessary to give relief to families when the breadwinners were out of work, it was done largely through the regular family welfare agencies, with scarcely any increase in their personnel. The Community Chest appropriated extra funds to be used by the private agencies on unemployment cases. Due to the fact that the case workers of the relief societies knew absolutely that relief funds would be furnished, they were able to handle the problem of relief intelligently. The condition of panic and uncertainty that so often exists among relief workers and their clients in an unemployment crisis was almost entirely lacking in the Cincinnati area during the last winter.

Over 8000 families in which unemployment was the major cause of distress, in addition to those given industrial relief, were taken care of by private agencies during the winter.

The total cost for relief in Cincinnati, as carried by private and public agencies from June 1, 1930, to June 1, 1931, is slightly in excess of $650,000. This is a comparatively small sum for a city the size of Cincinnati. Planning and effective organization has made possible a very good job with relatively low cost.

The question of legislation as a relief for unemployment, such as the matter of unemployment insurance and old-age pensions, has not been discussed by the Permanent Committee on Stabilizing Employment, but our program includes a thorough study of such types of legislation, with the hope that the committee might find something which it can unitedly support before the community.

In brief, the Cincinnati committee has accomplished cooperation between government, the social agencies, and Chamber of Commerce, the university, labor, and industry, for the study of the problems of unemployment.

Progress in Materials Handling

Contributed by the Materials Handling Division

Executive Committee: G. E. Hagemann, *Chairman*, M. W. Potts, *Secretary*, F. D. Campbell, C. D. Bray, E. D. Smith, and F. L. Eidmann

ALTHOUGH the year has been marked by no spectacular developments in the field of materials handling, it has been one of growth and progress. The quiet business conditions of 1930 have had at least one beneficial effect—stressing upon manufacturing plants the need for making increased use of facilities to lower the cost of production. As soon as business conditions again offer the opportunity to make further investments in plant equipment, materials-handling manufacturers are certain to profit from the situation. Materials-handling equipment offers one of the most definite means for obtaining continuously lower production costs, not only through the substitution of mechanical operation for manual labor, but also through the elimination of useless steps in the manufacturing cycle.

In the following paragraphs are listed comments on such of the important new developments in equipment and methods of application as could be collected from manufacturers for publication in this Report. The work of compilation was divided among fifteen men, and, in each section of the Report credit is given, by means of a footnote, to the individual who prepared the material in that particular field.

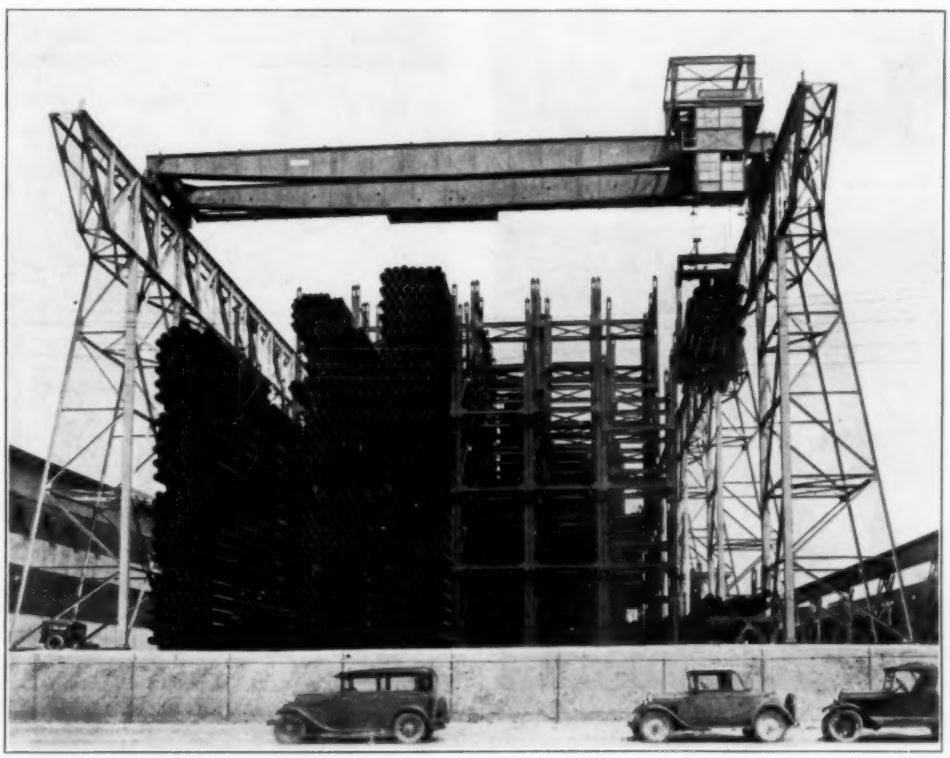

FIG. 1 HANDLING WELDED PIPE STORED IN UNIT FRAMES WITH OVERHEAD TRAVELING CRANE

OVERHEAD TRAVELING CRANES[1]

Engineers have collaborated with industry in designing cranes that provide a maximum of service under the hook, high speed, and low maintenance cost. Anti-friction bearings, improved lubrication, precision in manufacture, and flexibility of design have all contributed to this end.

[1] Section prepared by Henry W. Standart, President, Northern Engineering Works, Detroit, Mich.

Of signal importance is the application of the overhead traveling crane to special service requirements. In this effort all manufacturers have contributed generously, until today there is scarcely an industry which has not adopted the overhead traveling crane as a means toward the economical handling of material. A few interesting applications of the traveling crane are presented herewith.

The handling of carload shipments in containers has contributed to economy and efficiency in freight yards. The Harnischfeger Corporation recently has applied this principle in an interesting manner for the handling of carloads of welded pipes in units, as shown in Fig. 1. The pipe is stored in unit frames and, when shipped, the entire frame is lowered into the car.

Many new applications of the overhead traveling crane are found in handling paper, the Harnischfeger Corporation recently having developed an automatic grapple, shown in Fig. 2 for handling rolls of paper used in the manufacture of containers.

The rayon and dyeing industries, fields recently developed for the traveling crane, have brought about many new and novel applications. The Box Crane and Hoist Corporation has introduced the container principle into this development. Cranes are employed for handling containers, or racks, for dipping material into dyeing vats, as shown in Fig. 3.

Still another interesting use of the traveling crane is found in the field of sports. The Northern Engineering Works has applied the standard overhead traveling crane to the handling of speed boats in a motor-boat garage, as illustrated in Fig. 4. This crane is of the low-headroom drop-truck type, permitting applications within limited clearances. An adjustable head

beam is used for handling boats of various lengths. The boats, when out of service, are removed from the water and placed in storage cradles.

Electric Hoists and Cupola-Charging Machines[2]

Electric Hoists. Several new electric hoists, mainly in the small capacities, have been rather recently placed on the market. They are designed to supply the higher speeds now currently demanded. The single-speed reversing switch, which was adequate to handle the slower speeds previously prevalent, is no longer suitable to control these higher speeds, on account of the more severe resultant strains on the hoist mechanism. These

Fig. 2 Handling Rolls of Paper With an Automatic Grapple

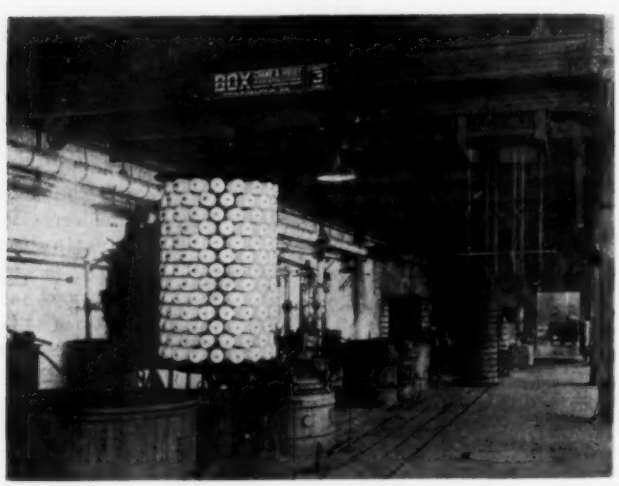

Fig. 3 Rack With Material to Be Dipped in Dyeing Vat

higher speeds also require more rugged brakes and greater braking area.

There is now a general use of heat-treated steel gears, of special-steel shafts, and higher-speed motors of special design for hoisting service only. The lack of lubrication being the greatest cause of trouble, there is a constant endeavor to cut down the number of places to be oiled or greased, so that no place will be overlooked.

A novel use has been developed for single-I-beam hoists made by the Northern Engineering Works. These hoists are now used for handling motor boats from the water into storage in a "boat garage" and then back into the water. Boats varying in lengths of from 17 to 28 ft., and in weight from 1500 to 4500 lb., are hauled out of the water, repaired, and launched again. Cranes are likewise used for this purpose as explained previously in the text and illustrated in Fig. 4.

Cage-Controlled Monorail Hoists. New cage-controlled monorail hoists, in small capacities have been developed to meet the

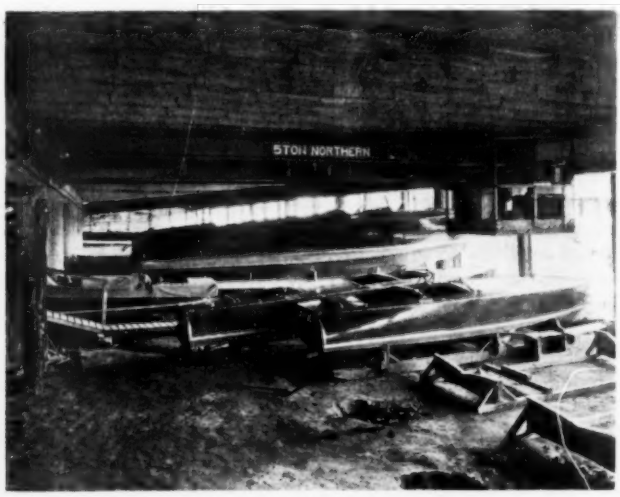

Fig. 4 Handling Speed Boats in a Motor-Boat Garage

Fig. 5 Light Cage-Controlled Monorail Hoist Rounding a Short-Radius Curve

overhead-transportation problem. These hoists can transport small loads at higher rates of speed around curves of small radius through narrow-throw switches, and operate on a system of transfer cranes. An installation view of such a light, cage-controlled monorail hoist, made by the Louden Machinery

[2] Section prepared by Robert T. Turner, Vice-Pres., Shepard Niles Crane & Hoist Corp., Montour Falls, N. Y. Assoc-Mem. A.S.M.E.

Company, is shown in Fig. 5 rounding a short-radius curve, and in connection with a transfer switch.

Heavy, rugged, cage-controlled monorail hoists have also been designed to perform work hitherto delegated to 5- or 10-ton-capacity overhead electric traveling cranes. These cage-controlled hoists are now designed to furnish the extremely long lifts that are required for grab-bucket and magnet service. The hoists are built to meet more restricted clearances than formerly, and are provided with larger cabs to contain the more complicated control apparatus required for handling grab buckets and magnets and for the three travel motions.

The cage-controlled hoist shown in Fig. 6, and made by the Shepard Niles Crane & Hoist Corporation, handles a $1^1/_4$-cu. yd. bucket. It has a 50-ft. lift and goes through a door that is 71 in. in height to the power house. The hoist unloads coal

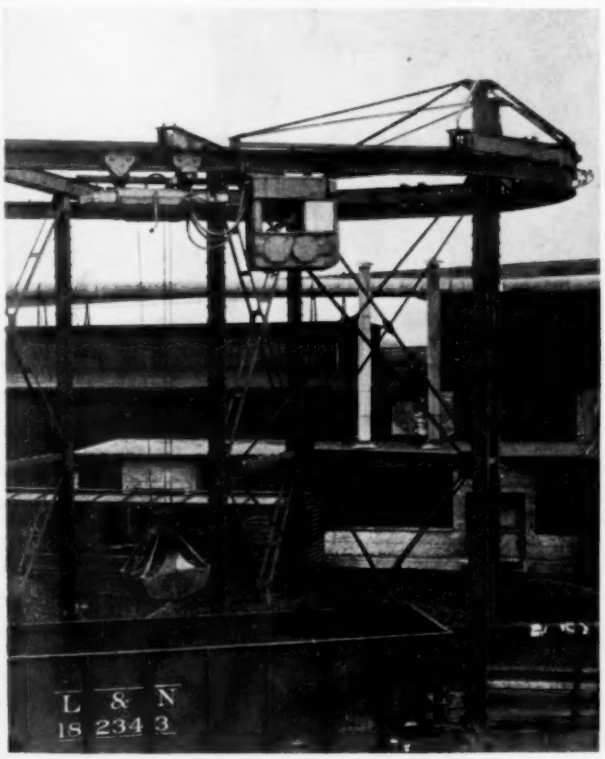

Fig. 6 Cage-Controlled Hoist With $1^1/_4$-Cu. Yd. Bucket for Unloading Coal and Carrying It to Hoppers

from cars to hoppers located on the third floor of the power house, takes the coal from cars to storage piles under a portion of the runway, and also reclaims the coal from storage piles to the hoppers.

Hoists and Cranes for Cupola Charging. Cage-controlled monorail hoists for cupola charging have been developed to handle the larger charges now required. They are designed to carry these larger charges in buckets either of the bottom-dump type or of the cone type and either to lower these buckets into the cupola or discharge them directly inside the cupola opening. These cupola-charging hoists are also used for grab-bucket and magnet service, and often in connection with transfer cranes. The transfer crane can be latched on to spur tracks leading into the cupolas, and the cupola-charging hoist run off on the spur track to deposit the charge in the cupola.

A simple manner in which a cage-controlled cupola-charging hoist of Shepard Niles Crane & Hoist Corporation design can be installed in a foundry having a very small melt is shown in Fig. 7. There is no covered portion either to the charging floor or crane runway. This charging floor was built over the roof of the foundry when the location of the cupola was changed. The materials are brought to a convenient location at the scale in the foundry yard by means of industrial cars, and from there put into a bucket by hand. This operation requires only one man. The charger is cage-operated, and thus two men are required to complete the cycle of charging. The man operating the charger takes care of hand charging the coke into the cupola,

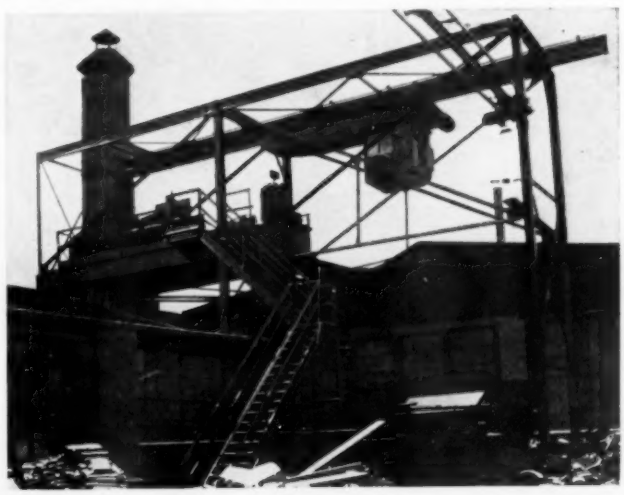

Fig. 7 Cage-Controlled Cupola-Charging Hoist

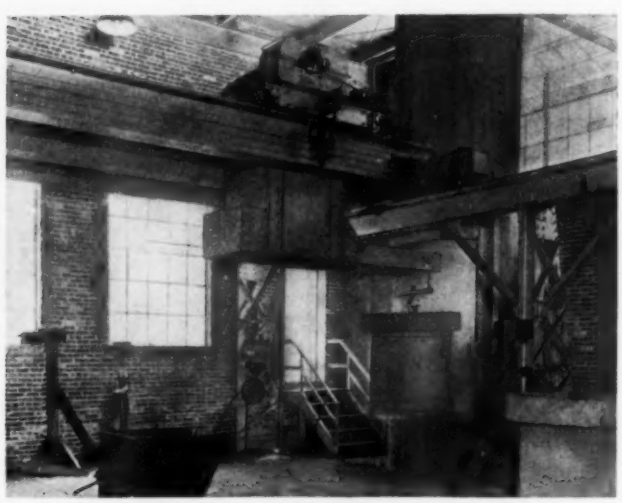

Fig. 8 Underslung Crane-Type Charging System Showing Cone-Bottom Bucket Entering Cupola

the coke being delivered by means of the charging bucket. This arrangement provides an inexpensive installation which operates at low cost.

Double-rail hoists for cupola charging have been developed by the Whiting Corporation. This horseshoe type of charger is useful for serving a single cupola. It is applicable especially to buildings where the headroom is low, because it can operate between the roof trusses.

A Whiting Corporation crane-type charging machine is shown in Fig. 8. This machine will serve a battery of six cupolas operating three one day and three the next, in long heats of from 9 to 18 hours. It can be installed on narrow charging floors with limited headroom.

Conveyors[3]

Coal-Handling Equipment. Coal-handling equipment of the full-automatic, trolley bucket-conveyor type has been designed and developed for the retail coal yard by the Gifford-Wood Co., designers and builders of complete coal-handling plants and ice-handling plants, so that coal can now be handled entirely automatically and with a minimum of breakage. The equipment is built in two sizes, one having a bucket of 65 cu. ft. capacity, and the other one of 100 cu. ft. capacity. It consists essentially of a hoisting unit for raising and lowering the bucket, and a traversing unit that controls the horizontal motion of the bucket over the various bins. It is necessary only to push the "start" button and the large bucket (see Fig. 9) lowers into the track pit, tripping the loading gate, which permits the bucket to fill with coal. The bucket remains in the pit for an interval of from seven to fifteen seconds, the length of this interval being adjustable and of a duration sufficient to enable the bucket to obtain a full load of coal. It then immediately ascends to the trolley (see Fig. 10), where it stops automatically; the trolley starts up and carries the bucket to a predetermined bin, where it automatically stops. The hoisting unit starts up in the reverse direction, lowering the bucket until the latch pads on the under side of the bucket touch the pile of coal in the bin, thus tripping the bucket and depositing the load of coal. At this point a specially designed bucket-return sheave, Fig. 11, immediately reverses the hoisting unit and carries the bucket up to the trolley, where it stops and is carried back by the trolley to a point over the track pit, where the bucket descends for another load. This full cycle of operations is entirely automatic, each separate operation being controlled by an electric control panel.

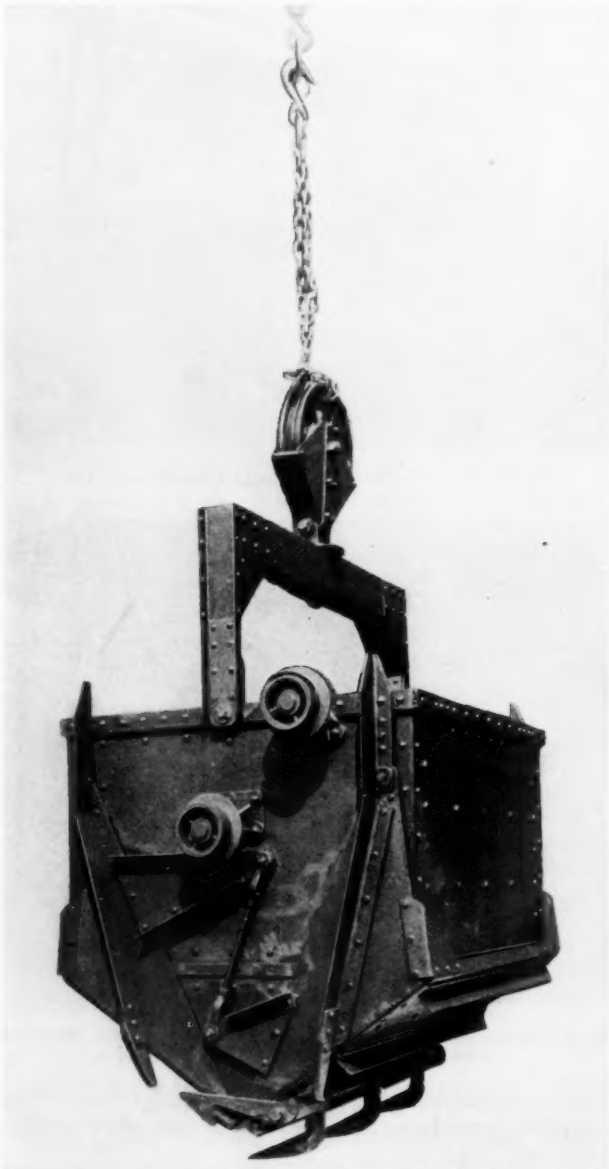

Fig. 9 125-Cu. Ft. Trolley Bucket Conveyor

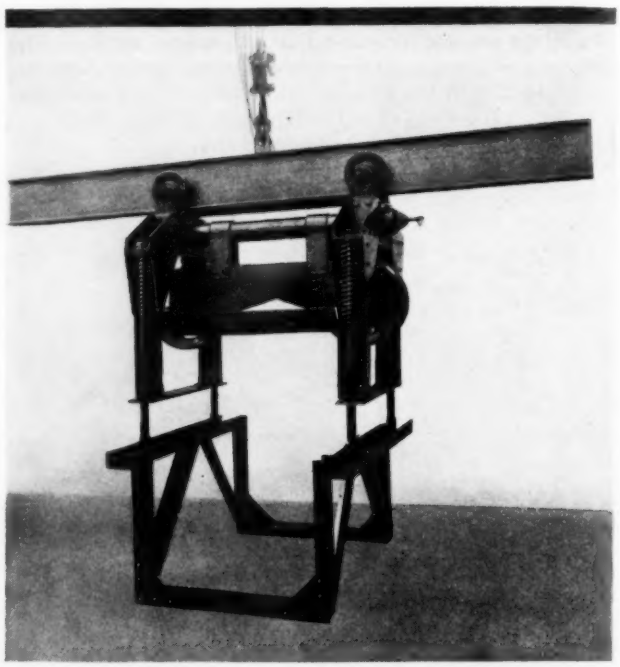

Fig. 10 Trolley With Bucket Buffer and Stabilizer

The equipment throughout is designed for ease of operation. Limit switches on both the hoisting and traversing units are readily adjustable, and it requires only a few seconds to set the equipment so that the coal will be delivered to any one of the various bins.

The trolley which conveys the bucket over the bin is provided with a spring buffer and stabilizer (see Fig. 10) which prevents the bucket from swinging while the trolley is in motion.

The bucket-return and cable-overload sheave (see Fig. 11) reverses the direction of the bucket after it has deposited its load of coal in the bin. It can be adjusted so finely for quick reverse that the weight of the bucket never rests on the coal already in the bin. This eliminates the crushing effect of the bucket coming in contact with the coal pile and, naturally, saves considerable breakage. This sheave also has another function in that it acts as a safety device. Should the progress of the bucket be impeded for some unforeseen reason, this sheave automatically shuts off the power, and consequently the equipment, long before sufficient strain is put on the cable to break it.

When the trolley returns to a point over the bucket guides which lead down to the track pit, an arrangement of limit switches slows it down gradually to a dead stop. If, for any reason, such

[3] Section prepared by Frank D. Campbell, Chief Engineer, Eastern Corporation, New York, N. Y. Mem. A.S.M.E.

as cable stretch, the trolley should go beyond the determined point over the pit guides, it immediately reverses and comes back to the right position. This provision always insures that the bucket will be exactly central over the guides.

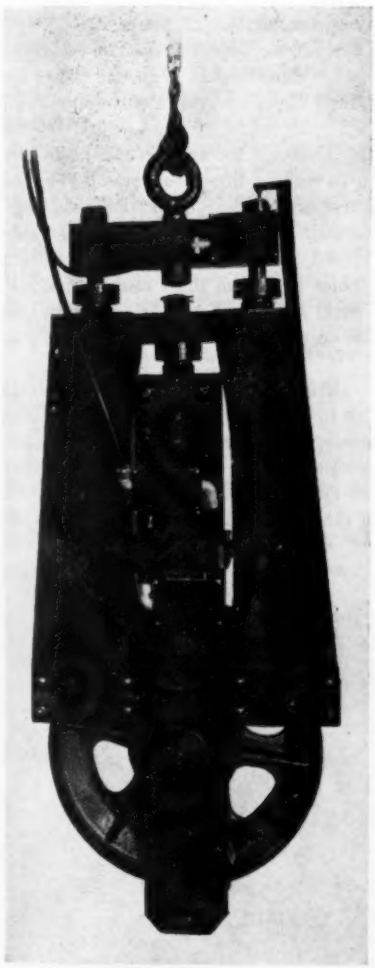

FIG. 11 BUCKET-RETURN AND CABLE-OVERLOAD SHEAVE

Fig. 12 shows a typical installation of the coal-handling equipment, utilized for storing and unloading coke.

Ice-Handling Equipment. Gifford-Wood Co. has recently put on the market several forms of ice-handling equipment to lower the cost of handling ice in manufactured-ice plants, by eliminating hand labor. Among these items are the multiple cake conveyors, spiral lowering chutes, and power transfer conveyors described in the following paragraphs.

Multiple Cake Conveyors. In a modern manufactured-ice plant, the practice of multiple cake pulls necessitated the development of equipment for handling these cakes from the dump to the storage room. The number of cakes pulled from the freezing tank at one time varies in different plants. There are a number of cases where as many as twenty-two cakes are pulled simultaneously. It was necessary to have a conveyor which would handle this full line of cakes at one time and discharge them to the storage room.

The tank-room conveyor, as developed by Gifford-Wood Co., is of the double-chain type, having a pusher attachment on each chain, which pushes the entire line of cakes as received from the dump. Although the two chains on the conveyor are always horizontal, the conveyor bed or ice slides are sloped, as will be noted in Fig. 13. This conveyor pushes the line of cakes at a speed of from 5 to 10 ft. per min., depending upon the conditions obtaining in the individual plant. A small doorway is cut through the wall to the storage room, and, as the line of cakes moves along, when each cake reaches this doorway, due to the incline of the conveyor bed, it slides off through the doorway to the storage room. The standard drive for this conveyor is from an electric motor direct connected to an enclosed spur-gear reducer which drives to the headshaft by means of a chain. This type of conveyor has eliminated all manual handling from the dump to the storage room. In cases where the tank room is located on the floor above the storage room, this conveyor delivers the ice to a spiral lowering chute.

Spiral Lowering Chutes. Chutes for lowering ice from one floor to the floor below were developed during the past year by Gifford-Wood Co. These chutes will handle the ice as fast as it can be fed to them. They also lower the ice without breakage, which is an important factor in the manufactured-ice plant.

The runway of these chutes is supported on a section of ladder-like steel frames distributed through a square steel chute, rigidly braced. The runway itself consists of an oak-slat bottom bolted to cross-pieces of the ladder-like frame. The sides of the runway are of steel plate with a 6-in.-wide rubber belt bolted to the plate.

FIG. 12 TYPICAL INSTALLATION OF COAL-HANDLING EQUIPMENT UTILIZED FOR STORING AND UNLOADING COKE

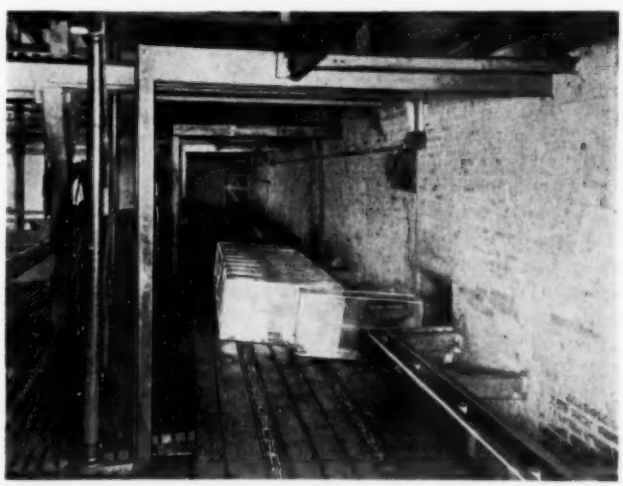

FIG. 13 CAKE CONVEYOR IN MANUFACTURED-ICE PLANT

Power Transfer Conveyors. A modern ice plant, in many

cases, requires numerous conveyors. Heretofore it has been necessary to transfer the ice by hand from one conveyor to the other, unless one conveyor was set higher than the other, in which case a gravity run was used. Gifford-Wood Co. has just developed a power transfer conveyor, Fig. 14, a unit for the mechanical transfer of the ice that can be installed between two conveyors, no matter at what angle the conveyors are set with respect to each other.

The power transfer makes it possible to synchronize two conveyors at angles to each other and eliminates the danger of ice jams and breakage at the transfer point which are liable to occur when the gravity run is depended upon to transfer the ice.

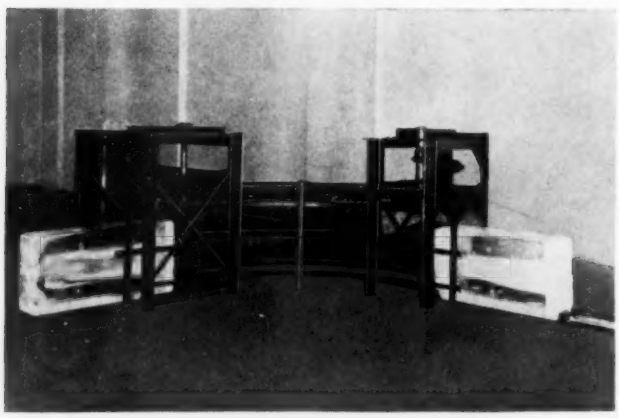

FIG. 14 POWER TRANSFER CONVEYOR FOR ICE PLANT

FIG. 15 ADJUSTABLE LEAD FOR LIVE-ROLLER CURVE

In using the power transfer, it is possible to convey the ice by means of a system of conveyors from any part of the plant to any other part without any labor beyond that of placing the ice on the first conveyor. The unit is very flexible in application, and it can be installed in any plant regardless of conditions.

The power transfer conveyor consists of a steel framework which supports a roller chain running in a horizontal plane, together with the necessary sprockets, driving mechanism, and ice guides. The chain is supported above the ice with pusher attachments extending downward, and is guided through a radial path by curved tracks. This unit is very compact and is driven from the other conveyors that comprise the installation. It is simple and inexpensive to install because it is placed entirely above the floor level.

Ship-Loading Conveyor. A recent installation of Lamson Company conveyors has been made to load bagged material into ships at a rate of over 100 tons per hour into each of two hatches, delivering the bags to any desired level in the hold and distributing them automatically over a sufficient area to enable the stevedores to stow them at this rate of speed.

The equipment is adjustable to varying sizes of ships, tidal conditions, hatch sizes, and spacings, and is also designed to convey bulk material. It consists of two automatic crane towers which receive the cargo from long belt conveyors at any point along the dock and deliver it through stainless-steel spiral chutes into the holds. The chutes are suspended from the tower booms. The equipment has effected great savings in labor and reduced the loading time of ships by approximately 50 per cent.

Developments made by the Logan Company in the conveyor field during the past year were described in a recent paper by H. R. Gotthardt,[4] from which the following items have been extracted.

Adjustable Lead for Roller Curves. To reduce the high cost of making roller curves and to make adjustments possible in the field, the Logan Company has designed a curve with longitudinally slotted holes in the outside rail for supporting the outside end of the roller shaft. Fitted on the outside of this rail is a secondary steel strip with holes to fit the shaft and hold it stationary. This secondary strip is bolted to the angle rail in such a way that it can be adjusted for loads in either direction (see Fig. 15).

Intermediate Delivering Device for Elevators. To elevate packages from the lower floor to several upper floors of a building, a recently developed intermediate discharge is used in connection with the regular simple-type pusher-bar elevator. This device, Fig. 16, consists of two endless chains connected at intervals with pushers for propelling the package over the bed and up the incline.

At each intermediate floor where a delivery is desired, a portion

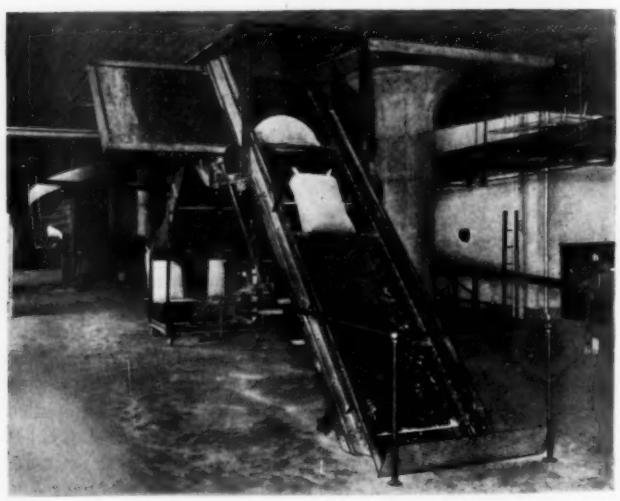

FIG. 16 INTERMEDIATE DELIVERING DEVICE FOR ELEVATORS

of the bed of the elevator is removable, that is, a panel of sufficient length to allow the largest package to pass through the bed is arranged to slide out through the side, leaving an opening in the bed. Attached to this opening is a secondary conveyor for carrying the packages away from the elevator to any point on this floor. When any panel is slid back into place, that floor becomes inoperative and the packages pass on until they come to an open gate, or until they are discharged over the top of the elevator.

Live-Roller Curve. A live-roller curve has been designed using the same principle as used on the live-roller conveyor; that is, a belt running underneath the load-carrying rolls and held

[4] Consulting Engineer, Logan Co., Louisville, Ky. Original paper contributed by the Materials Handling Division and presented at the French Lick Meeting of the A.S.M.E., French Lick, Ind., October 13 to 15, 1930.

in place by tension rolls. Through the use of ball-bearing idler rollers the belt is given sufficient twist at intervals around the curve to allow it to follow the circumference of the curve. The return belt, however, is brought back in a straight line across the chord of the circle formed by the curve. This is done by giving the belt a quarter-twist at both turning points. A take-up is arranged in the center of the return belt.

Alligator Switch. In the use of gravity conveyors, it is sometimes necessary to switch packages from a single line to two or more lines, or to receive them from two or more lines on to a single line. The usual method followed has been to place a pivoted section about 10 ft. long in the single line, this section being movable horizontally to connect to any of the multiple lines. However, when small packages were being handled, this switch section left too great an opening. A further objection was the abrupt change in direction of the rolls, which caused the packages to turn crosswise to the rolls and become jammed against the guard rail.

An "alligator" switch was therefore designed with a number of rolls at the pivot point, individually supported on steel brackets (see Fig. 17). These in turn are pivoted in the center, being tied together with a flexible lattice arrangement. When the switch section is swung at an angle to the single line of the conveyor, these individually supported rolls form a flexible portion of the switch section. They automatically arrange themselves in a radial position as regards the curve connecting the single straight

FIG. 17 "ALLIGATOR" SWITCH FOR ROLLER CONVEYORS

line of the conveyor and the switch section. This device holds the distance between the rolls to a minimum and eliminates the abrupt change in direction of the rolls, making an ideal turn for the package.

Selective Deflecting Switch. An alligator-switch section, operated electrically by means of a motor and a screw drive, has been developed to deflect packages or boxes from a main conveyor to any of several branch lines (see Fig. 18). The main conveyor here is equipped with two "floating" rolls just preceding the alligator switch and two others just following it. The branch line is also equipped with two of these floating rolls just following the alligator switch. Tote pans are handled on this conveyor. A key placed in one of the sockets on a tote pan completes an electric circuit when the pan passes over the floating rolls immediately preceding the switch section. This circuit connects with the motor on the switch section, moving the switch section to serve the branch line. As the package then passes off the switch section and over the floating rolls in the branch line, it sets the switch in the circuit for either of the two following results: If the next package is not keyed it passes over the first floating rolls and the motor for the alligator switch reverses, throwing the switch in a straight line with the main line of the conveyor. Or, if the succeeding box is also keyed, it passes over the first floating rolls without effect on the motor or the alligator switch.

It is necessary, of course, to have the packages spaced at least 2 ft. or 3 ft. apart. Where this cannot be done manually,

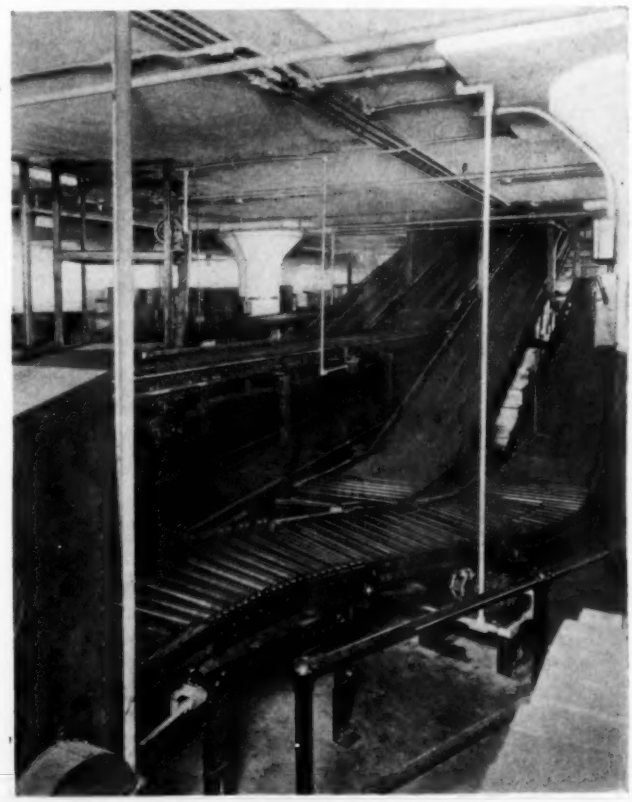

FIG. 18 SELECTIVE DEFLECTING SWITCH FOR GRAVITY ROLLER CONVEYOR

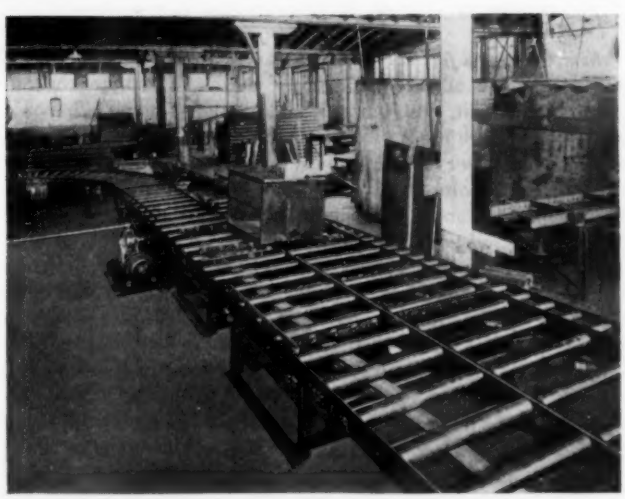

FIG. 19 ELECTRIC MULTIPLE-SWITCHING DEVICE

it is done electrically by placing in the main line, directly preceding the switch section, a power spacer. This device auto-

matically spaces packages, speeding up the first one enough to place it the proper distance ahead of the package following.

To keep the alligator switch from moving before a package is off it, or before it is ready to be moved for the next package, the circuit connecting the motor which operates it includes two recording switches. These switches are so arranged in connection with the floating rolls that a package is counted in to the deflecting zone and again counted out as it leaves it, the switch being inoperative until any package which has been counted in, is counted out.

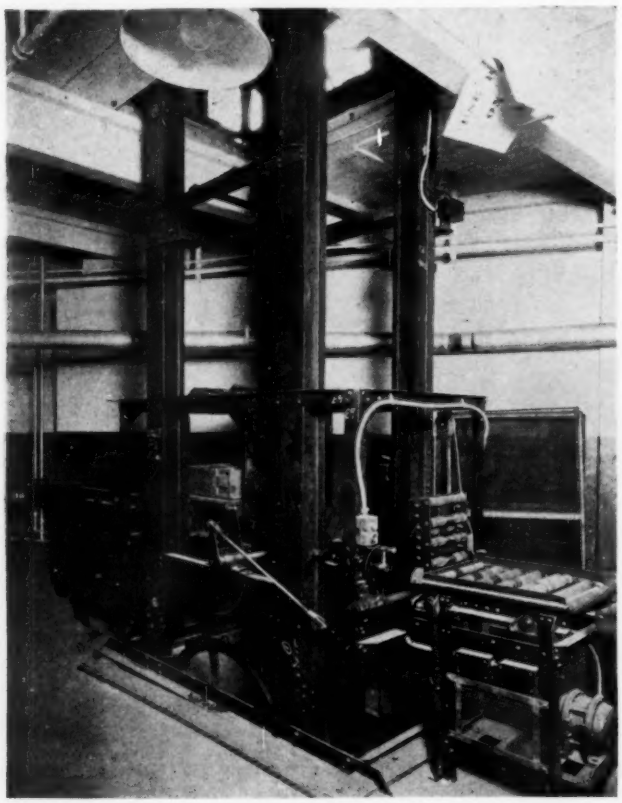

FIG. 20 AUTOMATIC SELECTIVE VERTICAL ELEVATOR

Remote Control for Alligator Switch. It is sometimes advisable to operate the alligator switch by means of remote control. An electric circuit, push buttons, and a series of signal lights on a control board are used. To move the switch to any other position it is necessary only to push a button for that particular station. The motor that operates the alligator switch is equipped with a solenoid brake, and suitable limit switches are placed in the path of the switch section to stop it at the proper points.

Electric Multiple-Switching Device. There has been designed and built an actual full-size working model of a selective, multiple-switching device, Fig. 19, by means of which it is possible to use as many as 300 or 400 selective stations. This device is operated electrically by means of a given setting of keys on some part of the package being conveyed. It is arranged with disappearing rolls placed in the main conveyor line at the deflecting point and is operated electrically. A package traveling along the main line and keyed for any certain station, raises a roller stop in its own path. This brings the package to a standstill directly over the disappearing rolls. As soon as the package comes in contact with the roller stop it closes a circuit, which elevates the disappearing rolls and the package with them. The disappearing rolls rise on an incline at right angles to the path of the package on the main conveyor, and therefore the package rolls off onto the branch line.

As soon as the package is off the main line and on the branch line, the roller stop and the disappearing rolls sink below the carrying surface of the main conveyor. Virtually any number of these selective stations may be inserted in the main roller-conveyor line. A package not keyed for intermediate stations will pass over these stations without effect, until it reaches the station for which it is keyed.

Automatic Selective Vertical Elevator. The automatic selective vertical elevator, as shown in Fig. 20, is equipped with a dial at each loading station on each floor. These dials are so arranged that they can be set for a discharge station on any floor. The operation is electrical throughout. The elevator proper consists of two endless chains connected at intervals by swinging tray carriages traveling upward on the loading side.

Some products handled, such as grinding wheels, are stacked up in piles on a flat pallet, presenting a package that must be moved very carefully to avoid spillage of the wheels. A roller conveyor leading into the loading station of the elevator on any given floor

FIG. 21 AUTOMATIC RECIPROCATING ELEVATOR

holds a pallet loaded with wheels ready for the elevator. The operator on the floor where this pallet is waiting to be picked up, sets his dial to correspond to the floor where the package is to be delivered. The remainder of the operation is automatic. Before reaching the loading station the empty carriage, moving upward, makes an electrical connection. This action automatically starts a motor by means of which the waiting package is automatically and positively moved into the pick-up station. If an ascending carriage is not empty, that is, if it carries a package from a lower floor, the particular station which is waiting to be loaded is inactive and the package does not move into the elevator.

The setting of the dial automatically sets the key on the car-

riage that is carrying the load. Therefore, when it reaches the proper discharge station on its downward travel, it automatically throws that station in and deposits the package there. The discharge is positive by means of a power conveyor. As soon as a package has been picked up from a loading station, or has been delivered at an unloading station, these stations immediately return to an inoperative position out of the path of the next carriage.

Automatic Reciprocating Elevator. The automatic reciprocating elevator, Fig. 21, as now developed, usually serves two floors, an upper and lower. Its purpose is lowering packages. When there are no packages to be lowered the elevator is inactive. However, as soon as a package reaches the loading station at the top it automatically starts the carrier down to the first floor. At the first floor the package is discharged automatically, and, when the load is cleared, the elevator automatically reverses and travels back up to the top position ready for another package. This operation continues as long as there are packages to be lowered. The same automatic type of reciprocating elevator

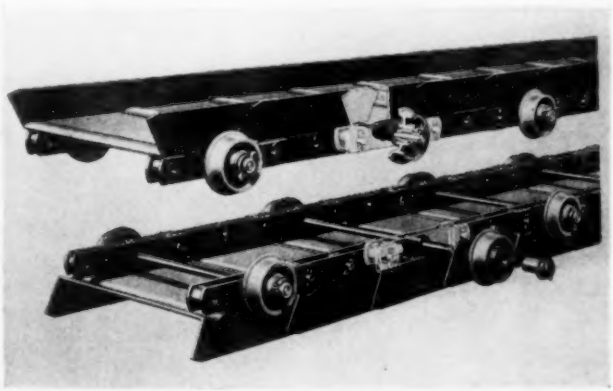

FIG. 22 LEAKPROOF APRON CONVEYOR WITH EQUALIZING SADDLE CONSTRUCTION

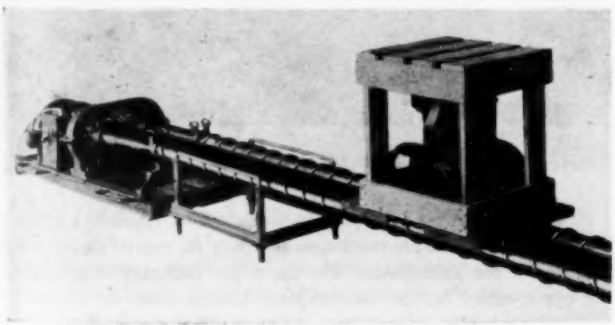

FIG. 23 TWINVEYOR USING SPRING-SUSPENDED RACK AND PALLET FOR HANDLING MISCELLANEOUS COMMODITIES

has been worked out for elevating as well as lowering, and for taking care of two stations as well as one.

Apron Conveyors. Another important development in the conveying industry has been the introduction, by the Chain Belt Company, of "Rex Leakproof" apron conveyors with equalizing saddle construction. Generally speaking, apron conveyors have always been made up with double strands of either malleable-iron or steel chains, the apron pans being attached to the inside sidebars of the chain, and the carrying rollers being placed at the articulation points of the chain between the sidebars. With this standard type of apron-conveyor construction, eccentric loads were set up on the inside sidebars of both strands of chain. It was also exceedingly difficult to construct the pans so that they would not leak. Moreover, in making repairs it was necessary to disassemble the complete apron, thereby losing valuable production of time.

For the Rex conveyor equalizing saddle construction, Fig. 22, the apron pans, instead of being attached to only one side of the chain, are fastened to an equalizing saddle. This saddle rests directly on the chain, being held in place either by through rods or pins extending through the chain and saddles. The load is

FIG. 24 TWINVEYOR TRANSPORTING AND STACKING SUGAR BAGS (1000 PER HR.)

therefore carried directly along the center line of the chain, and hence is distributed equally to both sidebars.

The chain draws straight and true, and its life is practically doubled. The saddle and through rods, together with the large-diameter outboard rollers, are entirely independent of the chain joint, and therefore the chain is called on to take tension loads only. As the dead load is practically divorced from the pulling medium, the natural wear occurs on the tread and bore of the hard white-iron outboard rollers and the hardened steel bushing sleeves which are locked to the ends of the rod. These parts can be readily and quickly replaced without disturbing the chain or apron assembly in any way, thereby cutting hours off the usual time required for apron-conveyor repairs.

Twinveyors. The Clark Tructractor Company has placed on the market a conveyor, escalator, or tiering machine (Figs. 23 and 24) of unique design for a variety of handling operations. The operating mechanism consists of two sets of tubular external screws driven toward each other by a power head. The direction of travel is reversible. The conveyor is sectional, portable, can be set up or taken down rapidly, and functions in any normal position. A change in the angle of deflection is possible at each intersection, the maximum angle being 15 deg. at any horizontal

or ascending joint and 10 deg. at any descending joint. Packages can be carried up grades as steep as 30 per cent.

Tubular screws come in lengths of 8 ft. each. The total length of the standard unit is 50 ft., consisting of five 8-ft. dual

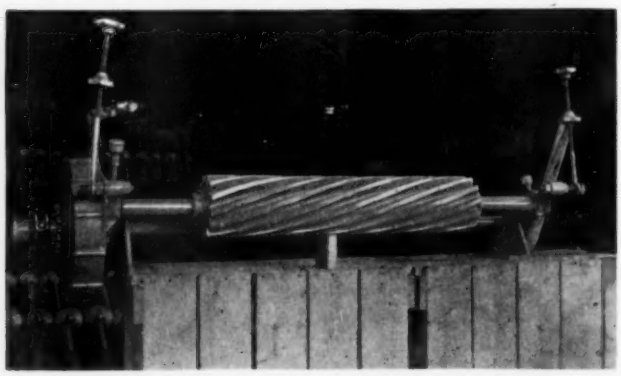

FIG. 25 RUBBER BRUSH FOR CLEANING CONVEYOR BELTS

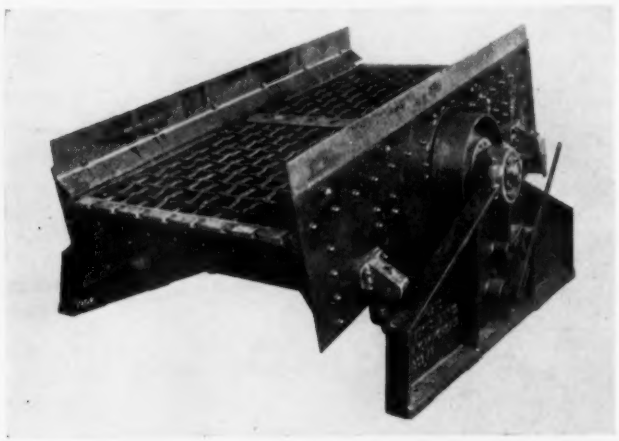

FIG. 26 IMPROVED SIZING SCREEN FOR USE WITH BELT CONVEYORS

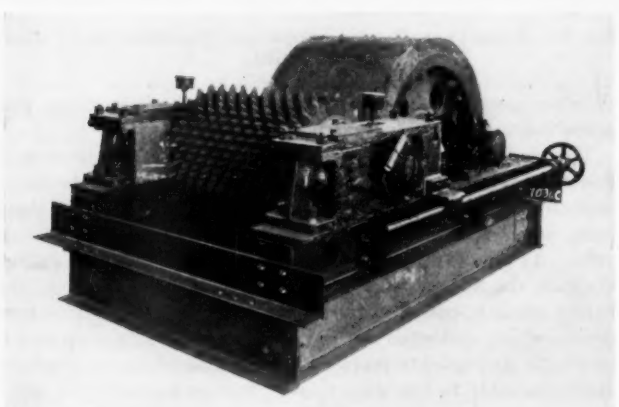

FIG. 27 COMBINED FEEDER AND CRUSHER

sections, two 4-ft. single sections, and a power head. If more than one unit is employed, a hurdle section carries packages across the intermediate power heads. Center distances between tubes are adjustable within a range of 6 in. minimum, for use with bags, up to 12 in. maximum, for large packages and bales.

Weights up to 100 lb. can be handled, and the traveling speed of the package is 90 ft. per min. Pallets, as shown in Fig. 23, pivoted to run between the tubes, are provided to handle boxes, crates, and bales which otherwise would be difficult to transport and would tend to leave the conveyor.

Right- or left-hand intersections are made possible by the use of spiral gravity chutes composed of bars curved in the direction of travel. The chutes are designed to set over power heads or tubes at any desired point.

A special hand truck, or wheel carrier, can be provided in which to move the power head. The power head is mounted on a wood base and can be kept on the truck set on the floor or set on top of a pile of bags or boxes, for stacking or unloading.

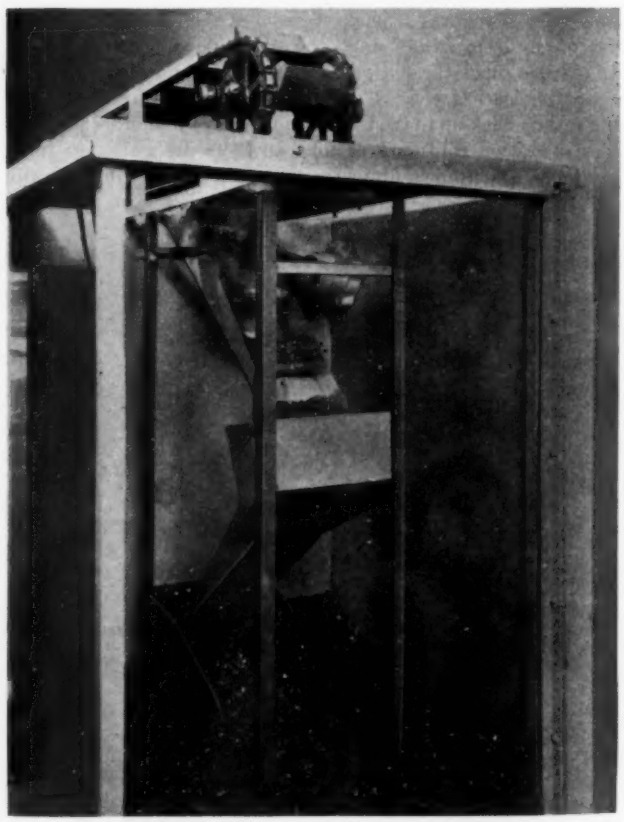

FIG. 28 "AVALANCHE" CHUTES FOR LOWERING FRIABLE MATERIALS INTO BINS

Equipment for the Foundry Industry. The Eastern Corporation has made numerous improvements in materials-handling equipment for foundries. The foundry industry has offered the opportunity for an outstanding development in the use of ball-bearing roller conveyors. Although this type of conveyor equipment has been employed in foundries for several years in a comparatively minor way, a wider range of use is now evident because of the availability of vastly improved types, quality suited to the individual application, and a more comprehensive knowledge of foundry requirements in process and arrangement.

Foundrymen have long claimed that such equipment could not be employed for the transportation of green-sand molds of intricate pattern design and core assemblies. The development of the sand-sealed ball bearing, however, which can be operated for years without relubrication, great precision in construction to provide vibrationless transit, and the ability to withstand the continual spillage of molten metal, have furnished in roller conveyors a simple and easy method of movement and a flexible mobile storage system for molds being accumulated for heats.

Other accessories to this equipment have been developed, such

as roller-conveyor discharge mechanisms adaptable to existing hand-discharge roll-over molding machines and adjustable to the pattern draw, various fixed and movable lateral-transfer mechanisms, and vibrationless turntables, as close-coupled direction changers, all constructed with sand and molten-metal protection features.

Standardization of widths and parts has been worked out for equipment to handle a wide range of sizes, types, and weights of molds, so that a single fixed width of conveyor can be utilized throughout an entire plant that may be engaged in making a great variety of work. This feature provides for periodic changes

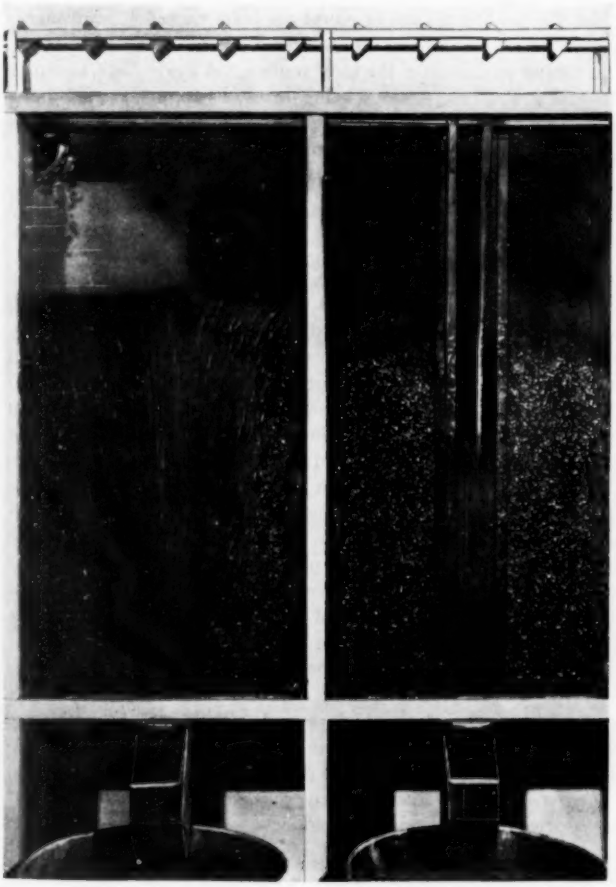

FIG. 29 "WITHDRAWAL" CHUTES FOR REMOVING FRIABLE MATERIALS FROM BINS

in arrangement, as dictated by changes in character or process of work, with practically no obsolescence.

These methods of mold transit provide the means for grouping and concentrating the work, to restrict pouring of metal to certain areas or zones in which safe and speedy overhead ladles travel over only short distances. The danger of accidents is thereby reduced.

The great flexibility of process and movement thus provided by these newly developed transit methods in the foundry has made it possible to produce a large miscellany of types and sizes of castings, in small quantities and requiring frequent pattern changes, by methods similar to those of straight-line production, and controllable by conventional planning methods. Applications of the roller-conveyor equipment have already been made to direct pouring into molds from the furnaces.

In the cleaning and finishing of castings, similar equipment

FIG. 30 CHAIN CONVEYOR IN AUTOMOBILE PLANT

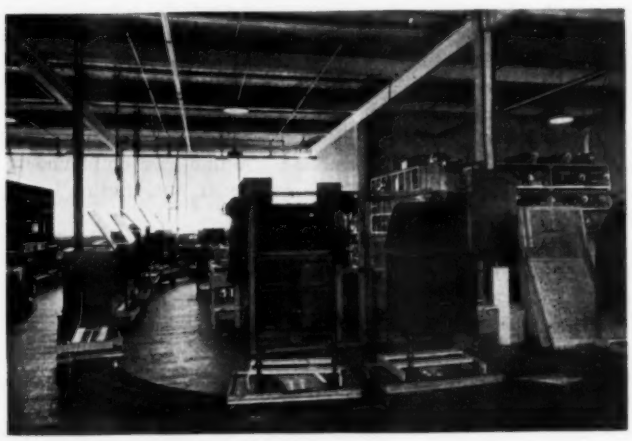

FIG. 31 SINGLE-STRAND DOLLY OR TRUCK PUSHER CONVEYOR OF THE "ON EDGE" TYPE

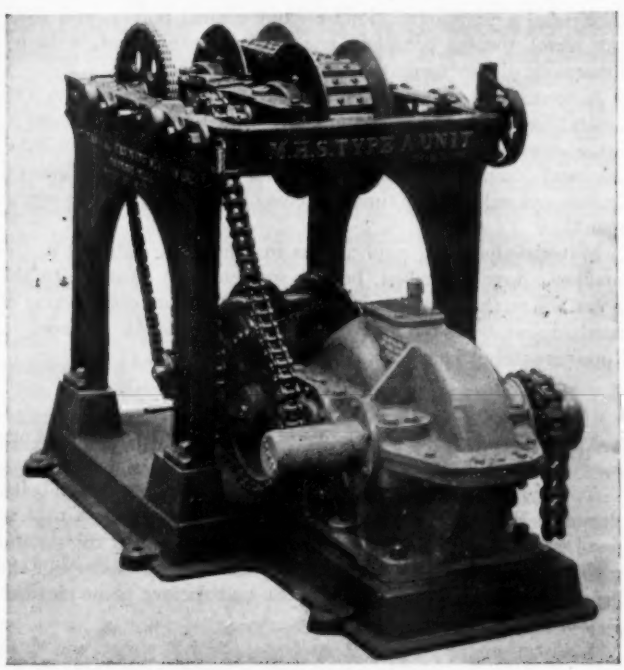

FIG. 32 (RIGHT) STEEL V-BELT VARIABLE-SPEED TRANSMISSION

and a like character of arrangement have provided the same order lines, sequence of process, and speedy manufacturing cycle as has been brought about in molding operations, with substantial reduction in semi-processed inventory, and coordination in pace for all foundry departments. These general systems, in many cases, have more than doubled the output per square foot of floor area.

Such systems have been made highly adaptable to simple and effective wage-incentive, piece-rate, and bonus plans. They have also brought about an easily maintained cleanliness, never before quite possible in the general run of the foundry industry.

Power conveyors have been developed, of higher quality, greater capacity, and wider utility for the handling of molding sands. Molding sands are now quickly removed from the foundry molding sections, screened, cleaned of metal and dust, automatically tempered, mixed, bonded, and carried to desired points in quantities and qualities to suit the various products—entirely by mechanical means that require the attention of but few individuals, and with much lower horsepower requirements.

To meet higher-capacity requirements without proportionately higher initial costs, higher speeds in conveyors and elevators have been attained without increasing the wear and tear or reducing the life of the equipment. Basic materials of higher durability to resist abrasion, and of greater strength, have been incorporated, with corresponding changes in design.

Fabrication by electric arc welding has been further developed, with the use of machined jigs for accuracy, uniformity, and symmetry of outline in assembling. A universal employment of interchangeable, self-adjustable, protected, anti-friction bearings has likewise come about.

Among the newer features are: integrally mounted, completely enclosed drives, motors, and controls; reduction of noise in operation; and lowering of breakdown hazards.

Improved sand-processing and conditioning accessories of the continuous type are now incorporated in the continuous stream of movement and coordinated with the general conveyor system. Better lubrication and adequate exhaust systems for dust abatement further improve the equipment.

Simplified methods of operation have resulted from the greater employment of high-class electrical controls, with methods of push-button operation by interlocking and grouping of units, to obtain complete functioning from central points, and from the trend toward complete enclosure of equipment, with oil immersion of moving parts.

A consistent, general standardization in design of parts and assemblies, with universal punching and uniform bolt sizes in attachments, connection plates, and flanges, and uniform widths, diameters, and sizes of frame members, has increased the general utility and reduced the time and cost of installation of the equipment.

Materials-handling applications in foundries, installed in the manner above described, have been generally effective to the point where the total labor percentage of the net dollar value of product has been reduced from an average of 48 per cent to approximately 25 per cent.

Belt Conveyors[8]

A number of useful developments have occurred in the belt-conveyor field during the past year.

Rubber Brush. The rubber brush for cleaning conveyor belts, shown in Fig. 25, is mounted on a pipe core carried on a rapidly revolving shaft. The brush proper is made of tough rubber and resembles a spiral gear of very wide face. The periphery of the brush is brought in contact with the belt surface to be cleaned. The rubber brush has demonstrated itself to be a decided improvement because of its ability to resist abrasion.

Holdback Rig. A new type of self-contained holdback rig has been developed to prevent a belt conveyor from running backward under load when the power is shut off. This rig consists of a ratchet wheel, on the hubs of which is mounted a yoke carrying a pawl. By means of springs rubbing on the faces of the ratchet wheel, the pawl is held free when the conveyor belt is moving forward and is forced into the ratchet when the conveyor belt starts running backward. This rig is a very inexpensive and effective device.

Rubber-Cushioned Idler. A rubber-cushioned idler is used under the loading points of conveyor belts carrying large pieces of heavy material which are delivered to the belt with impact. The rubber cushions on the idler pulleys act as resilient bumpers protecting the belt against being bruised or punctured by the lumps of material. The effectiveness of this unit is demonstrated by a pile-driver test, using a pointed 50-lb. weight. The weight, when dropped 18 in., will puncture an eight-ply belt supported on a plain cast-iron idler pulley, but the weight can be dropped 6 ft. without puncturing the belt when the latter is supported by a rubber-cushioned idler pulley.

Five-Pulley Idler. There is a tendency on the part of some users to abandon the type of belt-conveyor troughing idler having one horizontal and two inclined pulleys, which has been very popular during the past six or seven years, in favor of an improved design of idler having one horizontal pulley, two pulleys inclined $11^1/_4$ deg. and two pulleys inclined $22^1/_2$ deg. This new design includes such features as malleable-iron brackets, pulleys of equal length, angle bases, and improved bearing mountings.

Screens. An accessory which is of prime importance in connection with conveying equipment is a screen for sizing the product conveyed, especially in the case of coke, stone, sand, and gravel. A very popular form of screen is one having inclined screening surfaces which are given a very rapid gyrating motion of small radius. A screen of this type is shown in Fig. 26. This type of screen has been in use for a number of years, but the past year has covered a period of development of details resulting in the elimination of trouble from the great stresses set up by increasingly high speed. The improvements are principally in the design of the screen frame and the mountings on the shaft producing the gyrating motion.

Feeder-Crusher. Feeders and crushers are very important accessories to conveying machinery. Fig. 27 shows a combination of these two units, as developed for service in a plant where coal is received at times in a frozen condition. A large drum, or roll, which has a smooth face, except for widely separated small projections, turning at slow speed, serves as a feeder roll and also as a backing plate for the second roll, which is toothed and revolves at high speed. Thus coal is drawn in over the large roll and crushed between the large roll and the small roll.

Two-Motor Drives. In the past, the practice in connection with tandem drives on belt conveyors (where two pulleys are used to drive the belt) has been to gear the two pulleys together with gears which are somewhat larger in diameter than the pulleys, and to drive one of these gears, which, in turn, drives the other. There is a creep in the belt as it passes around these pulleys which is not the same on both pulleys. With the advent of extremely heavy duty came the problem of relieving the belt of the stresses set up by this belt creep. For this purpose, in place of gearing the two pulleys together, separate motors for each shafts are used. Under certain conditions it is advantageous to use motors of the same power, but under other conditions the motors may be of different sizes. Both of these arrangements are now in successful operation.

[8] Section prepared by M. J. Andrada, Chief Engineer, and E. R. Morgan, of the Robins Conveying Belt Company, New York, N. Y.

Adams Chutes. Conveyor accessories which have come into prominence recently are shown in Figs. 28 and 29. These are known as "avalanche" and "withdrawal" chutes, respectively, and are used in lowering friable material from conveyors into bins, and withdrawing the material from the bins. The photographs are those of models because, obviously, it is impossible to get such pictures of actual installations.

Fig. 28 needs very little explanation. Material delivered by the conveyor builds up on angle baffle plates so as to cover the bottom plates of the chute, and sloping avalanche plates still further baffle the material, until so much has accumulated in the chute that an avalanche takes place, permitting a large flow of material instead of the usual continuous flow. The actual savings in degradation due to this action have been compiled by several users and are quite remarkable.

No less noteworthy are the savings in degradation effected by the use of the "withdrawal" chute, shown in Fig. 29. In this photograph, two bins with bottom openings are shown in miniature, the one on the right being equipped with a withdrawal chute. The near side of the bins is a glass plate, and the photograph was taken with the gates open, so that the flow of material is shown. A large turbulent movement of material is seen on the left, which causes attrition of the material as it crowds down to the small opening. With the "withdrawal" chute, shown on the right, a vertical column of material moves down through the chute, being constantly fed from surface material only, which rolls in from the top and never below the top.

Chain Conveyors[6]

Progress in the chain-conveyor field has in general been confined to improvement of design detail and to the more extended use of existing types of equipment. There is appearing also a tendency to make the conveyor a definite part of the production process, as has already been done in the automotive field (see Fig. 30). The idea contained in the continuous molding conveyor, now so generally used in all large production foundries, is being applied to other processes, and it would appear that this development should have further and more intensive study.

Of the different types of chain conveyors available, the power-driven overhead trolley conveyor has undoubtedly found the greatest extension in application. This is probably due, in part, to its relatively recent development, but of even greater importance is its extreme flexibility, making it applicable to all sorts of handling problems—transportation, processing, and assembly.

Following the lead of the overhead trolley conveyor is the single-strand dolly, or truck, pusher conveyor of the "on edge" type, i.e., the chain operating with the pins vertical. This design, an application of which is shown in Fig. 31, uses a chain flexible in both directions, similar to the trolley conveyor. Being confined in its track by suitable attachments, and guided around horizontal turns by rollers, it can be curved or turned in either plane, run from floor to floor, and, if desired, can be made a continuous loop. Due to this flexibility of path, this type of construction may replace one or more of the conventional straight-line conveyors, thereby avoiding transfer points and allowing greater variety in layout. Its use has been largely in the automobile-body plants for assembly, paint, and trim, but installations have also been made in radio-cabinet, office-furniture, and refrigerator assembly, and in stock rooms, etc. A modification, with the load resting on and carried directly by the chain, is beginning to replace the gravity roller conveyor in some instances, notably in the dairy industry.

[6] Section prepared by N. H. Preble, Consulting Materials-Handling Engineer, Detroit, Mich. Mem. A.S.M.E. Illustrations for Figs. 30 to 32, inclusive, were furnished by Mechanical Handling Systems, Inc., Detroit, Mich.

Progressive assembly on chain conveyors, universally employed in automobile plants, is now being applied to a greater extent in other plants, particularly in the newer industries, such as radio, electric refrigeration, and the like. Its further use in other and older fields will probably be noted in the near future.

Another field for the chain conveyor which has had considerable extension during the year is in connection with high temperature in such processes as heat treatment, porcelain enameling, core baking, billet heating, etc. Various alloy chains are now available that will operate in high temperatures. Other designs, especially of the trolley type, provide for the protection of the conveyor from excessive heat.

In the various equipment parts available there have again been no radically new developments. No new chains of importance have been offered, and it would appear that progress might well be in the other direction: in the standardization on a fewer number of types and sizes, with detail improvement in those few. Greater use is being made of all-steel forged chain, not only for trolley conveyors but also for other chain conveyors, and, within proper limits, it appears that this tendency will become more notable in the future.

Greater attention is being given to the details of design which affect maintenance, especially with regard to lubrication. Centralized pressure greasing is largely employed on oven conveyors, and its use is extending to other constructions. There is some tendency toward the use of anti-friction bearings, not on account of decreased friction so much as because of the less frequent greasing required. Trolley wheels have also been improved, and can now be obtained to operate in high temperature, acid fumes, dust, etc., and can be equipped for automatic lubrication.

The chain conveyor naturally includes a power or driving unit, of either constant or variable speed, and, ordinarily, with a considerable gear-reduction ratio between the motor and the conveyor headshaft. The open gear train to obtain this reduction has become obsolete, except for extremely light-duty work, all drives now being fitted with some form of fully enclosed speed reducer. In this connection, the more frequent use of the herringbone gear reducer is noteworthy. These reducers are now available from stock in a large range of sizes and with standard ratios as high as 300 to 1. Variable speed is ordinarily required in all chain conveyors except those used purely for transportation, and, even there, speed variation may be desired in order to synchronize with other equipment. This variable speed in almost universally obtained by the use of the V-belt type of transmission, with infinitely adjustable cone pulleys. During the past year a modification of this transmission has been introduced by Mechanical Handling Systems, Inc., in which the V-block rubber belt is replaced by a steel belt with slidable, laminated steel plates which engage with raised sections on the cones (see Fig. 32). This design gives a transmission with positive drive and one which is fully enclosed, operating in a bath of oil.

Mention should also be made of the greater use of electric arc welding in the fabrication of chain-conveyor framework, giving marked economy and some decreased weight when compared with riveted construction. It is believed that this development will grow, and that the near future will see practically all conveyor structures welded.

Drive Chain, Variable-Speed Gears, and Skip Hoists[7]

Drive Chain. Bucket elevators and conveyors, slat and apron conveyors, foundry conveyors, skip hoists, and related equipment

[7] Section prepared by W. W. Sayers, Chief Engineer, Link-Belt Company, Chicago, Ill. Mem. A.S.M.E.

have not recently undergone any radical changes. Their field of application has been considerably broadened, however, by improvements and refinements in their construction. The chain, which is the principal medium used by these types of equipment for transferring, elevating, and conveying materials, has been greatly improved in its two major requirements—strength and durability.

Until recently, chain manufacturers were dependent upon mild or medium steels with no heat treatment. Medium steel was preferable to mild steel because it had slightly higher physical properties. The fact that low-carbon steel could be surface hardened by soaking in a carbon atmosphere has been known for years, this operation being called case-hardening. It did not contribute to strength, however, but only to durability against wear. By heat treatment the strength of medium steel

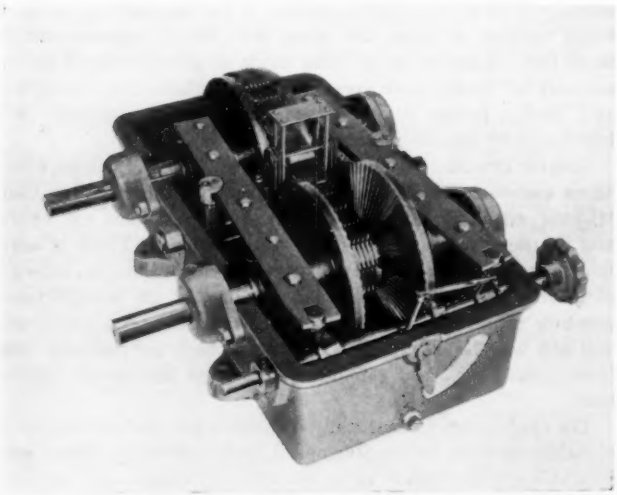

FIG. 33 POSITIVE-DRIVE VARIABLE-SPEED GEAR

is now raised from 75,000 to 95,000 lb. per sq. in. The strength of mild steel is not increased by treatment.

Medium-carbon steel bars having an analysis of:

Carbon	0.35 to 0.45
Manganese	0.50 to 0.80
Phosphorus, less than	0.04
Sulphur, less than	0.04

give a desirable leeway in design of steel-chain sidebar links, whether heat treated or untreated. The pins, or bushings, should be of either mild steel, case-hardened, or of medium steel, heat treated.

Recognizing that cumbersomeness and weight in chains are undesirable, and frequently prohibitive, for use with materials-handling equipment, manufacturers now use steels containing alloying elements, which, with suitable heat treatment, provide equivalent strength with considerably reduced size and weight.

Standard carbon steel (S.A.E. 1015-1020-1045), nickel alloy steels (S.A.E. 2320-2345), and chromium alloy steel (S.A.E. 3135-3245), chromium alloy steel (S.A.E. 5140), and molybdenum alloy steel (S.A.E. 4615), all react uniformly well to the heat-treatment control used in production methods, and are readily obtainable.

The actual example, shown in Table 1, of the development of a single size, or pitch, of drive chain used by the oil industry with rotary-type well drills, serves to illustrate the increase in strength, accompanied by a relative decrease in weight, of chains applicable to chain conveyors and drives.

TABLE 1 INCREASE IN STRENGTH OF DRIVE CHAIN FOR OIL-WELL DRILLS

Chain No.	Weight, lb. per ft.	Strength, lb.	Strength per lb.
103	4	9,600	2400
4103	5.7	22,000	3800
SS-40	6.6	28,000	4250
SS-40 Plus	6.6	40,000	6100
Hyper SS-40	8.1	75,000	9200
124	6.6	15,000	2200
4124	8.5	33,000	3880
SS-124	12.7	58,000	4570
SS-124 Plus	12.7	85,000	6700
Hyper SS-124	18.5	150,000	8100

Another steel chain of the drive type has recently been developed having a strength of over 11,000 lb. per pound of weight per foot of length, or almost five times as great as that of malleable iron, with corresponding increase in uniformity and reliability.

Cast chains of malleable iron are extensively used with elevators and conveyors because they are inexpensive and readily provided with special attachments, cast as a part of the link.

Cast chains having a hitherto unattainable combination of high tensile strength and great wear resistance, have been recently developed, and are now available. These chains are admirably suited for drives, elevators, conveyors, etc. A high-grade malleable iron is processed in such a way that it becomes practically a different metal, with vastly improved qualities.

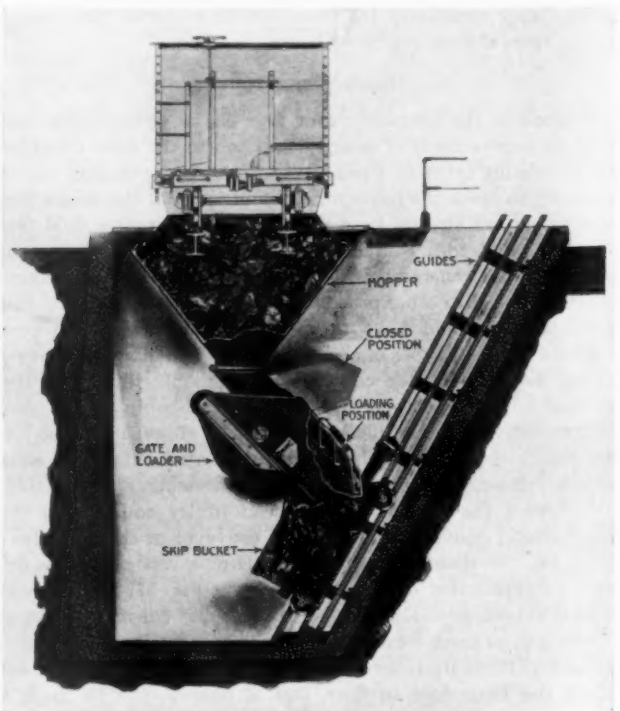

FIG. 34 AUTOMATIC LOADER FOR SKIP BUCKET

This new method of processing produces a metal with a perfectly balanced combination of the three qualities desirable in a sprocket chain—great toughness to resist tension and shock without permanent stretch; great strength in proportion to weight and bulk; and characteristics to resist abrasive wear.

Tests of this new metal, furnished in Table 2, afford an interesting comparison of its characteristics with those of other cast-chain materials.

Due to the structure of this new metal it resists abrasive wear far better than the usual cast chain. Worthy of mention is its exceptionally high yield point (25 per cent higher than that of

TABLE 2 PHYSICAL CHARACTERISTICS OF MALLEABLE-IRON CHAIN

Item	Processed malleable	Average malleable iron
Average yield point, lb. per sq. in.	45,000	36,000
Average ultimate strength, lb. per sq. in.	65,000	54,000
Brinell hardness	170–190	110–130

average malleable iron), which engineers recognize as of greater importance in chains than ultimate strength. In addition to having this high yield point, the metal is tough and ductile, and therefore better withstands shock and fatigue loads.

Cast steel of higher carbon content, and manganese steel having higher yield point, strength, and hardness, are available, but these are more expensive and require special patterns, whereas the new processed chains can be made at any malleable foundry having processing equipment, from standard patterns, at a cost slightly more than that of good regular malleable chain.

The improvements in wrought-steel and cast chains mentioned above greatly enlarge their field of application by making available chains of reduced weight having much greater strength and reliability. Weight and strength are exceedingly important factors with long or high conveyors and elevators.

Variable-Speed Gears. Conveyor and elevator driving machinery and terminals have been greatly improved by substituting speed reducers and anti-friction-type bearings in place of open gearing, and by shafts provided with plain pillow blocks distributed on separate supports. The constant attention required for lubrication is practically eliminated, and much more dependable operation and service are provided.

FIG. 35 TROLLEY MECHANISM OF AUTOMATIC TROLLEY BUCKET SYSTEM

A positive, infinitely variable-speed gear, shown in Fig. 33, requiring only a minimum of space, has been recently introduced by the Link-Belt Company. This speed gear can be readily and advantageously used for driving any elevating and conveying equipment whose speed of travel must be occasionally or frequently varied to obtain the best operating and production results. The positive-drive gear consists of a specially constructed chain and pair of sprockets, by means of which infinite variations in speeds may be obtained continuously (without steps) while running, and in ratios up to 6 to 1. The entire mechanism operates in an oil bath, within a fully enclosed housing. Due to its small size and other features, it is also used for driving machine tools and equipment of all kinds where the speeds must be positively and infinitely varied from time to time.

Skip Hoists. The winding machine for skip hoists has recently been improved by providing it with a welded steel housing, of great shock-resisting properties, in which cut herringbone gears operate noiselessly in an oil bath. The shafts for gears and drum are carried in anti-friction bearings. The rope sheaves, which usually are located in rather difficult or inaccessible positions, are also provided with anti-friction bearings. The steel housing of the machine is built integral with a large substantial steel subbase, on which the motor and traveling cam limit switch are mounted, thus insuring and maintaining correct alignment of all parts.

FIG. 36 VIEW SHOWING COMPLETE INSTALLATION OF AUTOMATIC TROLLEY BUCKET SYSTEM

A unique, clever, and simple loader which automatically controls the filling and operation of the skip bucket was developed during the past year. With this device, which requires no weighing mechanism, the bucket is hoisted only when it is fully loaded. It remains in loading position until filled, when it is immediately hoisted and continues to be hoisted, dumped, lowered, filled, and hoisted, as long as sufficient material is available to load the bucket. This automatic loader insures maximum hoisting capacity, and no attention from the operator is needed to start and stop the equipment. (See Fig. 34.)

A modified form of skip hoist, known to the trade as the trolley bucket, which has been generally used by wholesale and retail coal and material yards, has recently been improved by making all its operations entirely automatically controlled. The bucket is automatically filled, hoisted, trolleyed, lowered, and

emptied at the desired point; then rehoisted, trolleyed back, and lowered for loading at the track hopper. The attendant has only to adjust the selector dial and push the start button to accomplish the automatic repetition of the complete cycle until the stop button is pressed.

The equipment consists of separate motors and drums, electric control apparatus, a selector governing the points at which the bucket is lowered and emptied, and a loader for filling the bucket automatically. The trolley mechanism is shown in Fig. 35, and a complete view of an installation in Fig. 36.

FIG. 37 TERMINAL OF PNEUMATIC TUBE FOR SMALL MESSAGE WORK

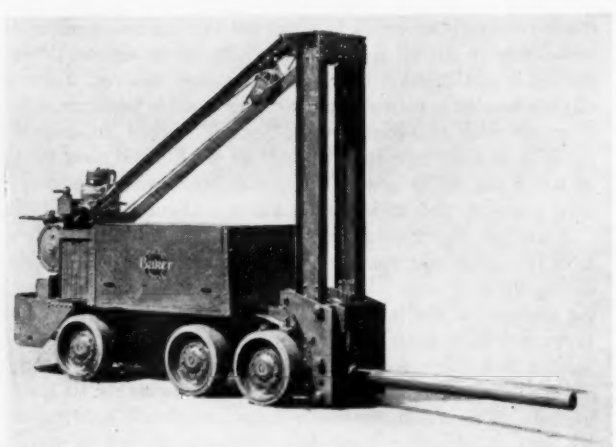

FIG. 38 8000-LB. RAM TRUCK WITH ARTICULATED FRONT AXLE

PNEUMATIC TUBES[8]

After many years of experimenting, the Lamson Company has recently introduced what is called the "Pneu-Art terminals" for pneumatic tubes. Former types of terminals were constructed of heavy metal. The new types are made to harmonize with the decorative surroundings in stores, offices, banks, and other business and manufacturing establishments. Colors are made to correspond with the office trim.

The terminals (Fig. 37) are constructed of a light metal, are rectangular in shape, and both receive and dispatch the pneumatic-tube carriers. They can be placed in fixture panels and therefore are practically hidden. Doors are spring-closed and fitted with felt gaskets to operate silently. Sizes correspond to those used for former types of installations, with which the new equipment is interchangeable.

HAND LIFT TRUCKS AND PORTABLE ELEVATORS[9]

Hand Lift Trucks. The outstanding development in the hand-lift-truck field during the past year has been its greatly increased use in connection with the shipment of goods on skid platforms. The growth of skid shipping has continued in the paper industry until nearly all customers specify skid packing, due to the saving in cost and greater ease in handling. In the larger cities, most trucking contractors have equipped themselves with hand lift trucks to handle skidded shipments consigned to printers and jobbers. An increasing variety of automotive assemblies are now shipped to assembly plants on skids. Skidded shipments

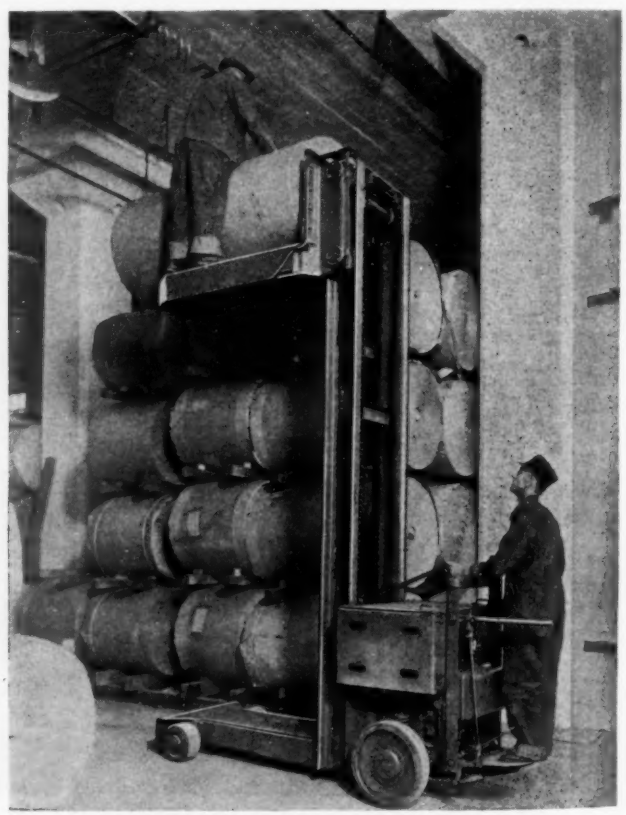

FIG. 39 6000-LB. HIGH-LIFT TRUCK

[8] Section prepared by C. S. Jennings, Chief Engineer, The Lamson Company, Inc., Syracuse, New York. Mem. A.S.M.E.

[9] Section prepared by F. J. Shepard, Jr., Treasurer, Lewis-Shepard Company, Watertown, Mass.

of slate, firebrick, canned goods, and other similar commodities are now being transported both by rail and water at a substantial saving in packing, handling costs, and damage to goods.

The use of hand lift trucks and skids in railroad stores departments has continued to expand during the year, and practically all the larger railroad systems have made initial installations or are increasing present equipment, with gratifying economies. Several intercoastal steamship lines are actively soliciting skidded freight, because economies in handling make this an attractive cargo.

Hand lift trucks of standard and special design are being widely used for handling desks, refrigerators, stoves, safes, machine tools,

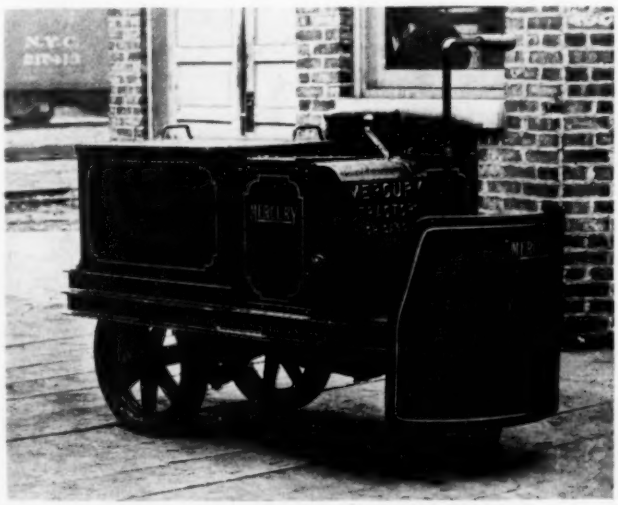

Fig. 40 Truck Tractor But 32 In. in Overall Width and With Correspondingly Short Turning Radius

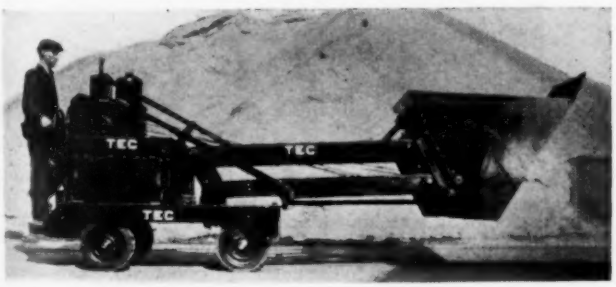

Fig. 41 Shovel Truck for Tunnel Work With 6 Ft. 6 In. Overhead Clearance

and other commodities that are provided with legs allowing entrance of the truck. Open-end lift trucks are also found satisfactory for handling reels of wire, crates, boxes, tote pans, etc., where platforms are not required. Many manufacturers are giving thought to redesigning their product to allow of handling in this way, as a marked saving is gained both throughout production processes and in warehousing.

A new type of truck, known as the Footlift, has been brought out by the Lewis-Shepard Company during the past year, which, as its name implies, is elevated by the operator's foot, using the leg and thigh muscles instead of the arm and back muscles to elevate the load. Among other advantages claimed for it are ease, quickness of operation, safety, and less strain on the operator. All manufacturers of hand lift trucks are giving more attention to refinement in design and safety features. It is now generally recognized that the jack-type, or multi-stroke, trucks should be used for handling heavier loads, and all hand-truck manufacturers are prepared to furnish this type of equipment.

Portable Elevators. In the portable-elevator field a large increase is noticeable in the number of special machines designed to perform operations that previously had been considered as requiring brute strength. Among the many types which are coming more into general use may be mentioned: warp-beam

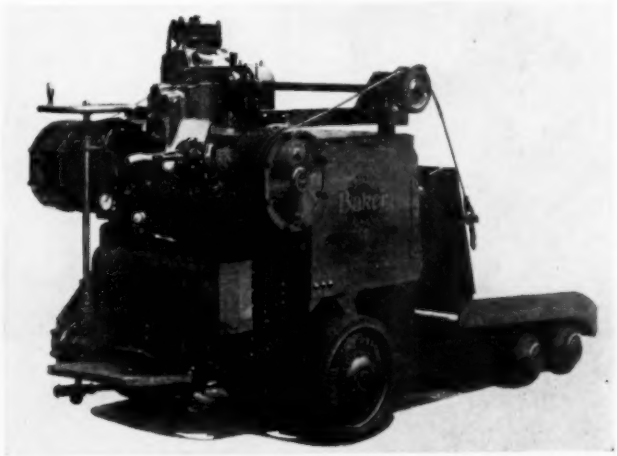

Fig. 42 Truck for Handling Cable Reels

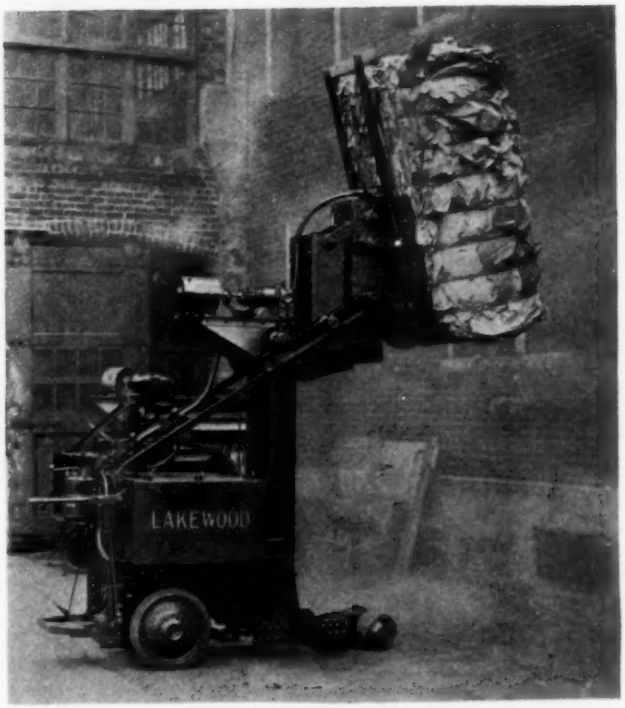

Fig. 43 Tilting Fork-Type Machine for Handling Bales of Waste Paper

carriers, barrel- and drum-lifting machines, oil-switch-tank lifters, refrigerator cranes, die lifters, and special-purpose machines for handling large work in process.

Many machines are handling loads not exceeding 200 to 300 lb., and, to make the machine as light and portable as possible, special section members are often used, constructed by arc welding.

Many installations of portable elevators are used, in connection with skid and lift-truck systems, to pile or rack the loaded skids. It is not uncommon to pile 2000-lb. loaded skids six high, with a corresponding saving in floor space. Machines of heavier capacity have been placed on the market during the past year, and installations of 6000 to 10,000 lb. capacity are not unusual.

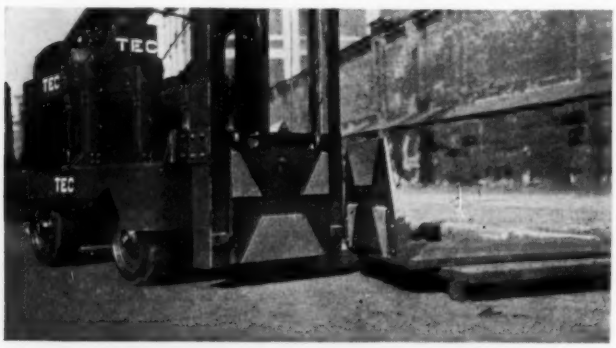

FIG. 44 DOVETAIL ARRANGEMENT FOR RAPIDLY ATTACHING A SHOVEL, PLATFORM, AND FORK OR RAM TO A TRUCK BODY

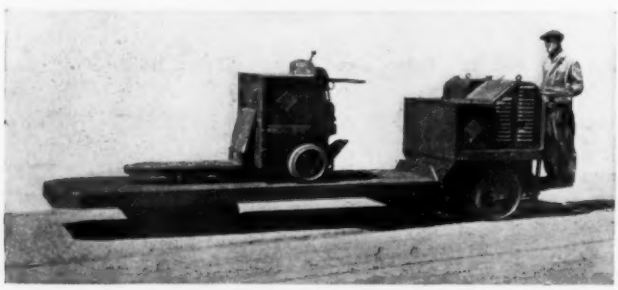

FIG. 45 ELECTRIC TRUCK WITH 12-FT. PLATFORM FOR HANDLING L. C. L. CONTAINERS
(1¾-ton truck resting on platform.)

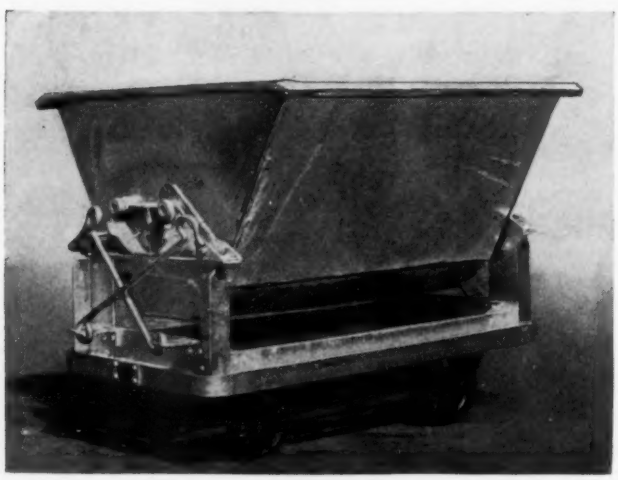

FIG. 46 GALVANIZED TRAILER FOR USE IN PACKING PLANT

Four-post or double-end machines, supporting the carrying platform at two sides, are being used in increasing numbers for adjustable loading docks. Capacities of from 4000 to 8000 lb. are not uncommon in this type of equipment.

A sharp increase in the percentage of power-operated machines has been noticeable, because it is far more economical to elevate commodities by electricity than by hand-power. Hand-power machines are now rarely specified for other than extremely intermittent use.

A gasoline-operated power machine has been developed for

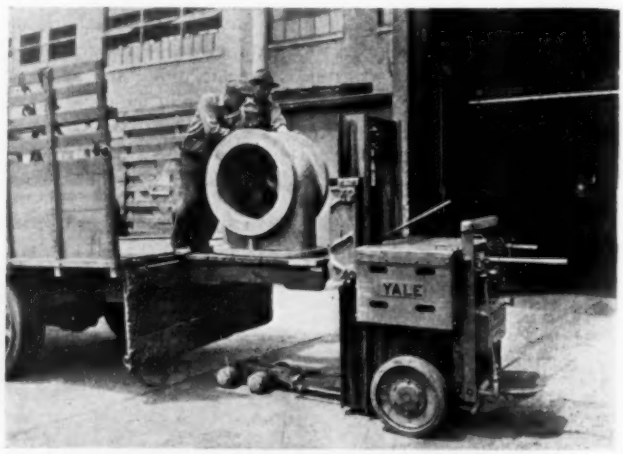

FIG. 47 400-LB. HIGH-LIFT TRUCK

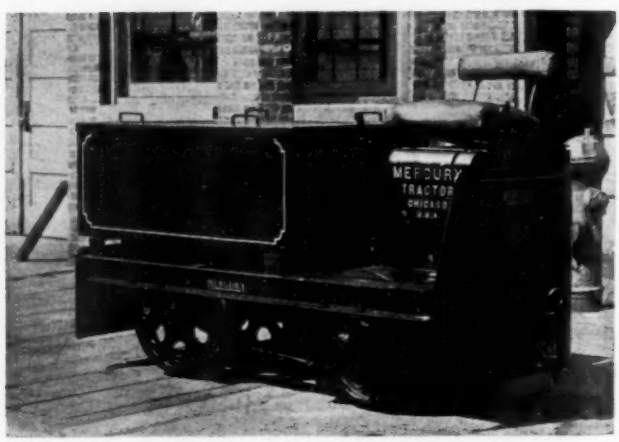

FIG. 48 NEW TYPE OF NARROW-GAGE FLANGE-WHEEL TRACTOR

use on docks, or in warehouses not wired for power. This machine is equipped with a small self-contained air-cooled motor operating through a clutch to the hoisting mechanism. Lowering is controlled by a centrifugal-type governor acting through a band brake. This type of machine is especially useful in loading automobile trucks and handling material on construction jobs and other out-of-the-way places.

ELECTRIC INDUSTRIAL TRUCKS[10]

Progress in the design and use of electric industrial trucks during 1930 has followed the general course witnessed during the past few years. The new developments have been, in general, in the shape of refinements, although one or two striking improvements have been seen.

Increased Capacities. During the past year, electric crane trucks have been developed with a rated capacity of 42,000 ft-lb. overturning moment. Another machine has been placed in service at the Jones & Laughlin plant which has a bifurcated platform and handles 20,000-lb. bosh tanks in the tinplate mill. Ram trucks, in general, have been limited in capacity to 3000

[10] Section prepared by C. B. Crockett, Secretary, Industrial Truck Association, New York, N. Y. Assoc-Mem. A.S.M.E.

and 4000 lb. By using an articulated front axle, the truck shown in Fig. 38 now handles 8000 lb. These machines have also been developed with a twin ram instead of the single one as shown. By the use of counterweights the capacity of the fork-type truck has been increased to over 10,000 lb. This year has also witnessed the increase of drawbar pull in tractors, the maximum available now being 7500 lb.

FIG. 49 INDUSTRIAL TRACTOR DEVELOPING DRAWBAR PULL OF 26.64 HP.

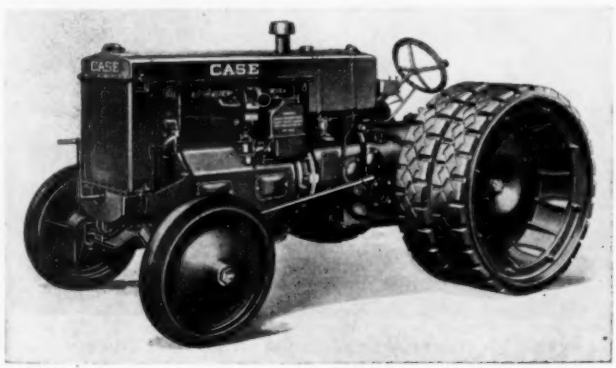

FIG. 50 INDUSTRIAL TRACTOR WITH TURNING RADIUS OF 156 IN. DEVELOPING DRAWBAR PULL OF 26 HP.

Not only has the weight capacity of these machines been made greater, but the hoisting speed of cranes and the lifting heights have been increased as evidenced by the high-lift truck of 6000 lb. capacity and 160 in. overall height, shown in Fig. 39.

Increased Maneuverability. Along with the introduction of newer and larger machines have come many developments to increase the maneuverability of the equipment. The leading manufacturers of storage batteries have developed a new type of cell providing a larger amount of power per square inch of area occupied by the cell. This development has resulted in the introduction of a new heavy-duty-type tractor which has the same clearance and turning radius as the standard machine, but with approximately 30 to 40 per cent more power. There has also been developed a tractor with the standard drawbar pull but only 32 in. in overall width, and with a correspondingly short turning radius. (See Fig. 40.)

Fig. 41 shows a shovel truck used to carry coal through a tunnel with 6 ft. 6 in. overhead clearance, and at the same time deposit its load in hoppers 8 ft. above the ground. This same principle of handling at an elevation, and yet maintaining low headroom, has been developed in the telescoping type of high-lift truck. One machine of this type can pass through the ordinary factory door, but can raise its load to a height of 10 or 12 ft. if necessary.

Safety features have been improved by means of switch interlocks, and trucks are now in use where motors, controllers, and limit switches are equipped with air-tight, gasketed covers so that the machine may safely be operated in a highly inflammatory atmosphere.

New Attachments and Machines. New and novel atachments and machines include the following:

1 A self-operated clamp for handling tinplate.

2 A fork-type truck in which the tilting mechanism operates automatically from the lift.

FIG. 51 THREE-WHEEL TRACTOR OF SHORT-TURNING RADIUS

FIG. 52 6000-LB. LIFT TRUCK

3 A truck for handling cable reels (see Fig. 42) with a limit switch on the winch, operated by the reel on the platform of the truck.

4 A mechanism for reeling in and out a predetermined distance.

5 A special tilting fork-type machine for handling bales of waste paper (see Fig. 43).

A new 6000-lb. high-lift truck has appeared during the year with the following features: hydraulic lift, flat springs, under-

driving wheels, internal brakes, and ball bearings in steering knuckles. A new method has been evolved for attaching tires to trailer wheels by which the wheels are sent to the tire manufacturers and the rubber tires are molded directly on the wheels.

There has been a marked development of attachments that may be used with standard equipment. Fig. 44 shows a dovetail arrangement by which a shovel, platform, and fork or ram may be attached to a truck body in less than a minute. A truck with beveled forks is now being used for handling paper rolls from the floors of freight cars.

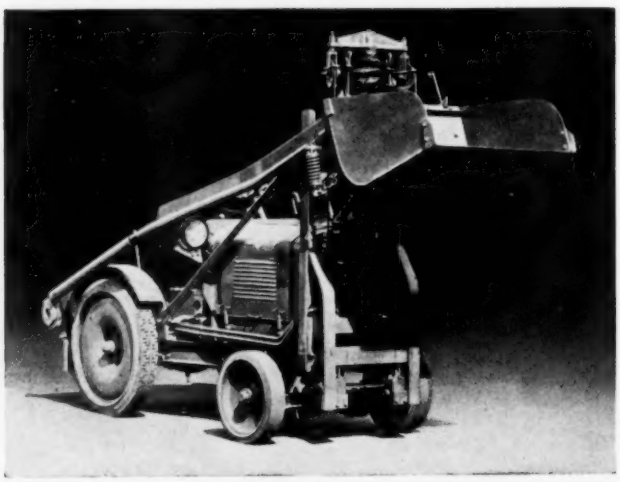

FIG. 53 POWER SHOVEL BUILT ON CHASSIS OF 40-HP. TRACTOR

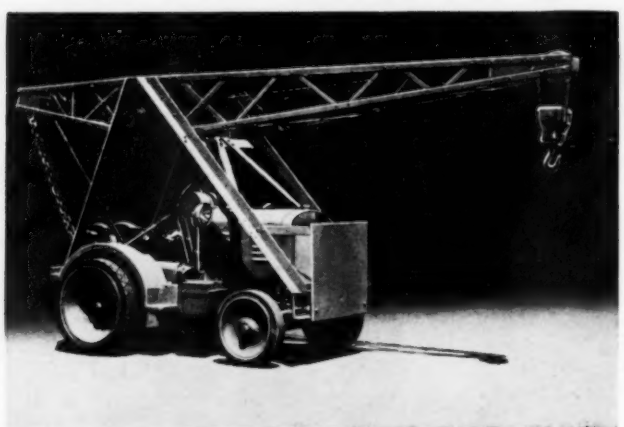

FIG. 54 ADJUSTABLE-HEIGHT BOOM CRANE BUILT ON CHASSIS OF 40-HP. TRACTOR

New Uses for Electric Trucks. New uses for electric industrial trucks include: the use of a tractor for regular car spotting at the repair shops of the Chicago Rapid Transit Company: the delivery of oil and grease by the means of a pump and tank mounted on a skid platform; the handling of concrete in plant construction; the use of equipment for plowing off snow; and, most important, the extensive handling of l.c.l. containers. Machines for handling these containers have platforms 12 ft. in length by 40 in. wide. Fig. 45 shows one of these machines with a $1^{1}/_{4}$-ton machine resting on the platform.

Fig. 46 shows an interesting combination of materials-handling and production equipment. These galvanized trailers are used in a packing plant to receive beef bones. When filled, the trailers are moved by tractor to another location where they are filled with hot water, and a steam line is connected to a manifold which runs through the water at the bottom of the trailer. A cooking process is thus carried on and the meat juices extracted. The fluid is then drained off and the bones are transferred in the same container for utilization in other departments.

During the past year railroads and large industrial plants have made considerable progress in eliminating the rehandling of waste products. At several locations, installations have been made in which unit containers, either mounted on skids or trailers, have been spotted at various points throughout the plant. These containers, when filled, are moved by lift truck or tractor and dumped in gondola cars or a pit. In addition to the saving of labor, the rehandling, or sorting, of scrap or waste material is thus eliminated by providing a sufficient number of containers.

Coordination of Handling Equipment With Other Types of Equipment. The Great Lakes Transit Company has coordinated the use of tractors and trailers with conveyors for unloading, sorting, and transporting flour from ships to warehouse and freight car. The conveyor is used to bring the bags from the hold, and becomes an automatic sorting table, the bags being lifted off the conveyor and placed upon the proper

FIG. 55 THREE-WHEEL TRUCK OF 500 LB. CAPACITY

trailer according to the various brands and consignees. In Chicago, l.c.l. freight is loaded directly from the tailboard of the truck to trailers at various freight depots throughout the city. These trailers are run directly into freight cars and moved without rehandling to the transfer house 16 miles outside the city. Because material for only one destination is placed on each trailer, these trailers are moved at the transfer house directly to the proper car, so that only two handlings have to be made, one at the unloading of the truck, and the other at the loading of the freight cars that carry the material to its final destination.

In coordinating the use of power lift trucks and hand lift trucks, the machine shown in Fig. 47 has been developed during the past year. This is a 400-lb. high-lift truck with a platform $6^{1}/_{2}$ in. high, in lowered position, for use with hand-lift-truck skids, but with a four-wheel compensating front axle for two-ton loads.

The stores department of the Chicago, Milwaukee, St. Paul and Pacific Railroad has successfully coordinated the tractor-trailer and skid-lift-truck systems. The Milwaukee shops, which cover some three square miles, are served by 11 receiving stations. Each of these stations is served by two trailer trains, each train starting at Station No. 1 and making the complete circle, traveling in a direction opposite to the other. The trains operate on regular schedules and provide pick-up and delivery service for each station at approximately 45-min. intervals. In this

way the long-haul transportation is accomplished by means of the tractor-trailer system, while the goods are handled by lift truck in and about the shops and storerooms. The trailers are designed for two 6000-lb. skids, although average loads are not so great as this amount. The average train consists of approximately eight loaded trailers and four empties for picking up loaded skids at intermediate points along the route.

A new type of narrow-gage flange-wheel tractor, or electric "locomotive," has wheels and axles so made that the gage can be adjusted within the limits of 18 in. minimum and 30 in. maximum. This truck is shown in Fig. 48. Another new four-wheel tractor is equipped with an extra large battery consisting of 24 cells of the 23-plate type.

Gasoline Trucks and Tractors[11]

Considerable activity has been manifest among the manufacturers of gas-powered industrial haulage vehicles during the year 1930. Twelve new gas-powered tractors and lift trucks have been introduced by seven manufacturers. Three large

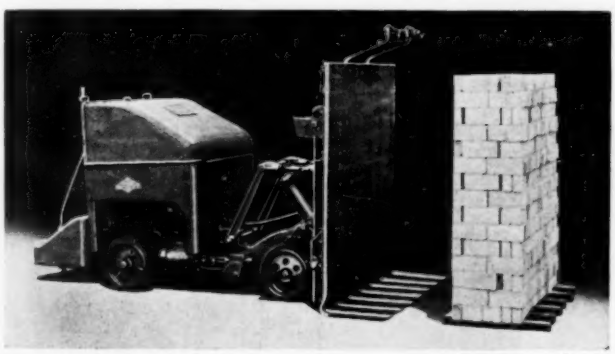

Fig. 56 Gas-Powered "Brick Hacker" for Handling Green and Pressed Brick

manufacturers of agricultural tractors have entered the industrial field in a substantial way, and the introduction of a new light passenger car by one of the large automobile manufacturers has led to the introduction of several light gas tractors powered by this automobile engine.

The Allis-Chalmers Manufacturing Company introduced this year its model "U" industrial tractor, Fig. 49, developing a maximum drawbar pull of 24.64 hp. The weight of the standard tractor is 4125 lb., and it comes equipped with a power take-off pulley and a number of special attachments, such as crawler treads, sweepers, side fillers, scrapers, air compressors, and other useful industrial equipment.

A new industrial tractor was placed on the marked this year by the J. I. Case Company. It is especially designed for use with industrial attachments, such as street sweepers and snow brushes, bucket loaders, cranes, and lift platforms. Model "C-I" has a drawbar pull of 17 hp. and a turning radius of 120 in. The larger model "L-I," Fig. 50, has a drawbar pull of 26 hp. and a turning radius of 156 in. This company also announces a special narrow-tread model of its "C-I" tractor, with a turning radius of 109 in., overall width of 48 in., as compared to the standard model having an overall width of 61 in. All models may be equipped with steel wheels for industrial use, and also with winter cabs and electric lights, when required.

The Charlier Manufacturing Company has developed three types of gasoline-motor-powered vehicles. A new "Brownie" three-wheel tractor, Fig. 51, has an exceptionally short turning radius of 72 in., a drawbar pull of 1200 to 2500 lb., weighs 1950 lb. and can be ballasted to suit the job. The spring-suspended third wheel allows the tractor to travel over uneven and rough roadways with the ease of the four-wheel type. It is powered by a Ford Model AA engine and has speeds of from 1 to 30 miles per hour (four forward speeds and one reverse). A heavy $^3/_8$-in. steel bumper plate is attached to the front.

A new four-wheel tractor made by the same company is similar to the three-wheel type, except that it steers on two wheels instead of one.

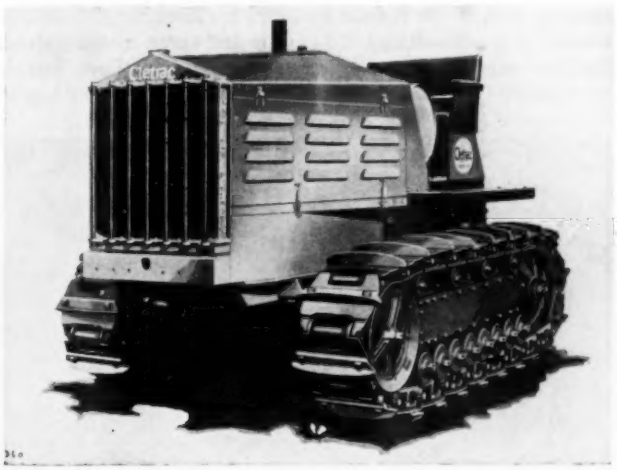

Fig. 57 60-Hp. Crawler-Type Tractor Equipped With 6-Cylinder Engine

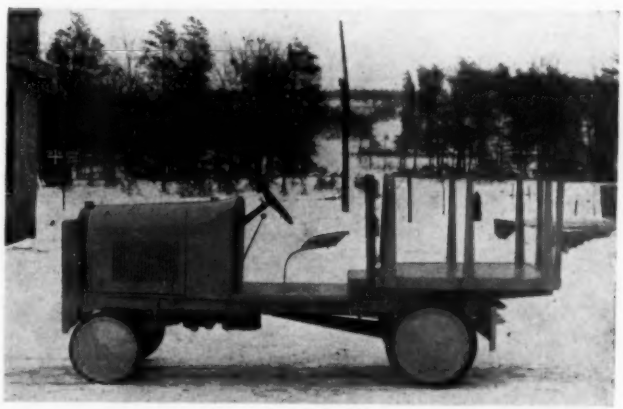

Fig. 58 "Shop Mule" Powered With Ford Model "T" Engine

A new "Brownie" lift truck, Model LT-3, made by the Charlier Manufacturing Company, and illustrated in Fig. 52, has a capacity of 6000 lb., a platform height of 11 in. or 17 in., a safety tread platform 56 × 24 in., a lifting speed of 4 seconds up and 3 seconds down, a turning radius of 120 in., is powered by a Ford Model AA engine, travels two to eight miles per hour, and weighs 2575 lb.

The Clark Tructractor Company, in May, 1930, introduced a new 40-hp. industrial tractor known as the "Clarktor." It is equipped with either solid or pneumatic tires and carries generator, battery, self-starter, and lights. The turning radius is 108 in. With this tractor as a chassis, the same company is putting out a high and low power shovel, Fig. 53, known as the "Clarktor," diggers, and also an adjustable boom crane, Fig. 54, with capacity from 1600 to 4000 lb. and with a maximum hook

[11] Section prepared by Ezra W. Clark, Vice-President, Clark Tructractor Co., Battle Creek, Mich.

height of 13 ft., for use on docks, piers, and railroad yards.

What is said to be one of the smallest straight industrial tractors has also been put out by the same company. It is known as the 4-wheel "Clarkat," has a turning radius of 92 in., a drawbar pull of 2000 lb., and a towing capacity, on the level, of 25 tons on trailers. It is designed primarily for factory, mill, and railroad work.

An improved model of the same company's 3-wheel "Clarkat" has been introduced. It has a turning radius of 51 in., and is equipped with a steel box platform 33½ in. wide by 29½ in. long, of 500 lb. load capacity, at the rear (see Fig. 55). This platform adapts the tractor as a stock chaser for the prompt delivery of heavy castings and tools in and about machine shops, foundries, and manufacturing plants. The platform can be removed in two minutes, making the standard trailer coupler

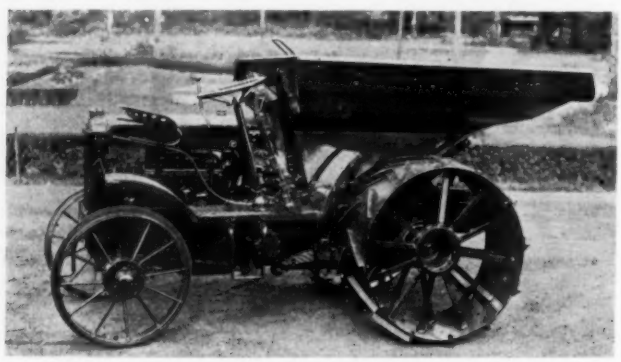

FIG. 59 THE "IRON MULE," A 2-TON DUMP TRUCK BUILT ON THE CHASSIS OF AN INDUSTRIAL TRACTOR

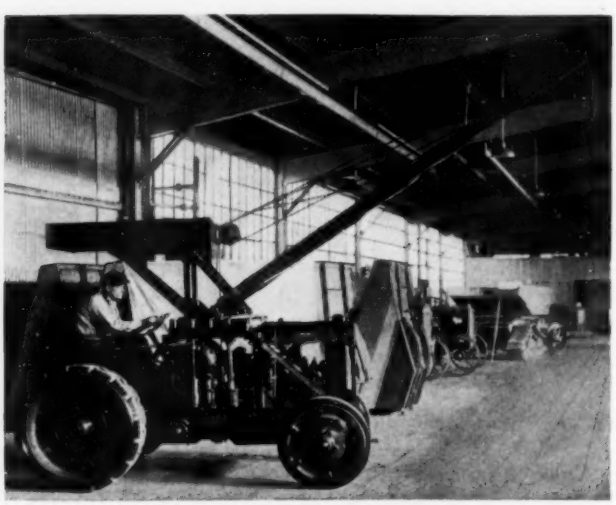

FIG. 60 SWINGING-BOOM CRANE ("ROUSTABOUT")

available so that the machine can be used as a regular factory tractor. The same company has also introduced to the brick and clay block plants a gas-powered "Brick Hacker," Fig. 56, with a capacity for handling a pile of 500 bricks. This machine is designed for the handling of bricks from kiln to storage, storage to shipping platform, to car, and also for barge movement.

The Cleveland Tractor Company, manufacturer of crawler tractors, introduced this year one new model, known as the 80-60 "Cletrac," shown in Fig. 57. It is rated at 60 hp., but is said to be capable of developing 80 hp. It is powered with a six-cylinder four-cycle engine governed to 1050 r.p.m., is equipped with Delco-Remy starting, lighting, and ignition, and, when specified, is furnished with power pulley and take-off.

The "Shop Mule," which for years was powered with the Model T Ford engine and parts, has been put out this year by W. F. Hebard & Company in new form, and is now equipped with the Model A Ford engine and necessary parts. It is four-wheeled, is built with a spring seat for service as a tractor, and has

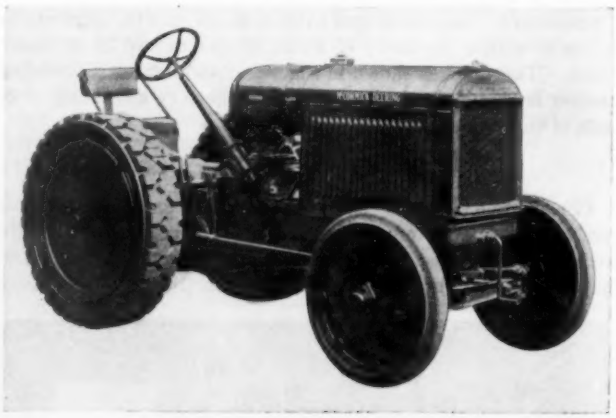

FIG. 61 36-HP. INDUSTRIAL TRACTOR

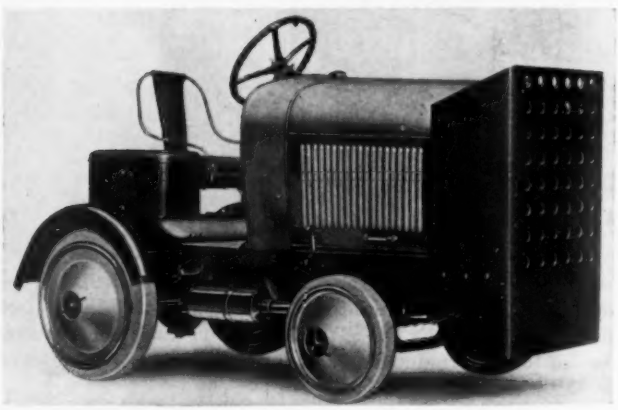

FIG. 62 SMALL 4-WHEEL GAS-POWERED INDUSTRIAL TRACTOR—THE "INDUSTRIAL TUG"

a capacity of 15 to 20 tons on trailers. With a longer platform, the model K will carry a load and also two trailers, and as model L shown in Fig. 58, it is a load-carrying tractor-type "Shop Mule." The Hebard machine is the oldest of the Ford-powered industrial tractors, and the three new models put out this year embody all of the former features, with certain refinements and improvements that make this an economical small tractor for general use.

Using the Allis-Chalmers industrial "U" tractor as a base, the Hughes Keenan Company builds what is known as the "Iron Mule." Equipped with a 2-yd. body, as in Fig. 59, it finds a wide usefulness in the road-building field.

A swinging-type, general-utility crane known as the "Roustabout Crane" is also a new product this year of this company, being built both to the Allis-Chalmers model "U" and to the McCormick-Deering industrial tractor. It is a swinging-boom crane, Fig. 60, with overhead counter-balancing weight, with a rated capacity of 2000 lb. It will pass through a door 5 ft. 6 in. wide by 7 ft. 6 in. high with ample clearance. Control levers are within easy reach of the operator. It is believed that it will have a large field of usefulness among the railroads.

The International Harvester Company has placed on the market a new model, No. 30, of its McCormick-Deering industrial tractor, which provides a flexible and conveniently controlled tractor for heavy industrial jobs (see Fig. 61). It is built to the general design and construction of the previous model, No. 20, but is of larger capacity, and therefore available for heavier duty. Among its important improvements are heavy-duty, internal, self-energizing brakes. The driver rides at the rear of the machine and is always in control of the tractor. Rear rims and tires are quickly removable. The four-cylinder, heavy-duty tractor engine develops 36 hp. on the level.

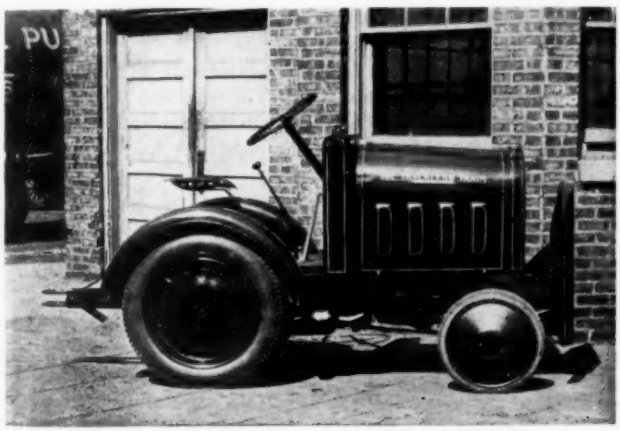

FIG. 63 NEW INDUSTRIAL-TYPE GAS TRACTOR

Removable cylinders permit of convenient, quick servicing. Special equipment provides for lighting, power take-off, and either solid or dual pneumatic tires. The turning radius is 198 in.

The Whitehead & Kales Company is a new entrant into the field of gas-powered industrial tractors, and is putting out a small four-wheel tractor, Fig. 62, known as the "Industrial 'Tug.'" It has a drawbar pull of approximately 1500 lb. and is powered with a Ford engine and parts. It is equipped with a tool box beside the driver's seat, and a heavy front bumper.

Using this tractor as a chassis, the same company has introduced the Whitehead & Kales golf-course tractor, equipped with steel wheels fitted with sod-puncture pins. The wheels are drilled to take extension rims. With a maximum of 1500 lb. on the rear wheels, this golf tractor has ample traction without excessive weight to pack the turf.

A new industrial-type gas tractor, Fig. 63, has been developed by the Mercury Manufacturing Company. This new tractor can be furnished equipped with dual solid tires on the rear wheels, and extra wide tires on the front wheels, with single solid tires, or with pneumatic tires on the rear wheels. It has a standard Model A Ford motor with electric starter, including an 80-ampere-hour battery, Ford radiator, and 6-gal. gravity-feed gasoline tank mounted on the dash. The normal drawbar pull is 1000 lb., with a maximum of 3000 lb. The machine has a turning radius of 104 in. and weighs 3600 lb.

The tractor was developed for outside work, mainly in yards and places where large wheels are desirable. It can be equipped with a power take-off to operate various attachments, such as brooms for sweeping snow, and other devices commonly used in handling materials in industrial plants.

INDUSTRIAL ELEVATORS[12]

Much publicity has lately been given to the really marvelous developments in automatic passenger-elevator equipment, but very little has been said about the increasing efficiency of freight elevators and the rapidly increasing standards of performance now demanded for this type of elevator in all classes of buildings. Even up to a few years ago, office buildings generally attempted to move freight, such as furniture, stationery, etc., in one of the regular passenger-elevator cars which was temporarily assigned for certain periods in the day for freight purposes only.

The tendency now, however, in these larger and monumental office buildings which are going up all over the country, is to install regular freight elevators for that purpose only. These elevators in the higher buildings are of the gearless-traction type, with car-switch control, running at speeds up to 600 and 700 ft. per min. Thus they are practically the same as the passenger elevators in the older office buildings. For instance, the Empire State Building, in New York City, now under construction, will have five distinct freight elevators.

The progress in freight-elevator equipment during the past

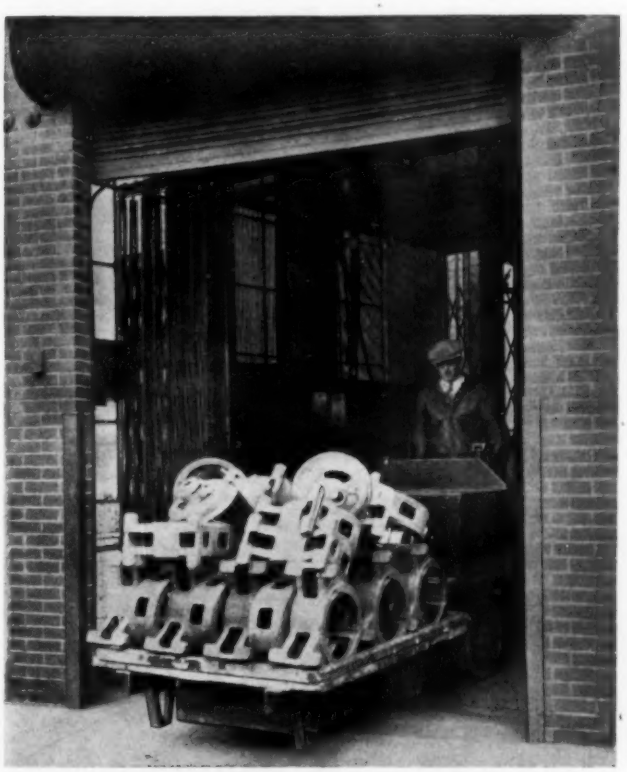

FIG. 64 USE OF LIFT TRUCK ON ELEVATOR

year has been more one of increasing standards of performance rather than the development of any particular new type of apparatus. The micro-leveling feature on freight elevators is rapidly coming into general use, owing to the increased efficiency of such elevators. Micro-leveling eliminates "inching" at the landings, thus obviating the possibility of damage to trucks or merchandise when the trucks are run on or off freight elevators (see Fig. 64). This operation also, by eliminating the false stops, reduces current consumption, cuts down wear and tear on the apparatus, and prolongs its life.

Another development of the smaller freight elevator, in locations where the service does not require an operator constantly on duty, is the use of the double-button type, which is rapidly superseding the old-style hand-rope control. The hand-rope elevator had its use where it was desired to have the elevator operated by those who were using it, rather than by an operator on

[12] Section prepared by E. A. Fitch, Vice-President, Otis Elevator Company, New York, N. Y. Assoc. A.S.M.E.

the car. The hand rope could be pulled from any floor, bringing the car to that point. This necessitated safety devices, such as a rope lock, to prevent the car being taken away from any one who was using it. It was also necessary, of course, to have self-closing gates or doors, which would be held open while the car was standing at the floor, and would close automatically when the car left, so as to prevent the possibility of any one falling down the hatchway under the impression that the car was at the landing.

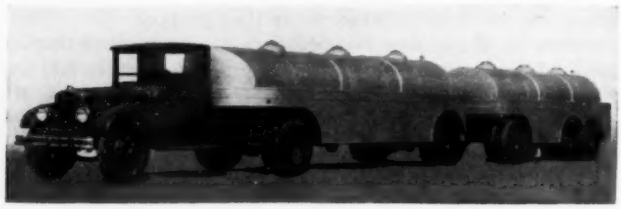

FIG. 65 MOTOR TRUCK WITH OIL-TANK TRAILERS

FIG. 66 MOTOR TRUCK WITH 8-WHEEL DRIVE

FIG. 67 BUNK BUILT BACK OF DRIVER'S SEAT IN MOTOR-TRUCK CAB

This new double-button type is operated from each floor by the pressure of the button, which calls the elevator to that floor if it is not already in use. "Up" and "down" buttons in the car then operate the elevator in the desired direction, constant pressure being exerted on the button employed until the destination is reached. These elevators are also equipped with gates or doors at each floor for protection.

Not so many years ago the freight elevator was not considered of very great importance in manufacturing plants warehouses, or, in fact, in any type of building. Many owners felt that any elevator which would get the freight up and down was good enough. This feeling has been gradually changing, however, and the last year has seen a material alteration of viewpoint, looking toward the installation of more efficient and time-saving apparatus.

Another factor of prime importance is the capacity and size of elevator as compared to the electric and hand lift trucks used in industrial service. Many a plant could save considerable money by installing freight elevators of sufficient size and lifting power to carry the largest electric trucks, with maximum load, that the plant could effectively operate.

It is now realized that freight elevators are as important in their place as passenger elevators. The machines manufactured by leading concerns in the elevator industry are now of the same high class in every respect as the passenger machines. They

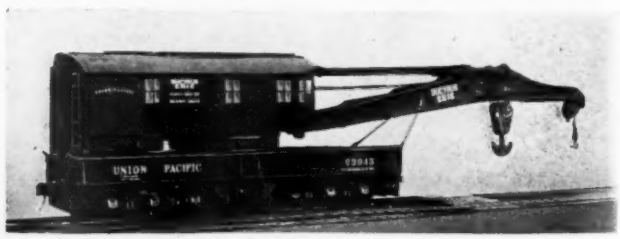

FIG. 68 NEW 200-TON WRECKING CRANE

FIG. 69 NEW TYPE OF HEAVY LOCOMOTIVE CRANE

are equipped with practically all of the same types of safety devices—so as to prevent accident either to the materials carried, or to the elevator apparatus itself—and also with devices to prevent interruption of service. This development is resulting in much more efficient operation, reduced operating expense, and a saving of considerable time in the transfer of freight, with consequent speeding up of production in the factories.

MOTOR TRUCKS AND TRAILERS[13]

So numerous and so complex have been the year's developments in the motor-truck industry, that any attempted report must be confined to a few generalities in order to conform to prescribed space limitations.

Most significant is the increasing tendency of industry to appreciate the flexibility with which trucks can be adjusted to the individual traffic and materials-handling problems of manufacturers. As an outgrowth of this realization, motor trucks

[13] Section prepared by Edward F. Loomis, Secretary, Motor Truck Committee, National Automobile Chamber of Commerce, New York, N. Y.

are coming more and more to be regarded as highly specialized units of machinery, each designed to perform a specific type of operation with the utmost efficiency.

Developments Resulting From Research. Research undertaken cooperatively by truck, chassis, equipment, and parts manufacturers has been productive of uncounted contributions to the more efficient and economical use of motor trucks in materials handling. To cite but a few instances:

1 The perfection of lighter and stronger metals in body construction, permitting a substantial increase in the truck's pay-load capacity. Aluminum and alloy metals in some cases have subtracted from 1500 to 2000 lb. from the truck's dead weight (see Fig. 65).

2 Devices for the chemical or mechanical heating and refrigerating of trucks, permitting the transportation of materials and produce under regulated temperature conditions.

3 Bodies and appliances for the safer movement of combustibles and explosives.

FIG. 70 RAILWAY MAINTENANCE CRANE

4 Improvements in appliances for the preparation and mixing of concrete and other plastic building materials in transit.

5 Bodies and equipment to expedite and to simplify loading and unloading of vehicles. In this division should be included auxiliary appliances, conveyors, improved side- and rear-dump-truck hoists, cranes for handling container-car units—the list is almost endless.

6 Mechanical improvements (see Fig. 66) in truck, tractor, trailer, and dolly equipment which have contributed materially to the economy of truck operation, or have made the truck capable of transporting bulky or unwieldy machinery and materials. One instance is the development of the double-deck trailer for transporting automobiles.

An index of the trend toward the use of balloon and pneumatic tires is provided by records showing that solid tires are supplied as standard equipment on less than twenty per cent of the models, and less than four per cent of the trucks, produced during the year.

Widening Field of Use. More than passing emphasis is merited by the increase in the use of truck-and-trailer, and tractor-semi-trailer-and-trailer articulated units, due to improvements in coupling and braking devices, and a better general understanding of the economic advantages of pneumatic- and balloon-tire equipment. This single development contributes to the greater efficiency of the power unit by permitting its operation while extra trailers are being loaded and unloaded, to say nothing of the increased pay load that can be transported at one time with such equipment.

FIG. 71 HEAVY-DUTY PILE DRIVER

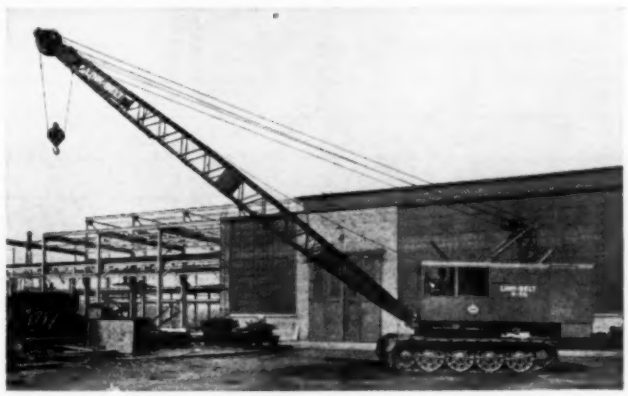

FIG. 72 CRAWLER-MOUNTED SHOVEL CRANE

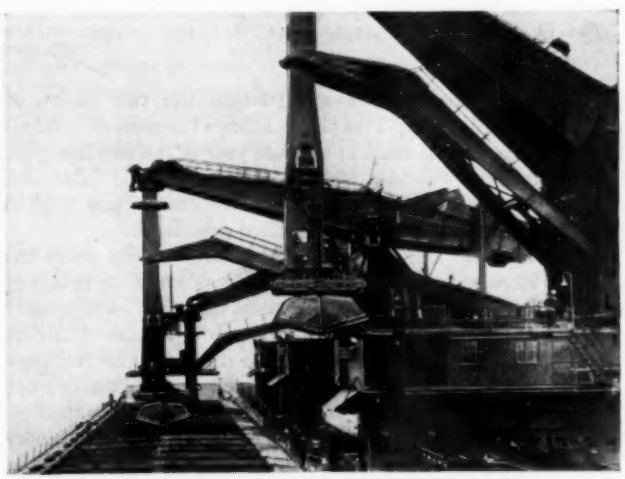

FIG. 73 UNLOADERS AT PRESQUE ISLE DOCK, TOLEDO, OHIO

Use of trucks by railroads in developing their shipper-to-consignee service has made spectacular advances, the number of

trucks operated by railroads exceeding 6000 vehicles, exclusive of the Railway Express Agency's 10,000-truck fleet.

Extension of operating radii is predicted by two additional developments—sleeping compartments in truck cabs for relief drivers, and radio receiving sets for trucks. While the last-named development has not yet been so used, traffic experts are seriously considering the possibilities of short-wave radio equipment in the dispatching and routing of trucks. This device has already been proved satisfactory by the police departments of several large cities. The relief driver's sleeping compartment is now manufactured by several companies. In most cases it consists of a bunk built into the cab, as shown in Fig. 67, directly over or back of the driver's seat.

Both of these developments, it is believed, will contribute particularly to the expansion of common-carrier, inter-city truck operation.

Locomotive Cranes[14]

For the purpose of this Report, "locomotive cranes" will include railroad wrecking cranes, although the two classes of equipment are distinct. This plan is followed because of developments that have been made in the past year in the wrecker type. The designation will also include crawler-mounted machines, although originally the term "locomotive crane" was applied only to 4- or 8-wheel cranes for standard-gage track.

Recent Trends. One of the chief trends of recent years has been the increased use of crawler mountings, enabling cranes of small capacity to work close to their loads, instead of using heavier cranes, with long booms, operating on remote tracks. Crawlers have also given mobile crane service to users with no trackage. On the other hand, where tracks are already laid, the railroad type has many advantages: faster operation, easier propelling, ability to switch cars, and less wear and tear on machinery from traveling on uneven ground. Each type will continue in demand, meeting efficiently particular combinations of needs.

Another trend is toward internal-combustion drives, due to their greater economy for intermittent work, and freedom from the limitation of small boiler capacity. Diesel drives are growing in popularity, and their high first cost is justified by operating economies where a high load factor can be maintained. Internal-combustion drive, however, imposes an entirely different demand on clutches and other elements than does steam, and therefore the best gasoline or Diesel machines are those specially designed for these prime movers. Steam continues in demand with many users and under many conditions. Where other conditions warrant it, a steam-driven crane will probably outlive a gasoline or Diesel machine.

There is a noticeable demand for increase in speed, all-steel construction, alloy-steel parts, frictionless bearings, splined shafts, interchangeability of parts, and, to some extent—with gasoline and Diesel drives—variable-speed transmission.

Wrecking Crane. A new 200-ton capacity Bucyrus Erie wrecking crane, Fig. 68, has been introduced, having holding-down rear rollers and equalized twin main-hoist lines. Its operating weight is approximately 370,000 lb., with low center of gravity for high speed in transit. Boom hoist and slewing are operated by spur gears, the former having an automatic self-locking pawl.

Steel Erecting Crane. In conjunction with one of the large steel-erecting companies, two sizes of a new type of heavy locomotive crane have been built by the Industrial Brownhoist Corporation, suitable for use with extraordinarily long booms up to 200 ft. in length, and designed to handle very heavy loads with shorter booms. The smaller crane, shown in Fig. 69, handles 75 tons at 13 ft. 6 in. radius, and the larger crane handles 150 tons at 17 ft. radius. Both are adapted to form the power plant for heavy bridge-builders' derrick cars of larger capacity than anything heretofore used as regular equipment. Each crane includes a separately driven high-speed, low-power hoisting drum which is a great steam saver, speeds work, and saves the main machinery.

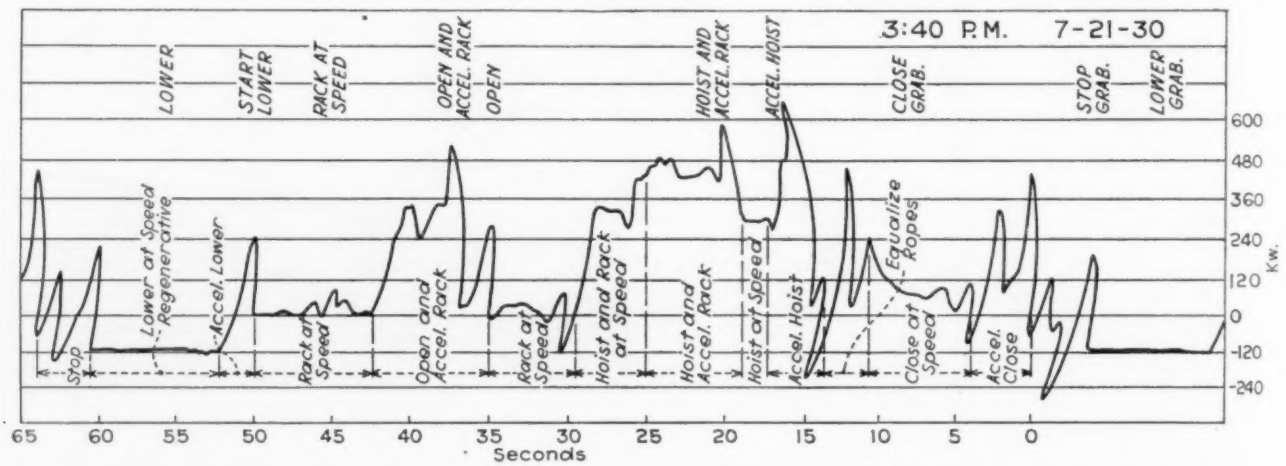

Fig. 74 Recording Graphic Chart Showing Amount of Power Turned Back Into Line When Lowering Load From Bridge Regeneratively

Gas-Electric Wrecking Crane. Two modern double-ended gas, electric, storage-battery wrecking cranes are being built to meet peculiar conditions in electrified zones of the Cleveland Union passenger and New York Central Riverside freight terminals. Each crane weighs 436,000 lb.; is 67 ft. long; is carried on four 4-wheel trucks equalized in pairs; and will handle 105 tons through a 180-deg. arc at either end of the crane. The motive power consists of two 220-hp. gasoline engines direct-connected to electric generators, plus a 208-cell storage battery of large capacity. The propelling equipment is comparable to that of electric locomotives.

Railway Ditcher. A heavy-duty, high-speed railway ditcher and maintenance crane has been developed by the Industrial Brownhoist Corporation for traveling up to 18 miles per hour and handling a spreader, in addition to working between 30-yd. air-dump cars, and cleaning out ditches with a 1¼-yd. shovel,

[14] Section prepared by H. H. Perry, Vice-President, Industrial Brownhoist Corporation, Cleveland, Ohio. Assoc-Mem. A.S.M.E.

which reaches to the far end of the dump car. It handles its own train of tender, dump cars, and spreader, from work to dump and back. The shovel and crane boom are readily interchangeable. The machine weighs about 200,000 lb. and, as a crane, will lift up to 60 tons. The engines are 10-in. × 12-in., and steam is supplied by a 75-in.-diam. 200-lb. fire-tube boiler.

Railway Maintenance Crane. A number of railway maintenance cranes of a new type, Fig. 70, have been delivered by the same company to one of the eastern roads, whose object was to obtain the largest possible lifting capacity without outriggers and without fouling passing traffic by a long rear overhang. The crane carries a machinery unit and boom, operator's stand, and counterweight, all of which revolve through about 110 deg. either side of the track center line, without projecting the rear end beyond clearance. The boiler, tanks, and auxiliary equipment are on the other end of an unusually long and heavy car, mounted on trucks made specially heavy to carry the crane loading, which is concentrated at one end. The maximum free capacity is 12 tons at 15 ft. radius. The crane weighs about 200,000 lb. when equipped with an 80-ft. boom.

Heavy-Duty Pile Driver. To meet the needs of railroads in replacing wooden trestles with concrete structures of economical design, a special, heavy-duty pile driver has been developed to drive large concrete piles and set large concrete-slab decks upon the piles after driving. This machine, shown in Fig. 71, is manufactured by the Industrial Brownhoist Corporation.

The machine is a compact, heavily built, full-revolving, railway pile driver with detachable truss and leaders, which may be replaced by a heavy, curved crane boom, when the machine will handle loads about equivalent to a 120-ton wrecking crane with boom swung over the end of the car. The crane boom is used for setting the concrete-slab decks.

All the desirable features of the most modern railway pile drivers are present in this machine, including a locomotive-type boiler and a two-speed travel mechanism. The leaders fold up and down quickly, and the driver handles itself alone on the main line. Inclined piles may be driven, not only in a plane at right angles to the track, but in a plane parallel with the track. The maximum leader capacity is 22,000 lb. at 31 ft. 11 in. radius.

Crawler-Mounted Shovel Crane. An impressive 2-yd. heavy-duty crawler-mounted shovel crane, or dragline trench hoe, has been introduced by the Link-Belt Company. Its maximum lifting capacity is 40 tons at 12 ft. radius, and the machine weight 125,000 lb. as a crane. The maximum dragline pull is 40,000 lb. The crane is illustrated in Fig. 72.

Bridges, Car Dumpers, Towers, and Handling Systems for Bulk Materials[15]

Greater attention has been given recently to the economic phases of installations for bulk handling, where formerly the technical features received the closest investigation. This demand for high economy has resulted in mechanical refinements, such as pressure lubrication, roller bearings, heavier construction, special selection of metals, etc., to reduce maintenance charges. Likewise a more general use of generator-voltage control—the advantages of which afford simpler control apparatus, greater accuracy of speed control, regenerative retardation, low maximum kva. demand and kw-hr. consumption per ton of material handled—reflects a reduction in operating costs.

Car Dumpers. The car dumper built for the New York Central Railroad at Toledo, in 1929, by Heyl & Patterson, Inc., represents a distinct advance over previous machines for loading coal into Great Lakes freighters. Novel features are the car retarder on the cradle and the new arrangement of ropes and sheaves.

The car retarder is made up of nine units (six having individual control), so that the desired braking pressure can be exerted against all wheels of the incoming loaded car without gripping the wheels of the empty car as it is leaving the cradle. The loaded car can be stopped from a speed of 8 ft. per second in a distance of about 22 ft.

Instead of the usual gravity "hump" yard requiring a crew of car riders, this dumper is fed from a flat yard by electric pusher locomotives. Standard railway retarders and electrically operated switches on the run-off track control the passage of empty cars to their yard. This arrangement of yard with the efficient retarder on the dumper gives higher speed of operation at reduced cost.

The rope system designed for this dumper, using $1^1/_8$-in. rope on 75-in. sheaves with forged high-carbon-steel grooved slip rings, together with a new arrangement or location of sheaves, for the first time in the history of the Great Lakes coal trade has permitted the dumping of over 5,000.000 tons of coal with one

Fig. 75 General View of Coal-Dock Gantry Bridge

set of ropes (which from present indications will handle 7,000,000 tons). The best average for previous dumpers has been slightly over 2,000,000 tons.

The maximum rate of dumping is one car per minute (cars up to 120 tons capacity), and the average over cargo, including time for shifting the boat, etc., is 40 cars per hour.

The dumper is electrically driven with a Ward Leonard system of control for the cradle and Barney haulage engines, each of which has two 500-hp. motors. Forced ventilation of filtered air to the motors and motor-generator sets prevents accumulation of coal dust in the windings.

Unloaders. A noteworthy development by the Wellman Engineering Company, in 1929-1930, is incorporated in the new Hulett unloaders recently installed by them at the Presque Isle Dock of the Hocking Valley Railway Company (now C. & O.) at Toledo, Ohio, and shown in Fig. 73.

The general type of these machines is the same as past installations, the machine traveling on runways having a span of 72 ft. 6 in., and having the trolley with walking beam and stiff bucket leg with 17-ton ore shells. All machines of this type in the past have been operated by direct current, but in this case a radical departure is made and all the functions of the machine, including bridge travel, larry travel, hopper disks, larry gates, and bucket-leg rotation, are operated at 440 volts by 3-phase 60-cycle 6600-volt alternating current which is stepped down from the incoming line at the substation.

The remaining functions, including beam hoist and trolley travel, are operated by direct current at 275 volts, with variable voltage control, this current being supplied by a 3-unit motor-generator set located on the walking beam. This set includes a 500-volt synchronous motor, operating on a primary voltage of 440 volts, 3-phase, 60-cycle, flexibly connected to a 200-kw. d.c. generator

[15] Section prepared by C. D. Bray, New York, N. Y., Vice-President of the Mead-Morrison Manufacturing Company, East Boston, Mass. Mem. A.S.M.E.

for the hoist, and a 125-kw. d.c. generator for the trolley travel.

The advantage of variable voltage control is fully realized in this installation, and the use of alternating-current motors for the functions described seems to produce an operation which is entirely satisfactory.

Bridges. Among the outstanding developments in the past year is one connected with a large gantry bridge designed and built by the Mead-Morrison Manufacturing Company for the Consolidation Coal Company (North Western Fuel Company) for their Milwaukee, Wisconsin, coal dock. This bridge handles a 10-ton coal grab and has been developed to operate on 440-volt, 3-phase, 60-cycle alternating current. Most of the man-trolley bridges developed in recent years have been for use on direct current, in order to obtain the advantages recognized as inherent in direct-current service.

This alternating-current bridge, however, has more than met expectations, in that the combination of regenerative braking with graduated air braking gives full control of all movements of the man trolley itself, as well as of the grab bucket. This system has worked out very successfully, as is indicated on the recording graphic chart, shown in Fig. 74, which shows clearly the amount of power turned back into the line when lowering regeneratively. The power consumption itself, per ton handled, is as low, if not lower, than on any existing direct-current bridge. The man trolley is fully equipped with Timken roller bearings.

Fig. 75 shows the general outline of the bridge, and Fig. 76 the 7-ton clean-up grab, which has a spread of 24 ft. and a cutting edge of 10 ft.

Shiploader. A loading tower of novel design has been placed in operation by the Robins Conveying Belt Company, New York, at the plant of the Alabama State Docks Commission in Mobile. The outstanding feature is its flexibility and range of operation, which are such that, in addition to cargo loading, it is applicable to bunkering operations, reaching all hatches irrespective of location, a feature which most loading towers are lacking.

The tower, which is movable along the dock face, is arranged to receive material from a trunk-line conveyor and deliver it to ship or to storage inshore over the loading belt. The loading conveyor is mounted in a shuttle frame, which, in turn, is supported in a pivoted cradle, which swings through an arc 20 deg. above and 20 deg. below the horizontal.

In operation, the tower is moved to the proper spot, the cradle swung to the desired angle, and the shuttle is then run out between the shrouds, over the ship's rail or life boats, and the end of loading belt is registered over the hatch. Further flexibility is provided by a hinged telescopic chute. For delivering to storage, the shuttle is run inshore and the conveyor direction is reversed.

Industrial-Railway Equipment[16]

In quarries, a growing use is being made of industrial cars for hauling stone from the quarry face to the crusher. Bodies of similar sturdiness have also been mounted on trucks used for the same purpose. The opportunity is opening up to apply bodies of these special types to contractors' trucks used for handling stone dug from excavations for buildings in large cities, and in other types of construction work. Rough bricks and heavy stones likewise can be handled by the same equipment.

In the handling of transformers in large electric power plants there is used what is known as a transformer transfer car. This is a special car built for a special purpose and ranging in capacity from 20 to 150 tons.

[16] Section prepared by W. E. Farrell (New York, N. Y.), President Easton Car & Construction Company, Easton, Pa.

Practically all the newspaper plants erected in recent years use industrial cars and track for handling newsprint into storage, and out of storage to the reels on the presses. A notable installation of such equipment is in the new building of the *Daily News* in New York.

In the erection of most tall buildings, the concrete for the floors has been handled by a kind of a two-wheel scoop body, but for handling this material in the new Empire State Building in New York City, dump cars, industrial track, and turntables have been used.

Large-capacity structural turntables find many applications for industrial purposes. These turntables vary in capacity from 25 to 150 tons, range from 8 to 15 ft. in diameter, and are sometimes equipped with standard-gage track of heavy rail. The General Electric Company and John A. Roebling's Sons Company use such turntables for handling heavy reels of wire at points where it is desired to change the direction of rolling of such reels.

Development in Aerial Wire-Rope Tramway Construction[17]

Double Reversible Tramway. An instance of the adaptability of aerial wire-rope transportation is found at the sand and gravel plant of J. F. Fitzpatrick, Auburn, Massachusetts. A double reversible type of tramway, having a capacity of 75 tons hourly, was installed by the American Steel & Wire Company. It carries raw material from the pits to the screening and washing plant on top of the storage bins. About a year ago a single reversible tramway was installed to take excess sand and gravel from the bins, at a point just above the truck-loading chutes, and form storage piles for contract shipments and winter use.

Recently, a ready-mixed concrete plant has been installed. The aggregate bins were located under the track cable of the single reversible tramway. The operator who loads the bucket is provided with a set of push buttons by which he throws the tripper into place over the proper bin. The tramway bucket automatically dumps its load, and the operator returns the bucket to the loading terminal by means of the drum control of a slip-ring-type induction motor. Whenever there is an excess accumulation of either sand or gravel that is not required in the concrete mixing plant, the bucket is run out over the storage piles and dumped automatically.

Automatic Tripping Carriage. An automatic tripping carriage has been developed by the American Steel & Wire Company which has resulted in direct economies in the operation of reversible tramways. Merely by reversing the direction of the tramway carrier, the carriage operates levers on the bucket, which discharges the load before the carriage has traveled 30 in. in the reverse direction. The operation is simple. As the loaded carrier runs out toward the dump pile, a revolving ratchet passes by a beveled pawl at each revolution of the carriage wheel. When motion is reversed, the ratchet and pawl engage. The pawl is mounted in a chain wheel which is made to revolve with the carriage wheel, gradually winding up a short length of chain connected to the bucket latch system. The motion thus obtained is utilized to trip the load. While the chain wheel has slowly revolved, the pawl mounting has engaged a stationary cam, which gradually raises the pawl out of engagement with the ratchet.

The outstanding advantage of this device is that the dumping point on a reversible tramway is not dependent on any attachments on the track cable. In the case of a single reversible, or one-bucket, tramway the operator may change the dumping

[17] Section prepared by E. J. Lloyd, Engineer, Tramway Engineering Department, American Steel & Wire Company, Worcester, Mass.

point at will, making it possible to increase the hourly tonnage during rush periods by making short hauls, and filling up the more distant end of the pile during slack periods. Since it is no longer necessary to send a man out in a bucket, or on the cables, to change the position of a tripper, the safety of operation is greatly increased. When the dumping point of a double reversible, or two-bucket, tramway is changed, it is necessary to release the traction-rope clamp on one bucket and run the other to the new dumping point.

Banana-Plantation Tramway. A tramway has been installed at a banana plantation in an 8300-ft. circuit, capable of being extended to a 25,000-ft. circuit. Single stems of fruit weighing about 70 lb. each are loaded at supports about 300 ft. apart while the rope is in continuous motion. The rope may be run in either direction, to accommodate the harvesting operations, the direction being determined by the shortest haul to the discharge point. Motive power is supplied by a 30-hp. Diesel engine geared to an 8-ft. plain-groove sheave. Constant tension is maintained by

FIG. 76 CLEAN-UP BUCKET USED ON BRIDGE SHOWN IN FIG. 75

passing the rope around a sheave which is mounted in a light steel structure, in turn supported on standard-gage railroad trucks, and the whole attached to a suitable floating counterweight. Here we have an out-of-doors counterpart of the overhead conveyor chain, capable of being loaded and unloaded while in motion. The field of application of such a system has yet to be fully explored. For instance, bags of coffee or light mechanical parts can be carried long distances.

Colliery Waste-Disposal Tramway. A waste-disposal tramway of the continuous type was designed by the American Steel & Wire Company and installed late last year by the Houston Collieries Company, near Kimball, West Virginia. It is illustrated in Fig. 77. A special feature is that loads weighing about 4600 lb., gross, are raised vertically 443 ft. in 879 ft. horizontally. Taking the cable slope into account, the maximum slope is 78 per cent. The friction grip is required to develop a minimum resistance to slippage of 2830 lb. This is probably the most severe duty required of any similar system in the United States.

After the buckets ascend to the top of a ridge, they pass over an almost level 1600-ft. span, at the end of which is a structure containing track-cable counterweights and a 16-ft.-diameter sheave. The buckets pass around this sheave automatically at a speed of 500 ft. per min. and return to the loading terminal. A 36-in. feeder conveyor with push-button control loads the buckets instead of the usual bin gate. Buckets are sent out from the loading terminal by an electrically operated bucket spacer and dispatcher, which eliminates much manual labor and insures uniform spacing.

Grip Sheave for High-Speed Transmission of Power by Wire Rope. A notable improvement has been made in the design of a grip sheave for the high-speed transmission of power by wire rope under high tension. The Hallidie design of grip sheave

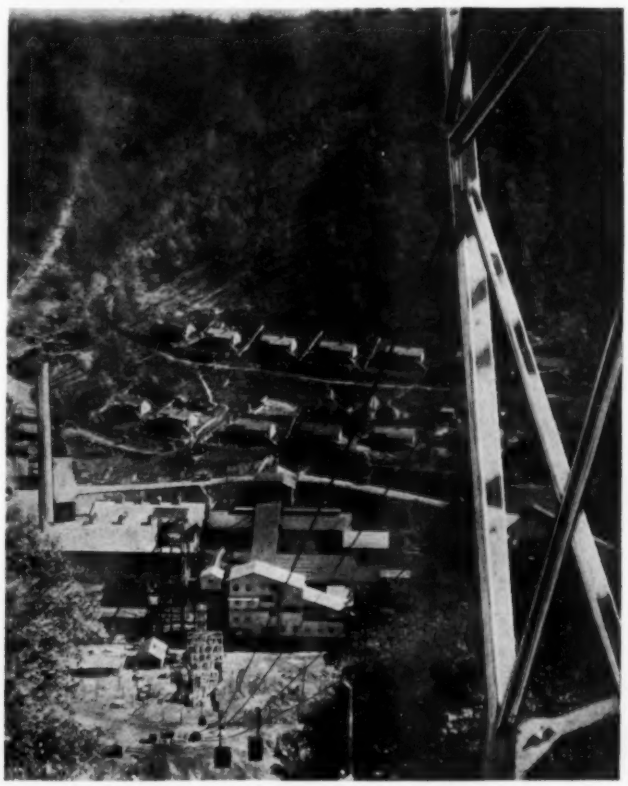

FIG. 77 COLLIERY WASTE-DISPOSAL AERIAL TRAMWAY OF THE CONTINUOUS TYPE

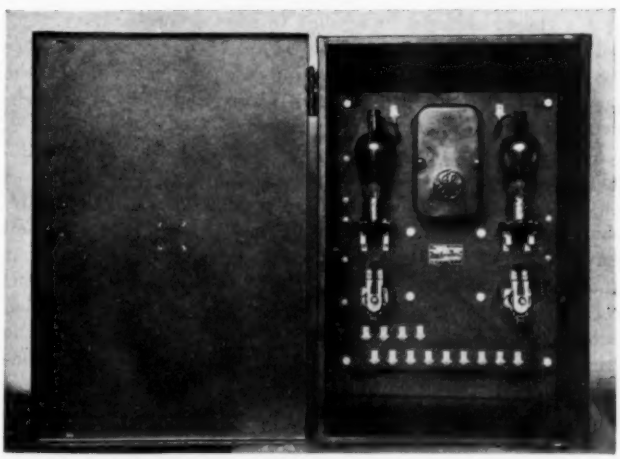

FIG. 78 THYRATRON CONTROL FOR COKE CONVEYOR

has generally been used in this country where a half-lap drive was necessary, and where the power to be transmitted could not safely be entrusted to a plain grooved or wood-filled sheave. At rope speeds over 700 ft. per min. the wear on the toggle jaws, pins, and segments increases rapidly.

When confronted with the problem of transmitting 250 hp. at 1800 ft. per min., the American Steel & Wire Company designed a grip sheave in which the jaw pins are eliminated. Each jaw is machined all over. Two pairs of jaws are placed in each of 48 machined pockets. The side-clearance tolerance is 0.007 in., maximum. Adjustment for rope size is secured by shimming back of the jaw retainers. The jaws are chrome-nickel-steel castings, heat treated to give a Brinell hardness of about 450. The sheave runs in a vertical plane, completely enclosed, and is splash lubricated. In operation, it is practically noiseless, and the rope shows less than normal wear after several months' use. There is no apparent wear on the sheave.

Application of Electrical Equipment to Materials-Handling Machinery[18]

From the standpoint of electrical apparatus, materials-handling equipment may be divided into two classes: first, that which

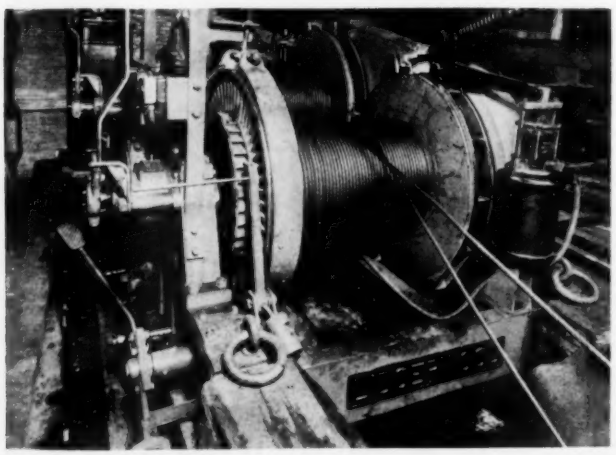

Fig. 79 Contractor's Electric Hoist With Electrically Driven Hydraulic Device for Operating Safety Emergency Brake

is driven by simple stock equipment, such as a single-speed motor and starter; and, second, that which requires special equipment which must be applied to meet a specific duty.

There is little chance for progress in the first class, so far as the application of electrical equipment is concerned. In the second class, opportunities frequently arise, and some accomplishments have been made in the last year.

Electronic Tubes. Perhaps the most interesting and novel development has been the use and proposed use of electronic tubes for controlling materials-handling machinery. In one case, where the amount of material fed by one conveyor on to a second conveyor must be kept proportional to the amount of a different kind of material already being conveyed by the second, this result is accomplished by a thyratron control, Fig. 78, which varies the speed of the first conveyor motor in proportion to the weight of material conveyed by the second. The second conveyor crosses a weigh pan located ahead of the discharge of the first conveyor, and the slight up and down movement of this pan due to the varying weight of material controls the grid circuit of the thyratron, which in turn controls the speed of the d.c. motor on the second conveyor by varying its field. Thus the proportion of the two materials mixed together on the second conveyor is kept very close to constant.

A photoelectric tube is used to provide interlocking between two machines on a grain-car unloader so that the second movement cannot start until the first is completed. It gives greater accuracy than a limit switch will give for this duty, avoids mechanical and electrical wear and tear, avoids the use of gearing or chain drive, and a failure of the tube or light source introduces a safety feature, because it prevents operation of the second motion, thus notifying the operator that it needs attention.

Other applications of electronic tubes have been proposed for controlling materials-handling machinery. Some of these, no doubt, will go into operation. All electronic-tube applications of this kind should be scrutinized carefully, however, because the tubes are a relatively new development and a few more years of experience in the industrial field are necessary to demonstrate their specific fields of greatest usefulness.

Remote Control. An interesting application of remote control has gone into successful operation on the cableway at the Owyhee Dam in Oregon. A 400-hp. induction motor, driving the hoist and trolley motions of the cableway, and a 75-hp. motor, driving the tower, are accurately controlled, including the operation of the air brakes and clutches, from a point 1300 ft. distant from the motors. Full-magnetic reversing control is used, and the air brakes and clutches are handled through electrically operated valves. This is believed to be the longest distance through which the control of a complicated, heavy reversing duty has ever been accurately handled by any means.

Another interesting remote-control application is found on a riderless transfer-car system for handling stone out of the quarry of the Trinity Portland Cement Company. There are four cars, each propelled by a.c. motors with solenoid brakes, operating on a track about a mile long between the shovel and the crusher. This track is divided electrically into about 20 sections and has a turn-out about the middle for passing other cars. The cars are controlled entirely by men in two towers, and by the shovel operator who has control of the track sections adjacent to the shovel. He can thus prevent collisions while loading, dispatch loaded cars, and bring empties to the shovel for filling. The two towers control all other operations, including switching, and the cars are kept correctly spaced by the inherent speed characteristics of the a.c. motors.

Generator Field Control. The use of generator field control (often known as Ward Leonard) continues to expand on materials-handling equipment and has been successfully used on coal and ore bridges during the year. In one place it replaced straight a.c. drive on a bridge, and an increase in capacity was obtained, with greatly reduced maintenance work, and a decrease in power consumption. A car dumper equipped with generator field control broke all records for dumping coal on the Great Lakes in August, 1930. Two hundred and forty-three cars (12,763 tons of coal) were dumped into a boat in 4 hours and $12^1/_2$ minutes, including all time for shifting the boat. This is an average of $57^3/_4$ cars per hour. The cost per ton was considerably less than with steam operation.

Most blast-furnace skip hoists installed within the year have used generator field control, and it has been ordered for use on a Hulett ore unloader for the first time. High-speed, high-capacity coal towers have been using it successfully for several years, and on a repeat order placed during the year, generator field control was again selected, due mainly to its freedom from delays, low maintenance cost, low power consumption, and flexibility of operation.

Ballast Cleaner. A rather unusual type of materials-handling equipment using electric drive is a railroad ballast cleaner which has operated long enough to prove its worth. This machine digs the rock ballast from between the tracks with grab buckets, which dump it on a conveyor, from which it goes through a screening and cleaning process. It is then deposited between

[18] Section prepared by James A. Jackson, Industrial Engineering Department, General Electric Company, Schenectady, New York.

the tracks again. The entire machine is pulled by a locomotive to the place where ballast is to be cleaned. The locomotive then runs ahead and sets its brakes. A steel cable is attached to the locomotive and goes to an electric winch on the front end of the ballast cleaner. The entire cleaner is pulled slowly along by operating this winch, while electric motors operate all other motions of the cleaner. Electric power is supplied from a gasoline-engine-driven d.c. generator.

Safety Emergency Brake. A novel use is made of a small electrically driven hydraulic device, shown in Fig. 79, for operating a safety emergency brake on contractors' hoists in New York. The setting of an emergency brake must not occur too abruptly, because this action may break the rope or overturn the derrick. When power is cut off from the hydraulic-device motor, the stored energy of the revolving armature and centrifugal pump causes the rotation to continue, but at a diminishing rate, thus applying the braking torque at a rate slow enough to prevent damage to the equipment, but fast enough to meet the safety requirements. This equipment has passed severe tests successfully.

Variable-Speed Transmission Systems as Applied to Materials Handling[19]

New Designs. In the development of the variable-speed transmission, mention should be made of several new designs which have increased its utility, making it adaptable for many special requirements. These new designs include: an electrical remote control, through which the speeds may be regulated from one or more push-button stations; an electrical automatic control, which provides entirely automatic speed regulation for certain requirements; an enclosed design, in which the operating parts are encased for protection against steam, acid fumes, dust, grit, and dirt in severe-service installations; a vertical unit, designed to occupy minimum floor space, and which may be enclosed and equipped with motor base; and a special unit with frame designed to receive motor and speed reducer, this forming a variable-speed power-driving unit.

The electrical remote-control variable-speed transmission makes it possible to locate several push-button stations at convenient points throughout the length of a conveyor, thus eliminating the necessity for the foreman to go to the driving end each time a speed change is necessitated. For other requirements the control stations for several conveyors, or sections, may be centrally located on one master control board, on which electrical tachometers may be mounted, indicating the speeds of each separate conveyor unit.

In general, the need for speed regulation is determined by: changes in operations; number of workmen on the "line;" change in size, shape, or construction of product; fluctuations in temperature; variation in quality of material in process; skill of workmen; exact synchronizing of two conveyor sections; change in composition of material; and changes in complete production schedules.

New Installations. The following descriptions of typical recent installations will serve to illustrate several special requirements, the results obtained, and the savings effected.

Sign Enameling. In a sheet-metal works manufacturing enameled metal signs, these signs are delivered from the stamping and enameling machine on to a small belt conveyor. From this conveyor the signs pass to a second conveyor that carries them through a continuous oven to bake the enamel. This second conveyor is on a lower plane than the first belt conveyor, and is equipped with vertical pins, spaced at regular intervals, between which the signs stand on edge while being carried through the oven. A Reeves variable-speed transmission is used not only to vary the speeds of the conveyors for different sizes and kinds of signs, but also to synchronize the two conveyors so that the signs will always drop between the pins in proper position.

Previous to the installation of the variable-speed transmissions it was necessary to use a workman at the intersection of the two conveyors, in order to guide the signs into position on the second conveyor. The variable-speed units timed the conveyors so accurately that the signs dropped into position perfectly, and this workman was found unnecessary.

Veneer Cutting. An interesting application of the variable-speed transmission is in connection with the conveyor which is used to carry the veneer away from a rotary veneer lathe as it is cut. Ordinarily, the lathe is so speeded that the log turns about 40 r.p.m. constantly. At this speed, on a log 24 in. in diameter,

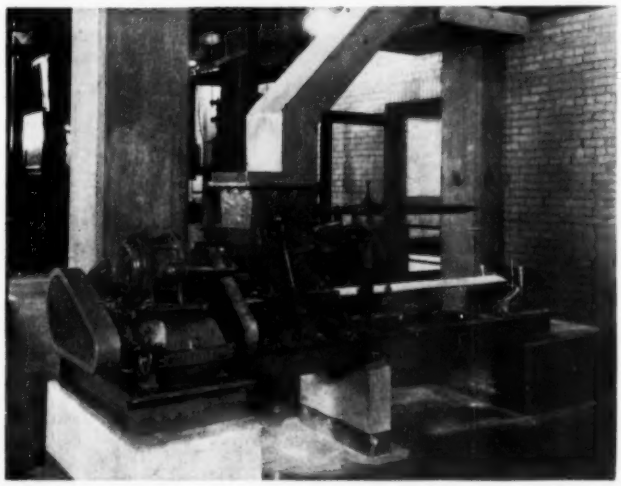

Fig. 80 Poidometer or Automatic Weighing Machine at Municipal Water-Purifying Plant, Minneapolis, Minn.

the lathe cuts 250 ft. of veneer per minute. As the log decreases in diameter, the production of veneer declines in exact proportion, until, at a 6-in.-diameter core, it is only 62.5 ft. per min.

In order to utilize a conveyor for taking the veneer away from the lathe, the conveyor speed must be synchronized with the veneer production and automatically reduced in exact proportion to the output of veneer. This is accomplished through a somewhat special type of variable-speed transmission just recently developed. Instead of the standard speed-shifting screw and handwheel control, a wedge-shaped cam is mounted between the ends of the shifting levers which govern the position of the disks and regulate the speeds. This cam is actuated by means of a connection to the knife carriage of the lathe, so that, as the knife moves into the log to cut veneer, the cam acts on the variable-speed transmission unit to slow down the conveyor automatically in exact proportion to the decline in production of veneer. As the knife carriage moves backward, the cam moves with it, thus increasing the conveyor speed in proportion to the diameter of the next log to be cut.

Bacon Slicing. At the plant of Oscar Mayer & Company, Chicago, short packing conveyors are used in conjunction with bacon slicers, both driven with separate Reeves variable-speed transmissions, which, however, are shifted simultaneously. Through this exact timing of the conveyor with the slicing machine it is possible to lay the bacon strips automatically on the conveyor in such precise manner that the packers, girls, who sit

[19] Section prepared by D. W. Clem, Vice-President and Manager of the Reeves Pulley Company of New York, Inc. Assoc-Mem. A.S.M.E.

along the edge of the conveyor, can pick up the correct amount of bacon of all sizes and thicknesses, to fill the box, and the weight will be uniform. The synchronization of speeds is responsible for this exact "lay," as it is called.

Poidometers. The variable-speed transmission has come into general use for regulating the feeding conveyor on automatic weighing machines or poidometers, such as built by the Schaffer Poidometer Company. These poidometers, of various sizes, are used in handling cement, lime, heavy chemicals, stone, etc., the material being fed accurately by weight instead of by volume. Fig. 80 shows a poidometer installed at the Municipal water-purifying plant Minneapolis, Minnesota.

The material, deposited through a hopper, trips an automatic scale beam when the predetermined weight has been deposited on the conveyor. By reason of the varying specific gravity of the materials, it is necessary to be able to regulate the speed of the conveyor in order properly to remove the materials being fed. Each poidometer is equipped with a recording device which

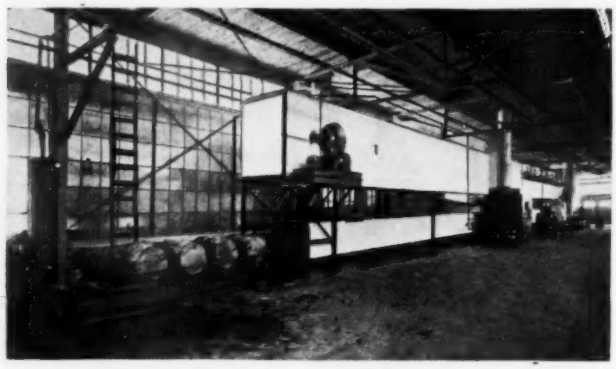

FIG. 81 DRUM-HANDLING EQUIPMENT PROVIDED WITH VARIABLE-SPEED TRANSMISSIONS

enables the operator to determine just what amount of material has been handled in any given unit of time.

Automobile Washing. A recent development in automobile washing, or laundry, conveyors is represented in the circular type called the "Merry-Go-Round," installed by the Sinclair Refining Corporation, in Cleveland. While conveyor systems for automobile washing, equipped with variable-speed transmission, have been in use for approximately three years, this is the first circular type, where the cars are discharged through the same door at which they enter.

Automobile Assembly. A recent development in the automotive industry has been the introduction of the American Austin "Bantam" car. Materials-handling systems are extensively used in the manufacture of this small automobile, and Reeves variable-speed transmissions are used on motor assembly, chassis assembly, and body "lines," timing the production accurately to the desired production schedule, and eliminating overproduction in any one department.

Foundries. The use of conveyor systems in foundries is expanding rapidly, and there is a possibility that foundry mold conveyors may ultimately revolutionize this industry. Variable-speed control on mold conveyors is essential because of changes in size of castings and consequent variation in length of time required for the mold to "set."

Paint Drier for Steel Drums. The drying operation is of major importance in the painting of steel drums. After being tested, the drums must pass through a predrier for drying off surface moisture before going to the painting machine. The drums are received at the painting machine, where they are spray painted as they revolve on their chimes. The ideal painting machine will handle all types and sizes of drums, rolling them on their chimes only.

After painting, the drums go through another drying oven, where they are dried uniformly and hard. The conveyors that carry the drums through the ovens must be capable of traveling at various speeds, depending on the oven temperature, method of heating oven, and kind of paint used. By means of the variable-speed transmission the conveyor also keeps in step with the other operations in drum handling. The speed through the predrier is controlled so that the drums do not pile up in front of the painting-machine operator before he is ready for them. Also, the drying rate of the drums after painting may be varied to suit delivery conditions at the discharge end of the oven.

In Fig. 81 are shown some units of Bartlett & Snow drum-handling equipment equipped with Reeves variable-speed transmissions. The tested drums are entering the predrier, through which they travel to the painting machine. The freshly painted drums of all sizes are then conveyed through the drying oven, located immediately above the drier.

Vanishing-Cream Conveyor. The conveyor installation at the Ponds Extract Company, Clinton, Connecticut, holds interest not only in the slow speed used and the nature of the product handled, but also in the amount of material handled, the total weight of the fully loaded conveyor amounting to 10,000 lb. of vanishing cream in jars while cooling after filling, this whole load being handled by a $^3/_4$-hp. motor.

The jars for filling are placed on a short cross-conveyor, whence they feed into the filling machine. They are placed on the main conveyor, from the filling machine, by hand, closely arranged on the belt, which moves from 10 in. to 30 in. per minute for a total distance of approximately 175 ft. This belt, 30 in. wide, is closely packed its entire length with these jars.

At the tail end of this belt the jars are pushed by their movement across a short plate, with its farther edge slanted to effect a staggered arrangement, on to a very short length of 30-in. belt conveyor, moving at just twice the speed of the main conveyor. This short conveyor, together with the preceding plate, acts as a feeder on to the cross belt at the right end, from which the product is finally removed for packing.

Metal-Stamping Conveyor. Another interesting installation is that of a 4-in. I-beam caterpillar-type monorail conveyor for handling stampings, installed at the Kelsey-Hayes Wheel Company, Detroit, Michigan, by the Whitehead & Kales Company.

The conveyor carriers are spaced on 32-in. centers and consist of suspended steel hangers with four shelves. The three upper shelves hold six stampings in their various stages and the lower shelf holds six blanks. The driving mechanism consists of two individual caterpillar units. Each drive has a Reeve variable-speed transmission with separate motor, the motors being wired to the same starter. This installation furnishes an example of the very accurate timing which can be secured by means of the variable-speed transmission, keeping the drives in step and giving production control.

Paint Drier for Automobile-Wheel Rims. A corner-sprocket-drive conveyor installation, shown in Fig. 82, has been made at the Studebaker plant at South Bend, Indiana. It is equipped with a typical Reeves variable-speed transmission. The conveyor is 450 ft. long, with a mean speed of 12 ft. per min., and it handles hand-painted rims through the drying ovens. The variable-speed feature is necessary for production and proper drying, according to the characteristics of the plant, oven temperature, and atmospheric conditions.

ACTIVITIES OF THE MATERIALS HANDLING DIVISION

The Materials Handling Division has carried on a number of important activities during the past year, among which those

outlined below are considered to be of particular significance.

Labor-Saving-Equipment Formula. The study and development of the labor-saving-equipment formula, also known as the materials-handling formula, has been furthered this year through the action of the subcommittee consisting of S. H. Libby, Chairman, Harold V. Coes, William F. Hunt, James A. Shepard, and Fairfield E. Raymond. By action of this committee the detailed study of the formula has been assigned to the Department of Economics of the Massachusetts Institute of Technology, where the work will be under the direct personal supervision of Professor Raymond. Professor Raymond is likewise a member of the Management Division Subcommittee on Formulas, and in this way the research activities on the labor-saving formula will be coordinated with similar studies to be carried out under the auspices of the Management Division committee. For the financing of the work on the materials-handling formula the project is being submitted to the Research Division of the Society for action.

Manufacturers' Committee of the Materials Handling Division. Undoubtedly the most important move made by the Division during the year has been the organization of the Manufacturers' Committee of the Materials Handling Division. The chairman of the Division, after considerable discussion and correspondence regarding the need and opportunity for cooperation among manufacturers in the field of materials handling, to further the science and its application throughout industry, laid a proposal before the Executive Committee of the Division early in 1929, and was authorized to proceed with its development. A dinner meeting was held at the National Management Meeting in Detroit in May, 1929, and the manufacturers present cordially endorsed the suggestion and indicated a willingness to cooperate with the Materials Handling Division in some practical plan to attain the objective. Individual units of the materials-handling field, among which are the electric-crane manufacturers, the hoist manufacturers, and the electric-truck manufacturers, already had trade associations. For this reason, and also because the interests of the entire industry were too widespread for united action along commercial lines, it was decided to carry out the development of cooperation along professional, engineering, and educational lines, under the auspices of the Materials Handling Division, rather than to attempt to form a large trade association for the industry. Moreover, the Division could not ethically participate in the advertising and sales-promotion activities that naturally are performed by a trade association.

A meeting to organize the Manufacturers' Committee of the Materials Handling Division was called on Friday, June 27, 1930, in New York. To this meeting representatives were invited from various representative manufacturing concerns and from trade associations in the materials-handling field. An attempt was made to give representation at this initial meeting to every important division of materials-handling equipment. Seventeen men attended the meeting, which was presided over by R. H. McLain, of the General Electric Company, organizing chairman, and a former chairman of the Materials Handling Division. The following program was observed at the meeting:

1 Call to order by the chairman
2 Presentation of the Society's viewpoint. R. H. McLain
3 Place of the Materials Handling Division in the Society. P. T. Wetter, Assistant Secretary, A.S.M.E.
4 Plan of coordination between the Manufacturers' Committee and the Materials Handling Division. G. E. Hagemann, chairman of the Division
5 Presentation and discussion of tentative program of activities:
  a Nomenclature
  b Standardization projects
  c Simplification (reduction in number of types and sizes of parts)
  d Research
  e General classification of equipment
  f Collection and publication of engineering data
  g Development of the economic phases of materials handling
  h Development of cost-accounting methods for materials handling
  i Securing papers for materials-handling meetings
  j Collecting leads from which magazine articles could be prepared
  k Arranging for lectures in colleges
  l Ethics concerning engineering services to prospect users
  m The field of the consulting materials-handling engineer

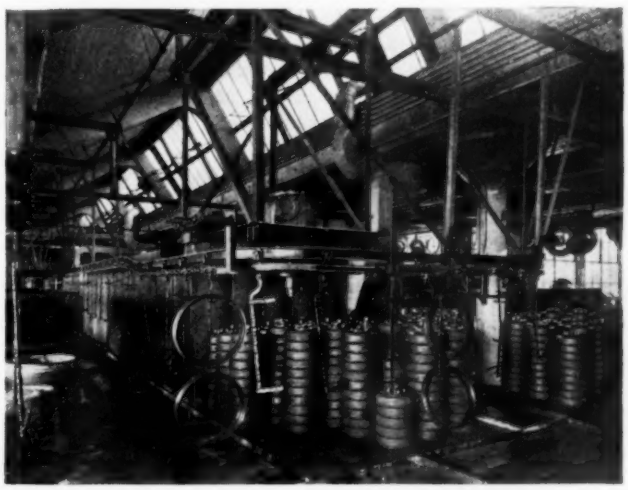

FIG. 82 CORNER-SPROCKET-DRIVE CONVEYOR INSTALLATION IN AN AUTOMOBILE PLANT

  n Classification of materials that are handled in industry
  o Compilation of an engineering library on materials handling
  p Assistance to the Division in preparing the Annual Progress Report
6 Plan of organizing the committee on a permanent basis
7 Election of officers of committee
8 Fixing of dates and places for future meetings
9 Planning for a special session for manufacturers at the Annual Meeting in December
10 Other business
11 Adjournment.

It was decided that the committee should stand as at present constituted, until the representation could be more fully studied so that other groups not now included could be provided with representatives. Each definite field of materials-handling equipment eventually is to be represented by at least one man, and plans will be developed for the election, or appointment, of these representatives impartially from among the various handling-equipment manufacturing plants, with terms of office to run for regularly set periods. In other words, it is the aim of the committee to reach, interest, and secure the cooperation of every manufacturer of materials-handling equipment, so that the coverage may be complete.

Because the full committee of sixteen regular members seemed rather large for the holding of frequent meetings, it was decided to elect an executive committee of five to function in behalf of the whole committee. This executive committee consists of five members to serve at present for one year each the first term of office expiring in December, 1931. It was further decided that three officers should be elected—a chairman, vice-chairman, and secretary-treasurer—these to be three of the five members of the executive committee. The officers and members of the executive committee elected to serve until December, 1931, are:

Chairman, R. H. McLain, General Electric Company
Vice-Chairman, W. E. Farrell, President, Easton Car & Construction Co.
Secretary-Treasurer, C. B. Crockett, Secretary, Industrial Truck Association
Additional members of executive committee:
George L. Morehead, Vice-President, Link-Belt Company
F. J. Shepard, Treasurer, Lewis-Shepard Company.

After an extensive discussion, at both morning and afternoon sessions, of the various subjects that might properly come within the jurisdiction of the committee, and deciding to hold an open meeting for manufacturers at the Annual Meeting in December, the committee voted to adjourn to meet again in December.

Subcommittees of the Manufacturers' Committee. At an executive committee meeting held on September 9, the chairman of the Manufacturers' Committee, R. H. McLain, was authorized to appoint the following subcommittees to get the work of the group under way.

Subcommittee on Nomenclature and Classification of Materials-Handling Equipment:
George L. Morehead, Vice-President, Link-Belt Company
L. J. Kline, General Manager, Mercury Manufacturing Co.
S. Buckley, Shepard Niles Crane and Hoist Company.

Subcommittee on Performance Standards of Locomotive and Crawler-Type Cranes and Shovels:
H. H. Perry, Vice-President, Industrial Brownhoist Company
F. A. Smythe, President, Thew Shovel Company
A. J. Fries, District Superintendent of Motive Power, New York Central Lines, Buffalo, New York.

Subcommittee on Formulas for Figuring the Capacity of Containers:
W. E. Farrell, President, Easton Car & Construction Company
H. J. Brendlin, The Haywood Bucket Company
M. J. Andrada, Chief Engineer, The Robins Conveying Belt Company.

Subcommittee on Research:
Brinton Welser, Vice-President, Chain Belt Company.

Subcommittee on Materials Handled and Types of Equipment Used in Each Case:
M. W. Potts, Engineer, Alvey-Ferguson Company.

Subcommittee on Leads for Papers and Magazine Articles on Materials Handling:
C. B. Crockett, Secretary, Industrial Truck Association.

It is anticipated that from this beginning the Manufacturers' Committee of the Materials Handling Division will develop into a most effective medium to advance the professional, engineering, operating, and economic phases of materials handling in industry through constant and active cooperation with the Division. It is especially desired to stress the fact that the committee is absolutely impartial, and earnestly solicits the support and cooperation of every individual manufacturer of materials-handling equipment. Although actual individual representation on the committee by every manufacturing concern would make the committee far too large for effective operation, nevertheless each manufacturer is asked to consider himself and his company field members of the committee, with full liberty at any time to submit suggestions and otherwise participate in each of its activities in which he may be particularly interested.

National Meetings. The National Meeting, held annually in the spring at various important centers (Philadelphia in 1928, Detroit in 1929, Chicago in 1930, and Cleveland in 1931) continues to grow in interest. Commencing with the Detroit Meeting, the National Meetings have been combined with those of the Management Division because the fields of the two divisions are closely associated. Attendance at these meetings in the respective years was 300, 500, and 880, for those held thus far. The success of previous meetings; the care with which the 1931 National Meeting program is being arranged; the active cooperation of the Cleveland Local Section, the Cleveland Engineering Society, and a large local committee of manufacturers' representatives; and the opportunity for a number of most instructive inspection trips—all should serve to attract a still larger group to the 1931 meeting.

Materials-Handling Exposition. The first independent exposition of materials-handling equipment was held in Chicago in April, 1930, in connection with the combined National Management and Materials Handling Meeting. The show was arranged under the auspices of the Mid-West Exposition Association, because it was of a commercial nature and hence could not be sponsored by a division of the Society. It was endorsed and actively supported by the Materials Handling Division, however, and, in addition to its highly educational advantages, was satisfactory from an advertising and sales aspect to those who subscribed for space and exhibited.

The results in bringing manufacturer and user together to their mutual advantage were sufficiently definite to cause the management to plan a second exposition for the forthcoming National Management and Materials Handling Meeting to be held in Cleveland, April 13 to 17, 1931. At the time this progress report was prepared, 55 manufacturers had negotiated for exhibition space. The 1931 exposition should be unusually effective from the standpoint of the potential economies from efficient materials handling in the production cycle, which it will cause to stand out with particular emphasis. This feature is of special significance when dull business periods necessitate unusually careful measures to conserve the resources and energies of a company and to lower unit manufacturing costs to the minimum.

Discussion

C. M. Wilkinson.[20] The Executive Committee of the Materials Handling Division deserves much credit for the ably prepared Progress Report, for it represents an unusual amount of time and effort. It is especially noted that, in this report, the materials handling industry has been divided into several classes or groups. The Executive Committee for the Materials Handling Convention and Exposition in Cleveland has completed a classification which, it is believed, should be made the permanent basis or designating these classes or groups in the materials handling industry and which is as follows:

1 Electric hoists; 2, chain hoists; 3, overhead cranes; 4, electric trucks and tractors, 5, overhead monorail; 6, pneumatic conveyors; 7, package elevating and conveying; 8, overhead chain conveyors; 9, bulk elevating and conveying; 10, portable conveyors; 11, industrial railways; 12, gasoline tractors; 13, hand lift trucks and skids; 14, hand trucks and trailers; 15, locomotive cranes; 16, air hoists; 17, accessories.

Apparently only recently has the importance and size of the materials-handling industry as a whole or in part been understood or realized.

Attention was called recently to the fact that class 15, locomotive cranes, was doing a business of nearly $100,000,000 annually. With other classes, such as class 9, bulk elevating and conveying, doing a business of more than $15,000,000; with class 7, package elevating and conveying, having upward of $10,000,000 annually; with class 5, overhead monorail, doing upward of $5,000,000 in annual business, and the other classes doing business in much the same extensive way, one may obtain a comprehensive idea of the importance of the materials handling industry in the business of the country as a whole.

The materials-handling industry could well be called a basic industry, as there could be no buildings, steel plants, electric lights, etc., without first having some part of the materials-handling industry move the raw materials from locations where nature has left them, and then handle these raw products from clay banks, iron mines, coal mines, etc., to points of manufacture and thence to the ultimate consumer.

MH-53-2

Materials Handling in the Shoe Industry

By K. D. HAMILTON,[1] BROCKTON, MASS.

The growth of the shoe industry is described from its earliest establishment, from the point of view of mechanical handling of products. It describes the typical factory-production problem and the development of the mechanical conveyor in shoe factories. Mechanical drying and tempering of leather, as well as the adaptation of the individual motor to shoe machinery, are described, and also the installation of standard equipment for power house, dust collecting, packing, and shipping, to show that the shoe industry is searching for all methods to reduce production costs.

THE manufacture of shoes is one of the oldest in the country. During the pioneer days shoemakers went from town to town making shoes for the families in those early settlements. It was a hand-sewed shoe and simply designed, but substantially made.

Enterprising shoemakers in some of the larger towns opened small workshops near their homes. As the business increased, neighbors were called in to assist. These shoes were usually sold in a local market until the development of transportation made it possible to branch out for wider markets.

The machinery was elementary, although a few mechanical devices gradually had been developed. It was not until after the Civil War that the shoe industry really got its start and mechanical devices were invented to speed up production and to reduce cost, as well as to produce a shoe which would be better and more uniform in design and appearance.

Whenever an ingenious shoemaker developed a machine for performing an operation on a shoe he might form a company for manufacturing and marketing it. In a few years, therefore, there were several companies manufacturing shoe machinery of different types. Most of these have been absorbed into one company which manufactures the larger machines used in the industry today, although there are several independent manufacturers making machines for specific operations.

The trend in shoe machinery will be the development of equipment to speed up schedules and to simplify operations, eliminating as much as possible all hand work, in order to meet changes in style. New methods are being developed to eliminate operations, and thus there is a constant change in the design of shoe machinery. One instance is the development of the so-called stuck-on shoe, whereby the sole is cemented to the upper instead of being stitched on, as in a welt shoe.

Shoe manufacturers as well as machinery-equipment companies are beginning to find the need of economy through the introduction of new-process machinery and a speeding up of schedules in order to meet customer demand and style changes.

It was common practice 10 to 15 years ago to take from 20 to 24 days to make a pair of shoes. Today it is possible to reduce the schedule to 5 or 6 days in cheaper grades and to 11 to 15 days in the higher grades.

The method of moving shoes about the factory always has been by using a shoe rack. Shoes were made in lots of 24, 36, and 48 pairs. It was felt necessary to keep the shoes on the last a certain number of days to maintain fit and workmanship. Mechanical drying was considered injurious to the leather. Temperature and humidity control were unknown. The manufacturer realized that his shoes did not dry well in the damp, humid summer weather, while in the winter the factories were too warm, resulting in cracky sole leather and other difficulties.

The shoe manufacturer finally realized that it was necessary to reduce cost, to speed up the turnover of equipment and lasts, to reduce the amount of money tied up in goods in process, and to make better deliveries. Conditions were changing rapidly, and he could not continue on the 20- to 24-day schedule.

Conveying apparatus had been perfected for the automobile industry, and some of the more enterprising medium-grade shoe manufacturers looked into the possibility of mechanical conveyors. There were a few who made a start, these factories making in most cases a uniform grade of shoes of few styles and patterns.

It was found that in order to develop mechanical conveying it was impossible to introduce production schedules on a 24- or 48-pair basis as the racks were too large to be handled conveniently. A 6-pair rack was developed, and in some cases even a 1-pair rack system was anticipated. Other manufacturers reduced the manufacturing unit with a 12-pair rack system to obtain speed and a quicker turnover of goods in process. Reducing the factory unit was a radical step, but in actual practice a material saving in the time schedule resulted. Shoe production was kept flowing at a more constant rate with a smaller unit, and a greater output per operator was realized.

Another radical change was in the drying of the shoes. The time that the shoe was on the last was one of the retarding factors in increasing the production schedule. This resulted in the design and adoption by most of the progressive shoe manufacturers of drying and tempering equipment, as more uniform results were obtained with temperature-control apparatus. These radical ideas in the routing of shoes through the factory upset all accepted theories on the drying and conditioning of shoes on the last.

The problem of shoe-factory design and construction was one of the least troubles of the early shoe manufacturer. A building was put up or one was leased regardless of its practicability for the process, and the machines were located in the building without regard to light or power transmission.

Factory construction today, however, is thoroughly analyzed to conform with process requirements and machinery detail. Route charts for the material are made to conform to straight-line motion and efficient handling of product. The old-time factory was from 30 to 40 ft. wide, with headroom seldom over 10 ft., and the lighting conditions were poor and the windows

---

[1] Mechanical Engineer, George E. Keith Co. Mem. A.S.M.E. Mr. Hamilton was graduated from the Massachusetts Institute of Technology in 1913. He is a member of the American Society of Safety Engineers, the Plant Engineers Club of Boston, the National Fire Waste Council, and the Advisory Board of Engineers of the National Transmission Association.

Contributed by the Materials Handling Division for presentation at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, 29 West 39th Street, New York, N. Y. All papers are subject to revision.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

small. The factories of recent design are standardized, from 40 to 60 ft. wide, with headroom from 10 to 13 ft., insuring good light and ventilation.

The modern type of factory lends itself to the installation of conveying equipment because there is sufficient headroom for overhead ducts, driers, and conveying apparatus. It is wide enough to obtain three, four, or even six rows of machines, where

FIG. 1 ONE OF THE LARGER CONVEYORIZED SHOE FACTORIES

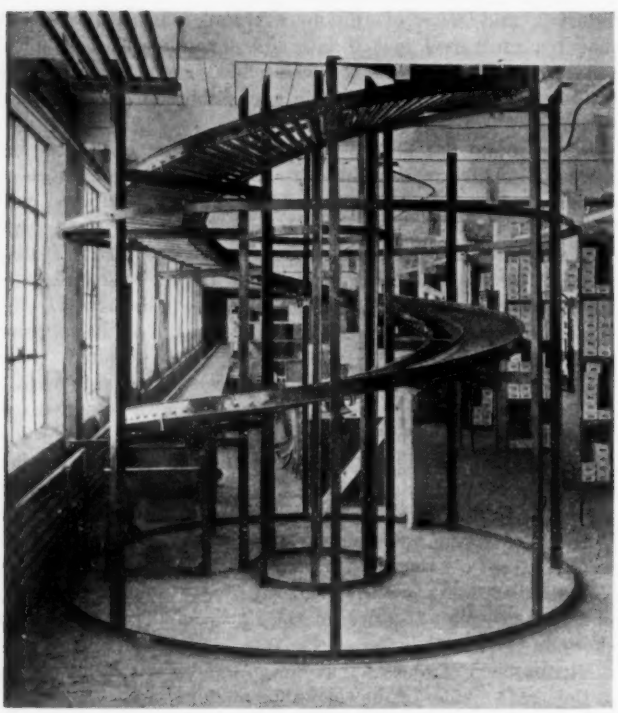

FIG. 2 SPIRAL CHUTE FOR MOVING GOODS FROM ONE FLOOR TO ANOTHER

the older factories could have only two rows of equipment, located near the windows of the outside walls.

The type of conveyor which was adapted for the major operations in the making room was of the roller design, and several installations were made in the larger factories. Some of these have since been discontinued because of change in manufacturing conditions, while others are being used with good results. Gravity rolls were used for flat sections, and the racks were sometimes moved by the operators, while in some other installations the rolls were power driven.

It was soon found that it was impractical to build mechanical conveying equipment for large units and that it was more practical to build smaller sections and to duplicate these units for the required capacity of the factory. Here again the question of shoe-factory design and construction developed as an important feature, in order to adapt this new idea to the present equipment and process.

The first installations of conveyor equipment were in New England and were operated for several years. There have been several installations through the Middle West which proved satisfactory for the type of shoe for which they were designed, and it is believed that several of these conveyorized shoe factories are still in operation. Considerable publicity has been given to a conveyorized factory in Europe, which has been operating steadily for several years at large capacity.

These installations have shown the trend of pioneer thought to adapt mass production to the shoe industry. Factory problems

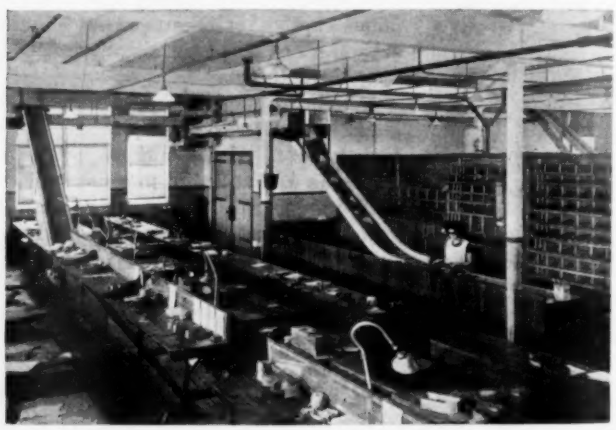

FIG. 3 BELT CONVEYOR FOR RETURNING PATTERNS TO A CENTRAL STOCK ROOM

of style and capacity have retarded the adoption of this idea by the majority of shoe manufacturers, and although practical applications have been made and are now in operation, there are many problems to be solved in view of the satisfactory results recently realized with the 12-pair rack system.

Only assumptions can be made for the future, but no doubt some additional adaptations of this idea will be made where specific shoes of standard design are anticipated.

The foregoing applies entirely to the leather shoe industry. Conveyors for the manufacture of rubber boots, canvas shoes, and allied products are common practice because of the standardized nature of the product. Belt and roller conveyors are indispensable with present-day mass-production methods in the large rubber-shoe organizations.

The illustrations herewith of shoe-manufacturing conveyor machinery show that there are two rows of rollers, one section of rollers being used for a through-way transmission path and the other for intermediate positions for the various operations. This system required the development of stops at different operations so that the shoes could be moved from the main path of travel to the operator at the machine. The operators were timed, depending upon the capacity of the equipment, and the shoes were kept in constant travel through the room.

Whenever it was necessary to dry shoes they were elevated to

especially designed driers. It is impossible to dry leather in a so-called dry atmosphere, because leather must be dried from the inside out rather than to seal the surface with a high temperature. If leather can be dried in a slightly humid atmosphere, this will eliminate the cracking of the grain.

For this reason it was necessary to install humidity-control apparatus, placing the shoes in a moist atmosphere at a moderate temperature, and subsequently carrying the shoe into a relatively higher temperature of 100 to 110 deg. for a definite period. The shoe was then cooled to room temperature before allowing it to proceed to the next operation. This system is still being employed in many factories.

The introduction of drying and mulling equipment, however,

FIG. 4 FACTORY EQUIPPED WITH SHOE CONVEYORS

has been made in a great many factories where the rack method is still employed for routing material throughout the factory. Conveying equipment is employed as a part of the drying apparatus, as will be shown later.

Belt conveyors have been employed for carrying small parts to and from their locations in the room. In one large cutting room all patterns are brought from the individual cutters to a central stockroom for patterns. Here they can be sorted and reassembled for other jobs in the room. This idea can also be employed for transporting dies to and from the stockroom. Overhead wire-basket conveyors on trolleys are sometimes used for distributing parts in the cutting and stitching rooms from a central point such as an upper-leather storeroom, a findings department, or a pattern department. Each application must be studied so as to adapt standard equipment to the individual problem, and so that the relative speed traveled and the design of the installation with relation to other apparatus will fit into the scheme of production without interfering with the flow of material through the factory.

The subject of drying has been mentioned several times, and as the drying equipment of larger size could not conveniently be installed without the application of conveyors, and as the conveying apparatus could not be installed without the application of driers, it seems fit to give attention to this apparatus. In some of the illustrations there is shown a chain conveyor used to transport the machines and the racks through the tem-

FIG. 5 INTERIOR OF A RETURN-TYPE DRIER SHOWING CONVEYOR AND SHOE RACKS

FIG. 6 OVERHEAD CARRIER TO TRANSPORT SMALL ARTICLES

pering room. This conveyor can be either of the drag-link or of the chain type. The reason for this equipment is to speed production in drying and not be dependent on natural atmospheric conditions. The results have been gratifying, and the time schedule has in some cases been reduced two to three days. The shoes are more uniform in texture, defective shoes are reduced in number, and there is a saving in goods in process because of a quicker turnover of lasts and racks. The decrease in production time per unit meets the customer demand for quicker delivery and reduces the amount of money tied up in merchandise in manufacture. It also results in a saving in floor area. The conveyor, of course, must be designed for each

specific job in order to meet capacity requirements for present output as well as for future requirements.

All conveyors should be installed so that they can be loaded and unloaded with the least amount of labor, and the maintenance cost must be reduced to a minimum. The speed of operation will depend upon the amount of moisture to be removed from the shoe and the varying temperature and humidity conditions which exist at different times of the year in the factory. The usual speed will run approximately 1 ft. per min., and the temperatures will range from 70 deg., with a slight amount of humidity, to 100 to 110 deg.

There are other departments of the larger organizations where conveyors of all types are employed. Such equipment as spiral chutes, elevators, lifts, and portable conveyors are used in the packing and shipping room for distributing materials to and from different floor levels and to freight cars. These installations of course are more or less standard in factories of today, each equipment being adapted from standard parts to meet specific building problems. Those concerns which are large enough to make boxes and cartons use conveyors of smaller types to transport materials.

The larger shoe companies maintain power plants of considerable size which employ coal conveyors of familiar types. Ash-handling apparatus is also employed.

The dust-collecting problem is a very important one in shoe-factory operation, and it is being given much thought by plant engineers in charge of equipment.

The author has designed several large dust-collecting units for shoe-factory installation and has found that a detailed design must be made for all piping, layout for fan equipment, and a design of the hoods which are attached to the individual machines. Sizes of suction pipes to each machine must be specified and the equipment so designed that a suction of at least 2 to 3 in. of water is obtained at the hood. Branch machine connections will vary in size from 2 to 6 in. State regulations will also affect such a design.

The location and the installation of fans and dust-collecting equipment are of paramount importance. Engineers who anticipate power-factor conditions frequently find it possible to employ synchronous motors to drive these fans, as they are in operation throughout the working day and furnish an ideal opportunity because of the steady power load. The installation of slow-speed, low-powered fans is advisable on account of the power saving, and where practical the size of the fan should be reduced to the minimum, even to the extent of separating the system into small units. It frequently occurs that various rooms operate at different intervals, when it might be advisable to shut down the fans for one of the other departments.

Conveyors are also used in some of the larger offices in shoe-factory organizations, even employing pneumatic tubes, basket conveyors, and lifts to assist in distributing office material about the building. The transportation department frequently employs belts, lifts, spiral chutes, and other ideas for expediting shoe cases from the shipping room and stock department.

Another item which affects the material-handling problem is the change in the distribution of power. The first shoe factories, as with all industries in this country, started to develop power from the engine drive and belt transmission. Large belts transmitted power through shafting to all corners of the factory, and it was necessary to place the machines so that they would be operated from the line shafting. In many of these old-type shoe factories the friction load has sometimes been as high as 70 per cent of the total load. With the adoption of the induction motor and the adaptation of the group drive to shoe-factory planning, it was found that the shafting problem could be partially eliminated and the machinery be grouped in smaller units to obtain flexibility. It was possible to drive stitchers, welters, trimmers, or other groups of one classification with a separate motor, and that unit could be independent of all others.

There are many benefits from individual motors in the shoe trade which are peculiar and perhaps would not occur in other industries. First, the small size of motor required lends flexibility to the machine. The changes in style in shoe design and manufacture require the frequent moving of this equipment from one location to another. Machines can be placed at the proper angle with the windows to obtain perfect light.

There are specific conditions where it may be possible to introduce mechanical means to transmit shoe products through the factory when applied to large units of standardized grade. The rubber-shoe factories have already adopted the conveyor as standard practice. To thoroughly develop this method an extensive study must be made of all problems of manufacture in each individual organization. A whole-hearted cooperation must be used in the operation of driers and tempering rooms. Engineering skill must be employed to cooperate with all phases of management to overcome the customs which are so strong in this industry. The economic trends are forcing themselves upon this industry and the necessity of reducing production schedules and operating costs will form an incentive to enterprising manufacturers to work out new methods to create the most practical work unit, whether it be transported about the factory on a conveyor or by the simple shoe rack.

MH-53-3

Materials-Handling Methods in the Fisk Tire Plant

By C. E. MAYNARD,[1] CHICOPEE FALLS, MASS.

The paper discusses the part that handling equipment has played in a program of cost reduction and quality improvement in the Fisk Tire Company Plant. In recent years there has been a tendency for the plant to become more "conveyorized," coordinating groups of operations. The Trucking and Mechanical Departments are mainly responsible for the materials-handling equipment. The Engineering Department, a subdivision of the Mechanical Department, is expected to develop improvements. The cost of improvements has to be justified by a reduction in operating cost or an improvement in quality. There are no limitations on the cost of materials-handling equipment providing a saving can be made within a reasonable length of time. Comparing trucking costs of 1925 with the present, a 50 per cent reduction is noted. In spite of the tremendous savings that were made in materials-handling methods during the last four or five years, the possibilities of further improvement are far from being exhausted.

LARGE reductions in manufacturing-labor costs have been made at the Fisk Rubber Company in the last few years. Part of this reduction has been due to improved handling methods. This paper will attempt to show what improvements in materials-handling methods have contributed to a lower operating cost and an improved quality of the product. During the last few years materials-handling methods have received much more attention in the tire industry than formerly. Tire plants in the past were more "departmentalized." Production men and engineers looked upon the tire-manufacturing process as a group of departments, each one more or less separate, but contributing to the finished tire. The straight-line idea of production began to appear in the tire industry but a few years ago, as it did in other manufacturing endeavors. With the straight-line idea in mind, the production engineers, unconsciously perhaps, began to look upon tire manufacturing as a single continuous process rather than as a group of processes. The first effect of this change in point of view was to tie departments more closely together by improved materials-handling methods. Development along these lines has been going on continuously for the last few years, and the savings have been extensive. In many cases, improved handling methods have obliterated some departmental lines completely, whole groups of operations being so coordinated that it was no longer logical to maintain certain departments as separate units.

The Fisk Rubber Company has been a pioneer in these developments. The production buildings of the Fisk plant are modern; consequently it has been possible, in spite of many improvements in the methods and layouts, to work out a satisfactory handling system.

Control of Material-Handling Equipment

At the present time two departments are mainly responsible for the care and maintenance of the materials-handling system—the Trucking Department and the Mechanical Department.

The Trucking Department has been assigned the general responsibility of operating all elevators, all interdepartmental trucking, where the use of electric trucks or tractors is involved, the laying out of all trucking aisles, the determination of the amount of trucks and trailers to be used in the various departments, and, finally, a primary responsibility for the maintenance cost of the aforementioned equipment. The supervisor of the Trucking Department reports directly to the factory superintendent.

The Trucking Department supervisor has two types of workers under him—elevator operators and electric-truck drivers. It is his responsibility to see that the elevators are operated with an optimum load, and also it is his responsibility to determine the fixed routes and the size of loads that the truck drivers shall handle. As production varies it is customary for the supervisor to send into equipment storage the excess trucking equipment, such as trailers, live and dead platforms, and special departmental trucks.

Other materials-handling systems, which are mainly conveyors of various types, are under the supervision of the mechanical superintendent, who in turn reports to the factory superintendent. He is responsible for the upkeep of the conveyors and is held accountable for any losses in production which occur because of their breakdown.

The Engineering Department, which comes under the Mechanical Department superintendent, is expected to develop improvements in the materials-handling system, whether it be conveyors or special trucking equipment. They, of course, do this with the cooperation and assistance of the Production Department supervisors. In many instances the ideas involving improvement of the materials-handling system actually come from the Production Department rather than from the Engineering or Trucking Departments.

The cost of every improvement in the materials-handling methods has to be justified by a reduction in operating cost or an improvement in the quality of the product. In some instances it is also a matter of saving valuable floor space. Incidentally, there never has been any limitation placed on the cost of materials-handling equipment to be used, providing the saving to be made could be paid for within a reasonable length of time.

[1] Factory Superintendent, Fisk Rubber Company. Mr. Maynard was born on January 13, 1895. He received the B.S. degree from Amherst College in 1917. His business history includes The Good-Year Tire & Rubber Company, 1917–1918; Naval Aviation Corps, 1918; went with the Fisk Rubber Company, 1919; Manager of Process Development Department, 1926; Mechanical Superintendent and then Factory Superintendent, 1930. Mr. Maynard is the author of several papers and the inventor of numerous machines and processes relating to the rubber industry.

Contributed by the Materials Handling Division for presentation at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of The American Society of Mechanical Engineers, 29 West 39th St., New York, N. Y. All papers are subject to revision.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

General Layout of the Main Production Building

It might be advisable to turn for a moment to the general layout in the main production building of the plant. Most of the crude materials come into the building on the second floor, this being the track level. From there they drop one floor to the Mixing and Milling Department. Adjacent to the Milling Department is located the Calender Department. It has been found advisable to place these two departments on the first floor on account of the weight of the machinery used. Rubberized fabric from the Calender Department is carried to the top, or fifth, floor of the building, where some of it is cut to the various dimensions required for tire assembly. The storage for this material is maintained there also. Some of this fabric is brought to the

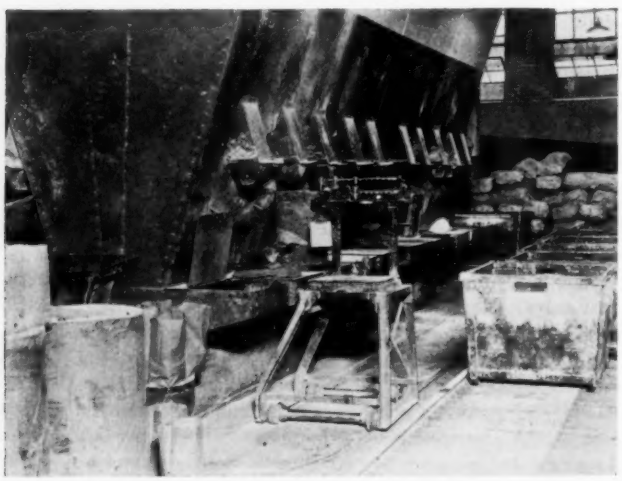

Fig. 1 Hopper System in the Compound Department

fourth floor, where cutting machines and band-building units are located. The cut materials from the fourth and fifth floors are then conveyed to the third floor, where the Tire Building or Assembly Department is located. From the third floor the raw tires are conveyed to another section of the first floor, where they are cured or vulcanized. On account of the curing equipment being heavy, it is necessary to locate it also on the first floor.

From the Curing Department the tires are conveyed to the Tire Finishing and Inspection Department, located on the fourth floor, which is the most convenient level from which to convey the tires to the storage building.

Course of Production, Compound Department

There can now be followed in detail the tire-manufacturing processes throughout the plant, noting as far as possible the materials-handling methods used.

The first department in the tire-making process is called the Compound Department. The storage place is located on the car level and very near the unloading point. The pigments, which come in bags or barrels, are generally emptied into sifters directly over the hopper system. These hoppers are large enough to hold from one day's to one week's supply of pigments. The outlets of the hoppers, which are on the floor below, are brought within the smallest possible area so as to reduce the walking time of the operator who weighs the materials. A roller conveyor circles the outlets of the hopper system and carries the batch boxes into which are loaded the various weighed pigments and rubber. The boxes of materials are checked for weight while on the conveyor, after which they are hauled to the Milling Department on live platforms. The Milling Department is on the same floor level and adjacent to the outlets of the hoppers.

The rubber for the compound batches is unloaded in two locations, some of it coming from the cars in the basement of the building near the washing lines and the remainder being taken off the cars on the second floor of the building near the rubber cutters and drying room, these being the operations that ordinarily follow the unloading of certain types of rubbers. The rubber taken off at the latter point is used for feeding the Banbury mixers, the loading openings of which are on the second floor. When it is necessary to move the rubber, it is handled in either large box-like trucks or in large batch boxes placed on live platforms.

Electric trucks are important pieces of equipment in the Compound and Milling Departments. They are used for moving the platforms loaded with batch boxes full of rubber and pigments and for hauling large box trucks filled with crude rubber to the various operations, such as the cutting, drying, and washing.

Milling and Calendering Department

As previously mentioned, the Compound Department is located on the same floor level and adjacent to the Milling Department, where the pigments and the rubber are mixed previous to their use on the calenders or extruders. This step in the course of handling the material has not been worked out

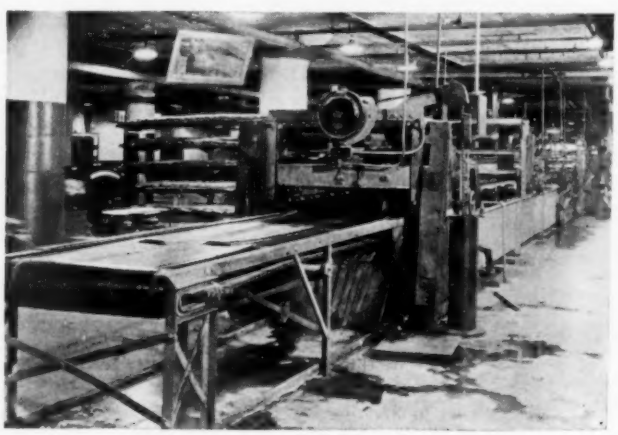

Fig. 2 Conveyor System in the Tread Department

to complete satisfaction. At present the pigments and rubbers in batch boxes are hauled to the mixing mills by means of electric trucks. After the mixing operation has been completed, the compounded rubber batch, which is then in slab form, is placed upon live platforms and hauled to the warming mills adjacent to the calenders or extruders.

Until recently it was common practice to store mixed stock in a storage department before transferring it to the various calender or extruding operations. This break in production tended to prevent delays encountered in the milling operations being transmitted to the calenders, and at the same time the calenders could quickly swing from one stock to another with an assured supply available. It also was claimed that the stock had to cool and age in storage to give standard processing conditions. This scheme, however, resulted in large inventories of stock and in comparatively high handling costs. It was found that this was not necessary; consequently, the stock now goes in most cases directly to the calendering or extruding operations without any delay. This of course reduced the inventory of material and also the handling costs.

In one section of the Milling Department the mixing opera-

tion is tied by means of conveyors directly to the warming mills of the calenders, which reduces the handling cost of the material between the mixing operation and the calendering to a minimum. It may be possible some time to follow this same idea throughout the Milling Department.

Although the warming mills were always near the calenders to which they supply stock, until recent years it has been customary to feed the latter by hand. Now it is common practice on calenders coating tire fabric to use a conveyor to carry a strip of stock from the warming mill to the feed bank of the calender. Because this continuous strip yields a more uniform feed, greater accuracy in weight of the coated fabric can be obtained than with the old hand method. The coated fabric as it emerges from the calender is wound into rolls containing as much as 500 yards. It is wound up in a fabric liner to prevent it from sticking together. The total weight of one of the rolls is about 1800 lb. A live platform with a steel superstructure which will hold two rolls in a horizontal position is used to transport them to the Stock Preparation Department.

Tread Department

In addition to coating fabric the Calender Department has as one of its main duties the production of treads. The tread is,

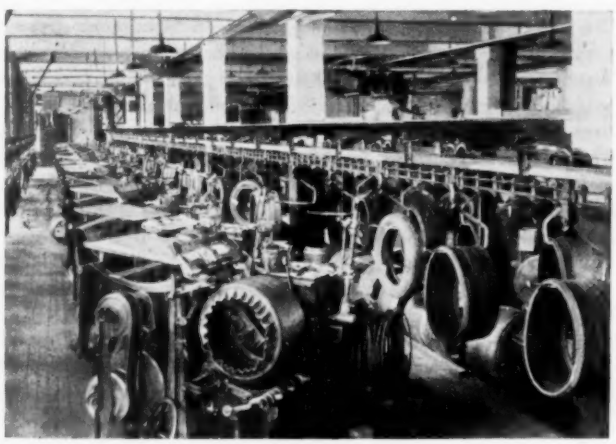

Fig. 3 One Section of the Tire Room
(On the left, the conveyor carrying the cut materials to the tire machines and on the right, the uncured, finished tires being taken away to be cured.)

as the name implies, the tread section of the tire and is formed by a calender in a continuous strip. Until a comparatively few years ago no attempt was made to link the tread-calendering process to any of the operations that directly preceded it, such as the mixing of the stock, or to any of the operations that followed it, such as the weighing of the treads and cutting them to an exact length. In other words, in order to produce the tread, from the mixing of the stock to the finishing of the tread to length and weight, three separate groups of operators or departments were required. Improved materials-handling methods were installed a few years ago which tied these three groups together, so that now the process is continuous and considered as a single departmental function.

The whole first floor in one of the main buildings was laid out so that it was possible to compound the stock, mix it, feed it directly to the calenders, cool the treads, weigh them, and cut them to a finished length. To do this four Banbury mixers were installed in such a way that the batches of pigment and rubber could be assembled on a conveyor and then fed directly to the mixers without any intermediate trucking. This conveyor is a combination of two types—pallet and roller gravity. It forms a rectangle about the Banbury mixers. The pigments and rubber are weighed out in batches and placed in boxes on one side of this rectangular conveyor system. This side of the system is at floor level and is a gravity conveyor. Boxes are carried by a pallet conveyor up an incline to a roller gravity section which runs parallel to the loading section at floor level and along the feed openings of the Banbury mixers. By using a roller gravity section here a small bank of batches can be kept ahead of the operator who unloads the boxes into the mixers. This section being on a higher level on account of the height of the mixer's feed openings makes it possible for the operator to easily return the empty boxes to the loading conveyor by

Fig. 4 Conveyor System in the Curing Department

merely shoving them down a sloping gravity conveyor section. In other words, the boxes make a complete circle of the Banbury mixers on the conveyor, being loaded on one side and emptied on the other without necessitating their removal from the conveyor system.

After the stock is mixed, it is conveyed directly from the outlets of the Banbury mixers to a series of blending and feed mills by means of belt conveyors, and from there carried to the feed of the calenders.

The calenders form the treads, which are then conveyed in continuous strips through the cooling tanks to shrink the stock. The strips, after leaving the cooling tanks, pass over continuous weighing scales in order to be certain that they are within the proper weight tolerances, and are then conveyed through automatic cutters, which cut them on a bevel to the proper length. The treads are then taken from the belt conveyor and piled on what is called a book truck. This is a live platform about 10 ft. by $3^1/_2$ ft., on one side of which is a steel frame $4^1/_2$ ft. high. This frame supports rods upon which cloth leaves slide, as they do in a loose-leaf binder. This truck is provided with 100 leaves, which give it a capacity for 200 or more treads. The leaves are used to keep the treads from sticking together. This truck thus serves as a means for storage as well as transportation. These trucks are hauled to the storage place adjacent to the feed conveyor of the tire-building units.

Due to the fact that the rate of productions of the tread calenders and the tire machines respectively are not the same, it is necessary to maintain a few hours' bank of material. Here a mobile bank, such as these trucks afford, proves very satisfactory.

This improved method of handling treads, together with the

mechanical improvements, practically wiped out a Tread Cutting and Weighing Department. At the same time it reduced the inventory of stock to a fraction of what was previously maintained and reduced the unit cost of calendering the tread about 38 per cent.

The foregoing description gives one who is not familiar with the tire plant very little idea of what has actually been accomplished in the improvement of handling conditions in the Milling and Calendering Departments. When the plant was handling as high as six or seven million pounds of mixed stock per month, it was not uncommon to have more than 800,000 lb. of mixed stock either in the Stock Storage Department or in transit. Under present conditions, even though the production tonnage is at times higher than in the past, about 300,000 lb. is considered normal. With compounded stock costing on an average over a

FIG. 5 CONVEYOR SYSTEM IN THE TIRE FINISHING AND INSPECTION DEPARTMENT

period of years around 30 cents per pound, it is quite evident that the interest charges on this first-mentioned inventory would amount to a considerable figure. The handling costs were tremendous in comparison with the present conditions.

STOCK-PREPARATION DEPARTMENT

As previously mentioned, the coated fabric after it leaves the calender is transported in rolls to the fifth floor, where some of it is cut and some stored, to be cut later on the fourth floor. This department is generally termed the Stock-Preparation Department, and is the department where the stock is cut to various lengths and widths for final assembly in the tire. It contains cutting machines of various types and also equipment for making bands containing two plies of tire fabric, one ply being laid diagonal to the other. A considerable amount of handling of rolls is required in this department to and from the cutting machines and also to and from the band-building machines. In order to facilitate this handling there has been developed an electric truck[1] with a large scoop which is capable of picking up and unloading these heavy rolls very easily. The scoop has an elevating attachment so that it makes it possible to deposit rolls in the supports of the machines regardless of their height or, if necessary, to place the rolls upon the floor or pick them up either in a vertical or a horizontal position.

[1] A product of Elwell-Parker Company, Cleveland, Ohio.

TIRE-BUILDING DEPARTMENT

Most of the material from the Stock-Preparation Department is carried in spools on conveyors directly to the tire builders. There are four conveyors, each about 300 ft. long, running between the Stock-Preparation Department and the Tire-Assembly Department. These conveyors run parallel to the tire machines on the floor below. They are provided with hooks that carry the treads and also the spools containing the tire bands, chafing strips, and padding and breaker combinations. There are a sufficient number of these hooks on the conveyors to provide for a bank of material so that delays will not arise from an insufficient supply or from the normal irregularities in production which exist between the two departments.

The installation of a conveyor at this stage of the process—namely, between the Stock-Preparation Department and the Tire-Assembly Department—not only reduced the materials-handling costs but also tended to insure a fresh supply of stock for the tire builders. This is a condition of considerable importance in a tire plant. Uncured rubber tends to bloom and lose its adhesive characteristic if allowed to age too long before vulcanization. Dry stock, as it is called in the industry, is liable to result either in higher building costs or in a poor product.

In the tire room there is practically no trucking of materials. As previously mentioned, the materials for assembly of the tire are conveyed to the tire builders on conveyors running parallel to the various lines of machines. Along the rows of these machines, running parallel to the feed conveyors, is located another chain conveyor for carrying the uncured finished tires away from the builders directly to the Curing Department, which is located on the first floor. This conveyor is 2800 ft. in length. It is a standard chain type, capable of moving in two planes, thus allowing it to pass by the various tire-building units and also by the inspection point before it drops to the heater room, where the tires are unloaded at two different points.

In years past it was common practice to transport the various materials from the Stock-Preparation Department to the Tire Department on dead platforms and also to transport by means of platforms and electric trucks a big portion of the tire production from the building machines to the Curing Department. The installation of these conveyors eliminated this trucking cost.

CURING DEPARTMENT

The Curing Department, as just indicated, is the next step in the tire process. The tires, after they are taken from the conveyor, are dusted and shaped, providing they are not already built to shape, and airbags are inserted. An airbag is like a heavy inner tube, in which pressure is applied during the vulcanization of the tire, the tire being forced against the mold by this pressure, thus forming the tread design and the lettering which normally appear on the finished tire. When the airbag is inserted, the tire is ready for the mold.

In order to handle the molds, which weigh on an average 600 to 700 lb., to and from the vulcanizers where the tires are cured, a rather elaborate conveyor system has been installed. It might be mentioned here that a vulcanizer or heater is a deep cylindrical tank on the bottom of which is a ram used for loading purposes and also for pressing the molds together during the vulcanization period. When these heaters are loaded with molds and the cover is on, steam pressure is applied, which, together with the internal air pressure on the airbags, brings about the vulcanization of the tires. These heaters are arranged in rows containing from 18 to 24 units, parallel to which runs one side of a rectangular conveyor system. There are four complete systems in this department. Each conveyor system is really a set of pallet conveyors of heavy steel construction.

As just mentioned, the heaters lie along one side of the rectangular conveyor system, and on the side opposite are located the various workmen who open the molds, strip the cured tires from them, and reload them with raw tires. The upper halves of the molds, for part of the distance along the loading section of the conveyor, are carried overhead after having been broken free. They are finally brought down into their proper position over the lower halves after the tires have been inserted. The loaded molds are then carried by the pallet conveyor to whichever heater is being filled. On this pallet conveyor are located presses for closing the molds tightly previous to their being deposited in the heaters. There are also spraying devices which spray a coat of lubricant on the inner surface of the mold in order to make it possible to easily remove the tire at the end of the curing process. The conveyor thus serves not only to convey the tire to and from the heaters, but it also becomes an integral part of the process of curing the tire. After the tires have been cured they are carried on a chute to the bag-pulling machines, and from there are conveyed to the Inspection Department on vertical lift chain conveyors.

This description is necessarily brief, but it suffices to show that the problem of materials-handling in curing a tire is of tremendous importance. The installation of these conveyors reduced the cost of curing a tire about 30 per cent, and at the same time considerable saving in space was made.

This conveyor installation is so important to the process that any breakdown in equipment disrupts production in this department completely. In order to avoid this possibility a weekly inspection of every part of the conveyor is made, and periodically, about on an average of every four or five years, the chain is completely replaced. Systematic check and replacement of worn parts have made breakdowns extremely infrequent in spite of the fact that these conveyors have been in operation for over 12 years.

The conveyors are not the only material-handling units in the Curing Department. When the raw tires are taken off the conveyor from the tire room, they have to be sorted according to size for the various groups of molds that are in the heaters. This necessitates a bank. It has been found through experience that it is advisable to maintain here a movable bank. In order to do this, a truck was developed upon which about 80 tires can be stored. At the same time it can be readily pushed from the raw-tire conveyor to the storage point and to and from the tire-shaping machines. This truck might be termed a "tree" truck in that it has a steel structure supporting a number of arms upon which the tires are hung.

Inspection and Tire-Finishing Department

The Inspection and Tire-Finishing Department follows the curing of the tire. The tire is carried from the heater room on vertical lift conveyors. Although there are several outlets to the main curing units, they all converge at one place in the Inspection and Tire-Finishing Department, which is located on the fourth floor of the building, and which is the floor most advantageous for conveying the finished tires to the storage building.

Until a few years ago the Inspection Department contained mainly dead platforms loaded with tires and tables upon which to trim and inspect them. There were no conveyors used except one to carry the tires to the storage building. It is necessary in this department to trim from the tire the mold overflow, balance it, inspect it, paint the tire completely, and also paint the trade mark upon the tire. In order to carry the tire through the various operations and not encounter delays, a series of belt conveyors and live-roller conveyors were set up parallel to each other. Between these conveyors are placed various groups of workers required to perform the aforementioned operations. Two of these conveyors are double-decked in order to save space, the lower conveyor being used for incoming tires and the upper conveyor being used for conveying away tires upon which the operations have been completed. The live-roller conveyors, which are always the feed conveyors to the operators, allow the tires to bank up, so that at all times the workers have tires available. At the completion of the last operation, which happens to be the trade-mark painting job, the tires are then carried on a chain conveyor to the operators who sort the tires for the wrappers. The sorters place these upon small steel round-top platforms. About 16 tires can be piled on one of these platforms. Due to the fact that they have four casters, they can be readily pushed about. The actual dimensions of one of these platforms are $6^5/_8$ in. high and 40 in. diameter at top. These platforms can be stacked in a very small space when not in use. This is another case where the material storage is also movable, a condition which is generally found to be desirable in a tire plant. The tires are taken from these platforms and wrapped, and from there are carried on a belt conveyor to the storage building.

Aside from a considerable saving in space which was made by the installation of this material-handling system, about 10 per cent labor saving was made in this department at the time by the installation of this system. The cycle of operation is reduced considerably, so that now a tire comes out of the mold and is wrapped within an hour.

Inner-Tube Department

The preceding description was confined to the manufacture of tires. The Fisk plant also manufactures a large number of inner tubes. Here again it has been found possible to make a saving by improvement in the materials-handling methods through the installation of conveyors and the development of movable storage trucks.

The standard method of making raw tubes in the Fisk plant is by means of extruding or tubing machines. As in the case of the tread job, formerly it was the practice to extrude tubes on to a short conveyor and transport them to a unit where they were weighed and cut to length and where the valve pads were applied. They were then transported to a splicing unit, where the ends were united, and from there were trucked to molding machines.

A new layout was evolved which tied the warming mills by means of a belt conveyor direct to a tubing machine, feeding the latter a continuous strip of rubber. A conveyor system was then built from the extruding end of the tubing machine which carried the tube over an automatic weighing scale and through a cooling tank, where the tube was shrunk, and then through a drier, and then to a device for marking the tube to length, and, finally, through a machine for pressing the valve pad into position. The tube is then cut to length and the valve hole punched. In other words, by the development and installation of special mechanism on this conveyor system a series of operations were tied together, eliminating the trucking and considerable manual handling that previously existed. The inventory of the tubes was reduced, and a considerable labor saving amounting to about 15 per cent on the afore mentioned operations was made.

In the past the means of storing tubes after leaving the tubing-machine line were unsatisfactory in that the ordinary types of trucks lacked adequate capacity. Recently, however, a truck[1] has been developed which is somewhat like the tread truck, but it has metal leaves or shelves instead of fabric leaves. As many as 200 tubes can be stored on such a truck, and on ac-

[1] A product of Economic Steel Rack Company, Everett, Mass.

count of the fact that each shelf is self-supporting and does not rest on the tubes underneath it, there is no danger that the tubes will be deformed or their walls pressed together. These trucks are also movable and can be easily hauled from the tubing machine lines to the splicing-machine units.

Handling the tubes between the raw splicing units and the tube molds has not been worked out to complete satisfaction. At present, however, tubes are transported between these two units on light steel trucks which look somewhat like book racks, the spliced tubes being placed upon the shelves.

After the tubes are cured they are placed by the operator directly on a chain conveyor which runs to the floor above, where the tubes are tested for leaks and finally inspected. This conveyor also passes by a group of operators who apply the washer and nut to the valve stem and tighten it down. On account of the fact that it is necessary to make this conveyor pass by three lines of tube molds and also the line of valving operations, just mentioned, it is a conveyor of considerable length, amounting to about 900 ft.

The finished tubes are taken from this conveyor and are carried through a water tank to be tested for leaks. From there they are put on a chain conveyor which carries them through a drying oven, and then by a group of operators who deflate the tubes and inspect them. The tubes that pass this inspection are placed upon a belt conveyor which carries them to the boxing operators. A break in the system is made here in order to sort the tubes according to style and size for the boxers. The boxing is done alongside a belt conveyor where can be located trucks of tubes and boxes. This conveyor carries the boxed tubes directly to a point where they can be placed in carbons and sealed. In other words, all trucking between the tube curers and the assembly of the tubes in cartons is eliminated except for a brief sorting period at the end of the tube-inspection conveyor. The saving made by the installation of these conveyors has amounted to a fairly large portion of the manufacturing cost of the tube. Previous to their installation several operators were required to transport the tubes on trucks between the various operations. By the use of conveyors the efficiency of the various producing units was improved. This was especially noticeable in the case of the tube inspectors. Approximately 14 per cent reduction in labor cost was effected on this operation. In addition to these savings there was a considerable reduction in punctured tubes, which ran high under the old method, where a great deal of handling was required. At the same time the inventory of tubes in process was reduced.

The preceding description covers briefly the main course of production of tires and tubes in the Fisk plant. There are other articles manufactured, such as flaps, sectional airbags, and rubber articles associated with tires. Improvements in their handling methods will not be discussed in this paper.

General Observations

One might judge from the preceding descriptions of handling methods that practically all the improvement in this direction was made by the installation of various types of conveyors. It is true that conveyors were responsible for most of the improvement in the handling methods, but there were many instances in the last few years where improved types of trucking equipment have accounted for a reduction in cost.

In spite of the fact that every effort is made to carry the product through the plant without interruption, there are many occasions where it is necessary to remove it from the regular producing lines either for some operation or for inspection. Then again there are places in the tire processes where it is necessary to maintain banks of materials in order to eliminate delays between operations. In such cases it has been necessary to develop trucks to store these materials and at the same time to transport them. As was mentioned in the case of the Tube Department and the Tread Department, there are many other instances where a mobile storage truck was invariably found to be better than stationary storage equipment.

Records show that there are 115 various types of trucks used in the plant. A great many of these trucks are built upon a standard type of platform. Standardization, in so far as parts and casters are concerned, is carried as far as possible. Maintenance alone on these trucks is an item to which it has been found necessary to give considerable attention. The same maintenance men are always assigned to work on repairing them; consequently, their increasing skill and knowledge of the equipment results in decreasingly lower costs.

The manager of the Trucking Department makes a special point of constantly calling the attention of the production supervisors to the damage that is being done to trucking equipment by their operators. Obvious abuse is traced down, if possible, to its source. Efforts along these lines have resulted in a reduction of 33 per cent in trucking-maintenance cost since 1925.

It was rather difficult to obtain figures in regard to the amount of money that actually was saved by improvements in materials-handling methods in the last few years. In many instances improved materials-handling methods not only made a reduction in trucking costs, but also reduced the direct labor cost of building the tire and improved its quality.

In some instances certain conveyors acted as pacemakers for the operators who were fed by them. A constant regular flow of material apparently tended to iron out the previous tendency to produce at an irregular rate of speed. Higher production figures resulted. Then again it was found possible, as in the case of the Tread Department and the Tube-Extrusion Department, to make the conveyor an integral part of the process, thus contributing to a lower labor cost over and above that which would normally be made by merely eliminating the trucking.

There are some figures, however, that can be used for comparison, such as the trucking cost for the years 1924–25 with the present cost. It was found that the present trucking cost per 1000 lb. of mill-room production is one-half of what it was during the years of 1924–25. This is a fact of considerable importance because during the period of 1924–25 the trucking cost, including the labor cost of operating elevators, amounted to approximately $200,000 per year. It is probably safe to estimate that this saving of approximately $100,000 per year would actually be doubled if all the other items of saving that were brought about by improved handling methods could be segregated.

In spite of the tremendous savings that were made in the Fisk plant in materials-handling methods during the last four or five years, the possibilities of further improvement are far from being exhausted. Tremendous strides have been made, but it is safe to assume that in the next five years improvements quite comparable to the last five years will be accomplished.

MH-53-4

Handling Materials at the Postum Company

By P. P. PRATT,[1] BATTLE CREEK, MICH.

This paper offers a discussion of various types of conveyors in general use, together with descriptions of a few specialized conveyors. Practically every phase of manufacturing at the Postum plant embraces operations performed on the material in course of handling—especially is this true of modern automatic packaging machinery, referred to in this article. An enlarged section treats with the operation and mechanical details of the "intercommunicating pilot-car package-conveying system," used as a connecting link between shipping points. This system automatically handles a wide variety of cased products and offers selective loading at each of four shipping points. It has effected quite considerable economies and has made it possible to utilize widely separated storage spaces, more or less as a unit.

THE production of food was man's earliest occupation, but the handling of materials in quantity was not a very serious problem. Today it is a problem of major importance in practically every industry. The food industry is no exception.

To meet the demands of the consuming public, a food must be clean and made under conditions of scrupulous cleanliness—even more so than exist in the average home. It must have an appeal, both to the taste and to the eye; it must be uniform in quality and packaged in an attractive container, with every safeguard taken to prevent deterioration either by absorption of moisture or contamination with insect pests; and, last of all, it must be sold at a popular price.

The development and growth of the cereal-food industry would not have been possible without automatic packaging machinery of various kinds, which made possible the rapid handling and packaging of the manufactured product, with a minimum of labor and handling of the food itself.

Similarly, the development of special machinery, made necessary by the growth of the business, has insured the rapid handling of materials and manufactured product under increasingly clean and uniform conditions, resulting in the high-quality product that exists today.

Proper handling of materials governs three very necessary factors of food manufacturing:

(*a*) Quality, which is accomplished by mechanical handling that regulates the flow of materials to produce the uniformity necessary for rigid quality standards.

(*b*) Cleanliness, which means the absence of human handling, that is replaced by mechanical handling, with special alloy equipment wherever food in process is contacted.

(*c*) Continuity of production, which insures that the manufacturer can produce a maximum quantity of the product with a minimum of material in process.

Before considering the details of equipment for materials handling, the five products made at the Battle Creek plant of the Postum Company, Inc., should be enumerated. They are: (1) Postum Cereal and Instant Postum; (2) Grape-Nuts; (3) Post Toasties; (4) Post's Bran Flakes; (5) Post's Whole Bran.

There are seven distinct classes of materials to be handled in the processes. These are:

(1) Grains—corn, wheat, and malted barley in bulk.

(2) Sacked materials—wheat, bran and dairy feed ingredients such as oil meal, cottonseed meal, and gluten meal.

(3) Flavoring materials—sugar and salt in bags, and syrups in barrels and tank cars.

FIG. 1 ORIGINAL PRODUCTION UNIT, THE LITTLE WHITE BARN, WITH NO CONVEYING PROBLEMS

(4) Products in process of manufacture and packaging.

(5) Products packed in fiber and wood cases for domestic and foreign shipment.

(6) Paper and boxboard materials for the manufacture of cartons and cases, together with handling to packing departments.

(7) Paper and wax stocks for manufacturing the protective wrappings characteristic of Post products packages.

MATERIALS HANDLING

The handling of grain is the foremost consideration in maintaining a proper standard of quality. To the uninitiated, corn is either white or yellow, and all wheat is either red or white. It is a fact, however, that there are several varieties of corn, together with some 60 varieties of wheat—only certain varieties and grades of these are suitable for the manufacture of Post products. By means of a number of storage tanks for grain, it is possible to segregate the various grains and blend these properly. Postum's grain-handling and storage equipment,

---

[1] Engineer, The Postum Co., Inc. Mr. Pratt is a graduate of Massachusetts Institute of Technology, 1923. Basic experience was gained in a two-year factory apprenticeship working through the departments of the Postum Company plant. For the last five years he has had charge of experimental work, especially with reference to changes and improvements in manufacturing processes and equipment.

Contributed by the Materials Handling Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

about a million-bushel capacity, is sufficient to provide raw material for 30 days' production. Sometimes grains contain relatively high moisture and develop "hot spots." The tanks are equipped with electrical temperature recorders that indicate the temperature every 5 ft. for the full 90 or 100 ft. depth of the tanks. To save heated grain, it is necessary to draw out the hot portion of the grain, aerate, and rehandle to a cool tank. Equipment is available to perform this operation with elevators and screw or belt conveyor at a rate of 6000 bu. per hour, in addition to unloading many cars of grain each day.

Sacked materials such as wheat bran present a very simple handling problem. For this raw material Postum depends upon controlling the supply to maintain a small but adequate storage and insure that it is fresh and sweet from the milling processes. Sacked material is stocked either on portable skids or in low piles and arranged to be used in stock rotation, i.e., oldest stock first. Since blending is performed at the flour mill, there is little necessity for blending at the plant. Dairy-feed materials are purchased in 100-lb. bags, combined with by-products of the food processes to govern the proteins, fats, and carbohydrates, and serve as an outlet for waste foods.

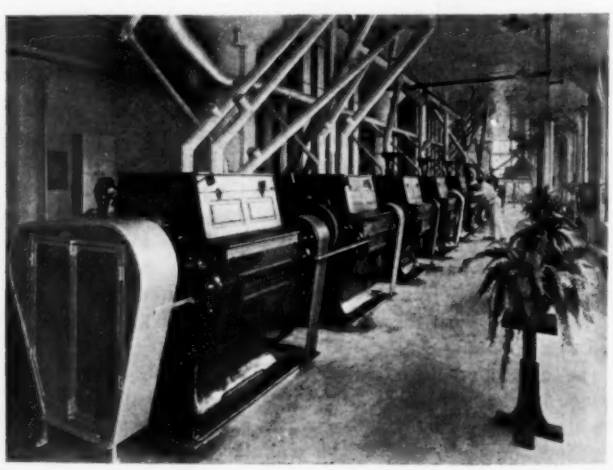

FIG. 5 MILLING WHEAT AND MALTED BARLEY FOR GRAPE-NUTS
(The material flows by gravity to and from the mill.)

Flavoring materials are a very important adjunct to the cereal-food industry. Sugar and salt are bagged products, of course; these are handled from the car by lift trucks and stored in the buildings on skids. Malt syrup is received in barrels and stored in cool areas, thence handled into process by barrel trucks. (See Fig. 3.) Sugar-cane molasses is received in tank cars, piped to specially constructed concrete tanks, thence pumped to process mixers for flavoring wheat bran before roasting for Postum Cereal.

Practically every step of the several processes involves the handling of materials. The essential operations of cooking (see Fig. 4), cooling, drying, flaking, toasting, and packing are performed on the materials in transit; in fact, only a few hours elapse between the time when corn hominy or bran enters the process and when it is passing into freight cars, as flakes. In milling corn to produce flaking hominy, it is continually moving through degerminators, reels, driers, coolers, rolls, aspirators, oil expellers, attrition mills, and sifters until all grades of flaking hominy, table hominy, cones, cornmeal, flour, corn oil, and

hominy feed have been derived from the original kernel of corn.

The processes of producing Grape-Nuts, including milling of flours (see Fig. 5), mixing, baking, drying, grinding, sifting, and packing, are operations performed upon the material in transit. Probably the most complete system of mechanical handling is evidenced at the Grape-Nuts bakery. Blended flour is conveyed from storage bins, weighed in hopper scales, and dropped into mixers; similarly, salt, yeast, and water are added in measured quantities. After mixing (see Fig. 6) for a predetermined period, the mixer is automatically stopped,

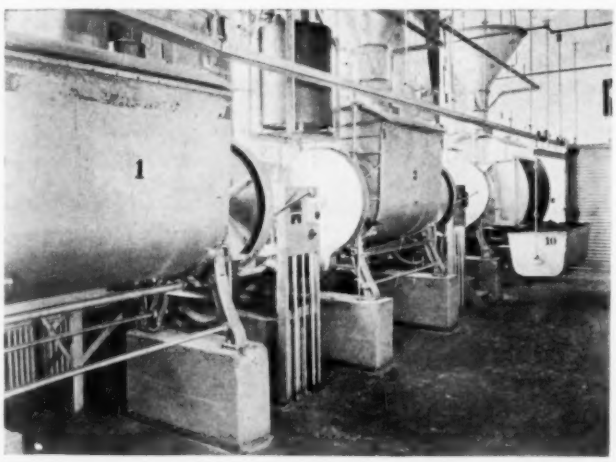

FIG. 6 DOUGH MIXERS, PREPARING GRAPE-NUTS FOR THE BAKING PROCESS

(The material is fed to the mixers by gravity; the finished dough is conveyed from the mixers in tubs on a monorail track.)

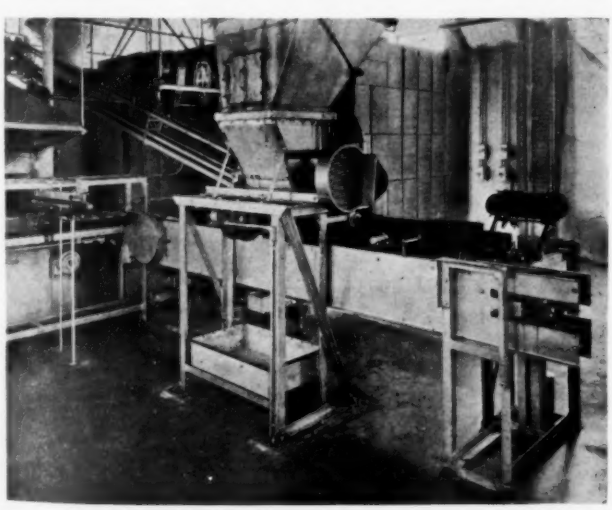

FIG. 7 AUTOMATICALLY FEEDING LOAVES OF GRAPE-NUTS DOUGH INTO THE OVEN

(Pans are sprayed automatically with grease while in transit, are turned over, and then filled with dough by an automatic feeder, and conveyed to the oven.)

electrically operated doors open from the raising room, and a dough tub traveling on a monorail track is placed in position to receive the dough. (See Fig. 6.) Pressing a button tips the mixer and discharges nearly a ton of dough into the tub, which is then guided to a position in the rising room to remain for a definite period of time under regulated conditions of temperature and humidity. After a proper interval for yeast action, the batch is positioned over a hopper, and dough is dropped into molding machines. Here it is automatically divided into loaves and dropped into baking pans at a rate of eight loaves per minute for each of three baking units. (See Fig. 7.)

FIG. 8 DELIVERY END OF CONVEYOR-TYPE OVENS BAKING GRAPE-NUTS LOAVES

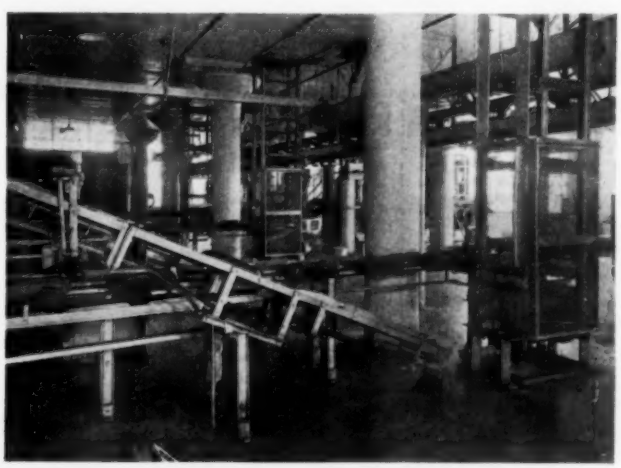

FIG. 9 GRAPE-NUTS LOAVES ON DROP-SHELF CONVEYOR, TRANSFERRING TO ELEVATOR

(Note the pan-conveyor timing and detecting devices.)

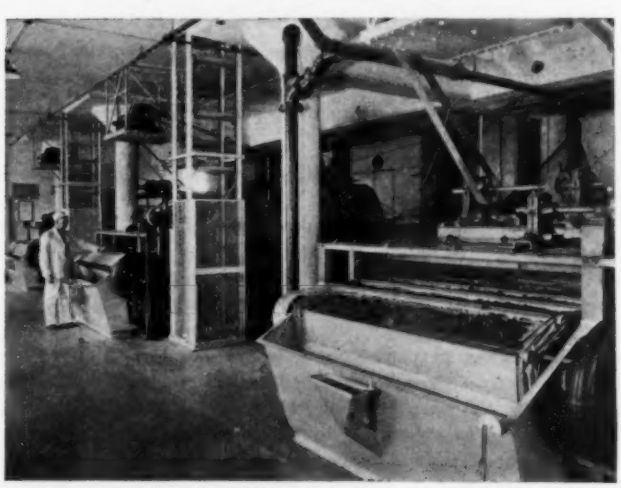

FIG. 10 CONTINUOUS CONVEYOR SECONDARY OVENS, PRODUCING GRAPE-NUTS TO BE GROUND AND PACKED

Baking pans are conveyed from the discharge end of the oven by a drag conveyor, to be passed through a spray greaser that covers the inside of the pan with a thin film of vegetable oil. Pans are timed to receive a loaf of dough from the divider, then pass to the oven inlet, where they are automatically arranged and fed into the oven in rows 17 pans wide. These ovens are of a conveyor type of traveling hearth with temperature and humidity automatically controlled to produce uniformly baked, golden-brown loaves.

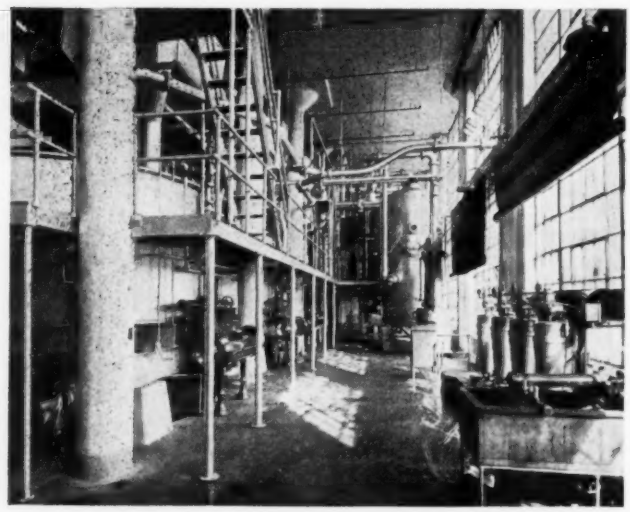

FIG. 11 PERCOLATORS, CLARIFIERS, AND EVAPORATORS PREPARING INSTANT POSTUM

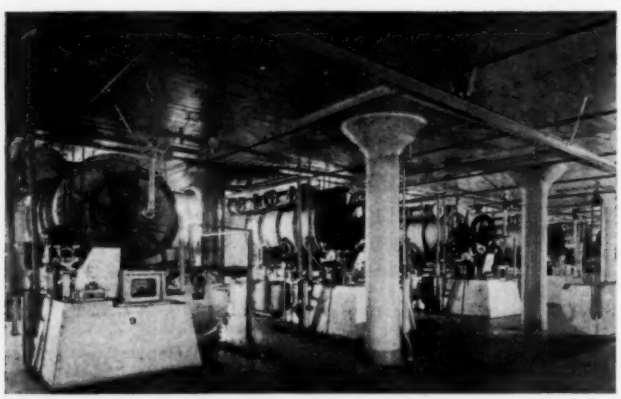

FIG. 12 VACUUM-TYPE DRUM DRIERS PRODUCING INSTANT POSTUM TO BE GROUND AND PACKED

(Liquid is supplied to the driers through pipe lines. The finished product is transferred from the driers to the grinding department on monorail tracks.)

Grape-Nuts, in the freshly baked state, are quite soft; hence it is necessary to handle the product manually and to inspect each loaf—overbaked portions, of which there is a very small amount, must be set aside to be trimmed. (See Fig. 8.) A loaf is removed from the pan and inspected, then placed on a drop-shelf type of conveyor, passed through a counter and transferred to a specially designed bucket elevator, where it is conveyed to the sixth floor for breaking and secondary baking. (See Fig. 9.) The shelf loaf conveyor is arranged to signal the inspector should a pan happen to lodge on the loaf conveyor—this is a protection to prevent a metal pan getting into the loaf breakers. Baking pans are inverted and placed in a magazine-type conveyor that automatically synchronizes these pans to be conveyed to the inlet end of the oven for receiving the unbaked loaves. An electrical device signals the inspector if two pans are together or if a pan is missing from the conveyor.

Returning to the loaf elevator, an automatic trip is arranged to distribute loaves alternately between two breakers that spread the broken particles of bread over a wide belt and deliver into a conveyor secondary oven. Food passes over eight conveyor flights designed to handle relatively soft, moist particles within the first half and smaller dry particles within the other half. The last conveyor section moves the food before an inspector, who is charged with responsibility of color and quality; this inspector can control the flow of food to reject all or a portion, if not up to standard. (See Fig. 10.)

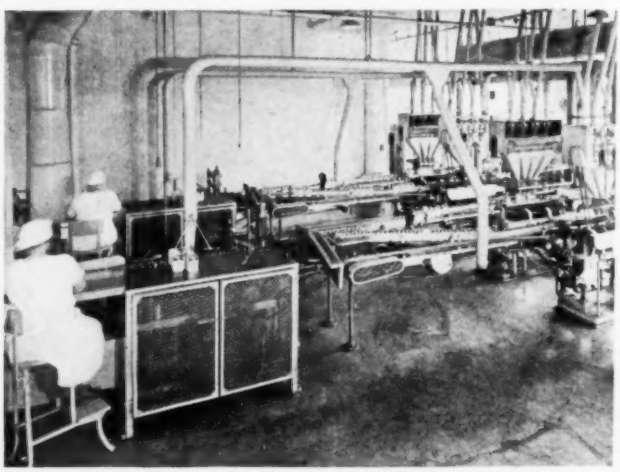

FIG. 13 FILLING AND INSPECTING CANS OF INSTANT POSTUM

(Food is supplied to scales and then to cans by gravity. The cans are filled in transit, the caps are applied automatically, and then the cans are transferred to packing tables.)

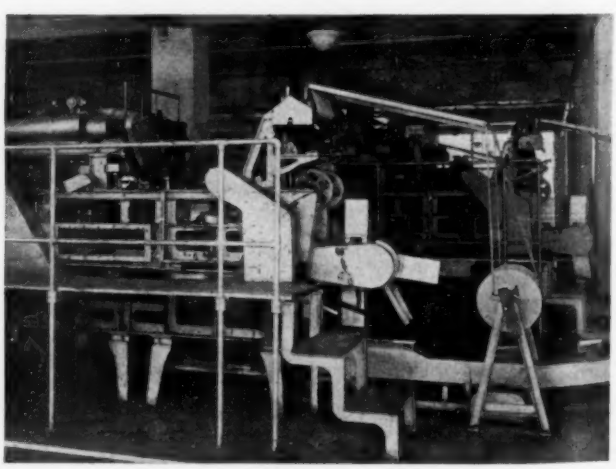

FIG. 14 CARTON-LINING MACHINE FOR POST TOASTIES

(All materials are assembled and the cartons are formed in transit.)

A troughed belt conveyor gathers finished baked cereal from three ovens and distributes this to reserve bins for grinding, sifting, and packaging.

Postum and Instant Postum are handled by machinery at all points of the roasting, blending, percolating, clarifying, evaporating, grinding, sifting, and packing operations; at no point in the process is it necessary to handle the food manually. (See Figs. 11, 12, and 13.)

In handling a vast number of identical units for 24 hours

each day, there are wonderful opportunities to develop special handling equipment. Post Toasties involves a production of more than five hundred thousand packages per day. Previously, it was necessary to place the carton on a block, glue the bottom, place paper sacks within the box, and hold these sacks beneath the filler spouts. Modern lining machines cut the proper size of sack paper from a large roll, form and glue this sheet into a sack on a moving block conveyor, remove one unglued flat carton blank from a magazine, convey this to the proper location, synchronized to meet the block carrying the made-up sack, then form this carton around the sack-covered block, glue the side seam and bottom of the box, as well as the liner to the inside of box. (See Fig. 14.) The finished box ready to receive food is dropped to a short conveyor, filled with flakes, tested for full measure, the sack is folded, closed, and top sealed. (See Fig. 15.) At this point it leaves the machine to be conveyed to an automatic wax wrapper, where a protective covering of wax paper, characteristic of Post Products, is placed around the package and sealed moisture-tight. This operation is an interesting example of handling, for a proper sized sheet of waxed paper is cut off a roll and conveyed to a position over the package "well." Paper is timed to arrive just as a package

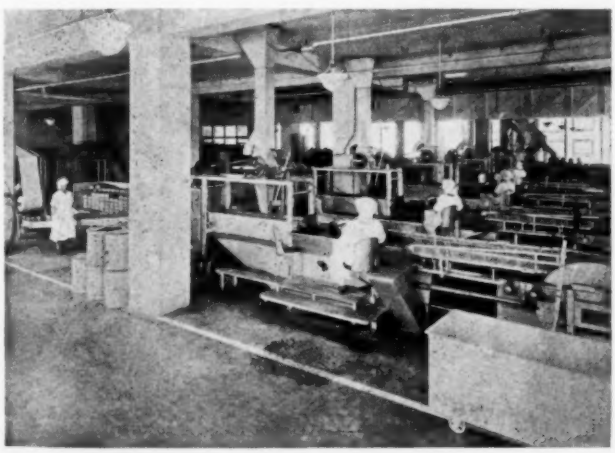

FIG. 15 FILLING AND INSPECTING PACKAGES OF POST TOASTIES WHILE BEING CARRIED ON BELT CONVEYOR

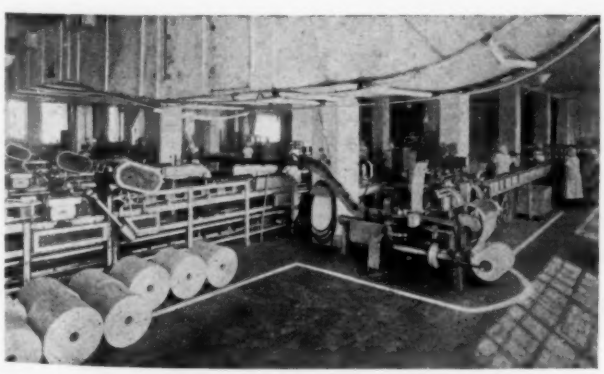

FIG. 16 SEALING, WAX-WRAPPING, AND PACKING POST TOASTIES WHILE ON BELT CONVEYORS

is being elevated through this "well," and it is literally enveloped by wax paper. While the package and wrapper are in motion, the trailing edge of paper is tucked beneath the leading edge at the side of the well, the ends are folded by a mechanical thumb and finger, and the paper is sealed by passing first over electrically heated hot plates to melt the wax contained on the paper, then over cold plates to set the seal. (See Fig. 16.)

The finished wrapped package is conveyed to packers who place the required number in cases and push them on a conveyor to be sealed and conveyed to the shipping floor. (See Fig. 17.) Within one of the departments automatic packing has been used successfully; a girl places the case in the packing

FIG. 17 CASES OF POST TOASTIES CONVEYED FROM PACKING LINES TO SHIPPING FLOOR BY BELT AND GRAVITY

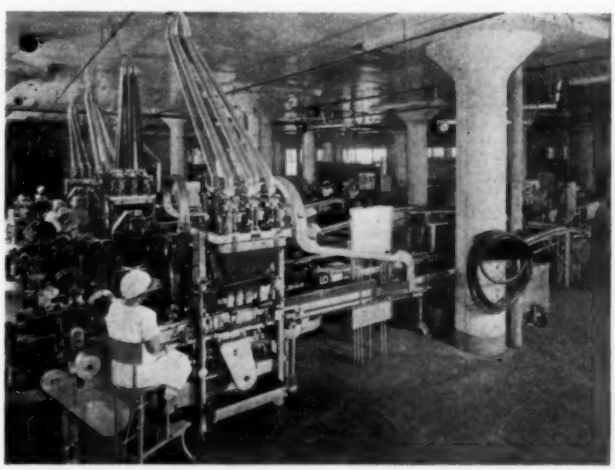

FIG. 18 FULLY AUTOMATIC HANDLING OF CARTONS TO PACK GRAPE-NUTS

machine, the packages are automatically inserted, and the case is transferred to the sealing conveyor.

Other types of packaging that do not require sack liners employ a small and compact machine to produce these units. Folded cartons are fed from a magazine by a mechanical finger and held by vacuum cups to a turret-type cam conveyor that transfers the folded cartons to a second turret conveyor, where cam-operated fingers grasp the cartons, force them open, and place them upon moving forms. The cartons pass beneath glue rolls and pressure belts to form boxes ready to receive food. Arriving at a point directly beneath a chute, a jet of air sweeps the box in an arc to the other side of the machine, where it lands open end upward to be conveyed beneath scales and receive the correct amount of cereal. Each box is checked for quantity and automatically rejected if not properly filled. Tested packages are conveyed beneath the glue rolls and pressure belts once more, where tops are sealed, then conveyed to

wax wrappers and packers. Each one of these machines will handle nearly one hundred thousand packages in 24 hours. (See Fig. 18.)

Products packed in fiber shipping cases involve a specialized system of handling equipment that is elaborated upon at the end of this paper.

Paper and boxboard material for cartons and cases are received at the west end of the plant; this moves steadily east-

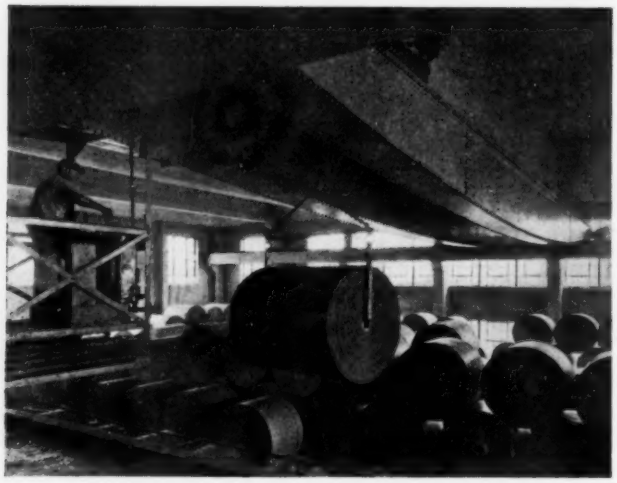

FIG. 19 HANDLING ROLL PAPER READY TO BE MADE INTO STOCK FOR SHIPPING CASES

FIG. 20 PRESSES PRINTING CARTONS AND DISCHARGING TO PORTABLE HANDLING TRUCKS

ward during the processes of board making, printing, cutting, and stitching or gluing; thence to receive finished products in the packing departments. In addition to packing materials for Post Products, this department furnishes cartons and cases for many other divisions of General Foods. There are many interesting examples of materials handling in this department, including traveling cranes to handle heavy roll stock (see Fig. 19); machines that print two colors, (see Fig. 20) as well as cut and crease shipping containers (see Fig. 21); a machine that glues the side seams of Jell-O cartons at a rate of one million per day (see Fig. 22); and cutting machines that cut and crease as many as twenty million cartons with one set of dies (see Fig. 21).

Handling materials for waxed wrapping paper involves the movement of heavy loads by special trucks and traveling chain-hoist cranes; similarly these materials and the finished product must be handled under exact conditions of heating and cooling; in fact, this situation is generally confronted in all departments of the plant. Reliance is placed almost entirely

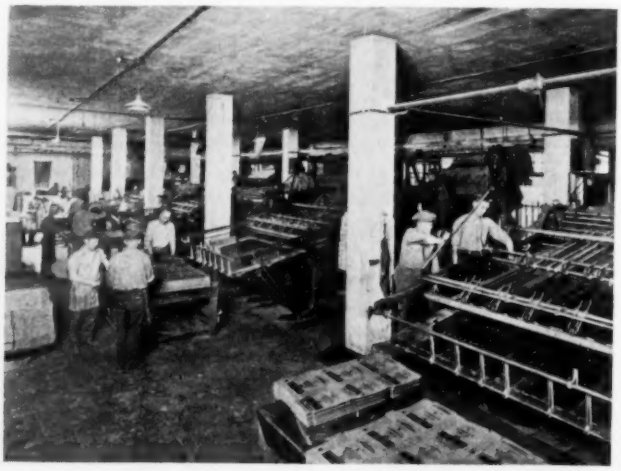

FIG. 21 CUTTING AND STRIPPING CARTONS, MANUAL HANDLING TO PORTABLE PLATFORMS

FIG. 22 GLUING CARTONS, WHICH ARE HANDLED ON BELT CONVEYORS

FIG. 23 LIFT TRUCKS FOR HANDLING CARTONS AND CASES

upon automatic control of temperature and humidity to govern manufacturing conditions. (See Fig. 24.)

HANDLING CASED PRODUCTS

When Mr. Post started to make Postum in the little white

barn on the site of the present plant, he little realized the extent to which the business would develop. As business grew, buildings were constructed, generally hurriedly, to take care of the phenomenal demand. Thus the plant expanded along the hillside orchard, and its location became quite firmly established. Although the site was far from ideal and the general contour of the land made it practically impossible to develop a plant with several distinct operating units grouped about a central warehouse, it is fortunate in that two large railroads are adjacent to company property and good railroad facilities are provided. Moreover, the products are generally bulky

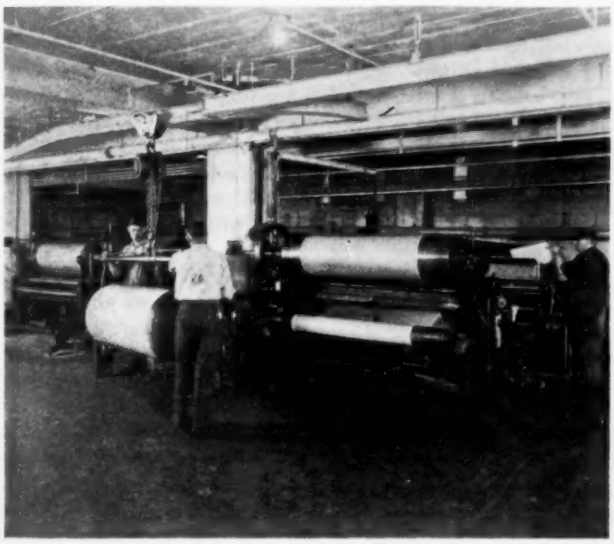

FIG. 24 MANUFACTURING WAX PAPER FOR WRAPPING CARTONS, THE ROLLS OF PAPER BEING HANDLED ON MONORAIL TRACK

FIG. 25 RECEIVING CASED PRODUCTS AT SHIPPING FLOOR TO BE LOADED INTO CARS

and produced in tremendous quantities—over a million packages of all products are produced daily.

The next best arrangement was to provide warehouse space for each product within the producing unit and to provide each unit with ample trackage; thus the loading of complete cars of a single product is not complicated. (See Fig. 25.)

It is the aim of the Postum Company to have its products delivered to the consumer as fresh as possible. For this reason it does not depend on maintaining a stock of all products in

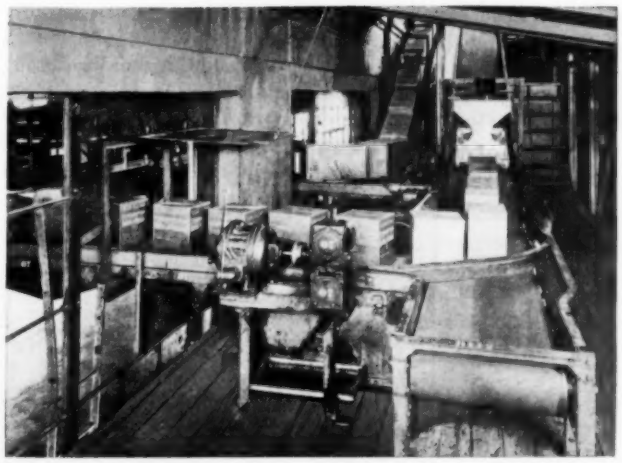

FIG. 26 CASES LEAVING GRAPE-NUTS BUILDING AT SAME TIME AS A LOAD OF POST TOASTIES IS BEING RECEIVED

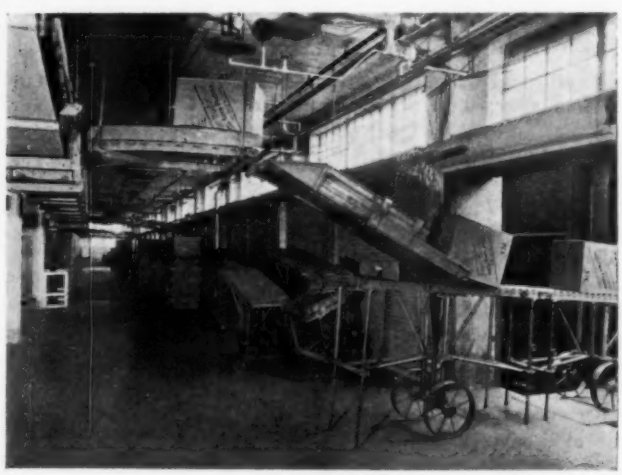

FIG. 28 CASED PRODUCTS LOADED INTO CARS BY OVERHEAD BELT CONVEYORS AND PORTABLE SECTIONS

various warehouses to supply local markets, but in practically all cases ships direct from the factory to the distributor. This means that each car leaving the Postum Company generally contains some of all of the products, and frequently these are in small lots to several customers who have combined their orders for carload shipping rates.

To assemble the various products at one or more points for

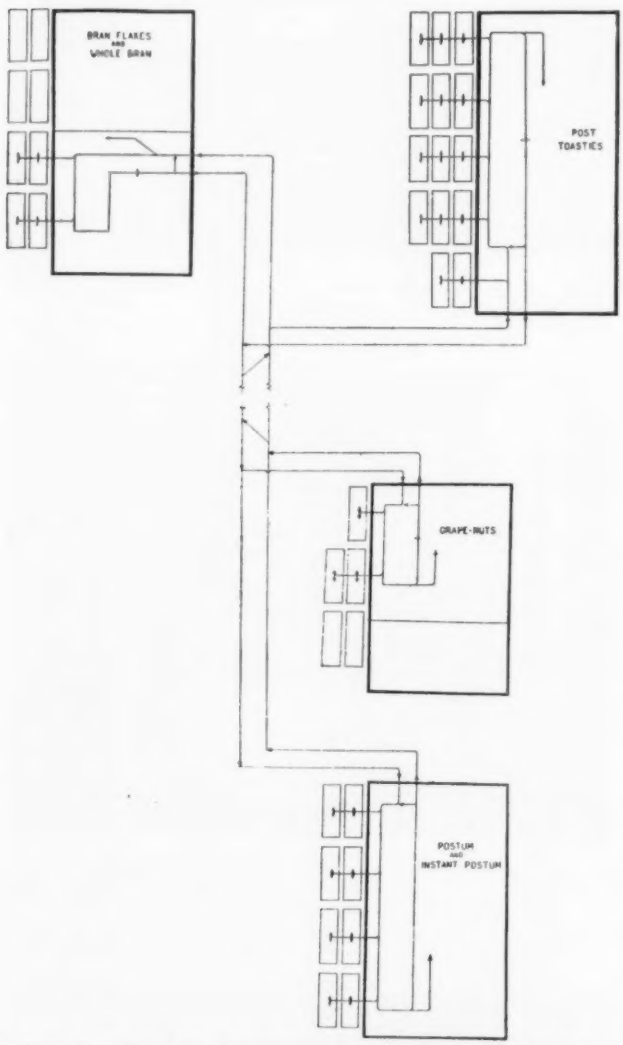

FIG. 29. PLAN OF MAIN LOADING CONVEYORS CONNECTING MAIN PRODUCTION UNITS

loading into cars has been a perplexing problem. Numerous conveying-system studies were made and installations investigated with the result that the present intercommunicating pilot-car package-loading conveyor system was installed.

These products are produced in four different sections of the plant, and although there are four group loading points, it is necessary to convey a portion of each carload from one or more of the three remaining sections. For example, a car may contain 60 per cent Post Toasties, 20 per cent Post's Bran Flakes, 5 per cent Post's Whole Bran, 10 per cent Grape-Nuts, and 5 per cent Postum. Naturally, of the four loading points, the one most convenient to Post Toasties would be selected, and the remaining products conveyed to the loading point. Before the conveyor was installed these miscellaneous cases were handled by auto truck or freight cars switched between the different buildings. Not only was this costly, but "stock" cars occupied valuable loading space and double handling was necessary. At present it is possible to dispatch the necessary number of cases to a designated car, and the so-called pilot car traveling ahead of the cases will automatically operate the system of conveyors leading into the proper car. Providing that certain portions of the system are in use, the train of cases will automatically stop until the system is clear, then proceed to the designated car.

A brief description of "pilots" and "cabooses," as used with this system, would serve to explain the almost human performance that one is able to obtain by electrical and mechanical means. Pilots and cabooses are identically the same and fully interchangeable. A pilot is so termed when it is leading a train of cases and preparing the various interferences and deflectors to "lock out" other trains of cases. A caboose is so termed when it is used to follow a consignment of cases. Both consist of a heavy base with vertical guide rolls at the four corners; these enable the car to move around curves easily. An upright section, mounted transversely in the center of the base, is arranged with 16 pinholes.

Each dispatching point is supplied with long and short pins to be placed in the pinholes of the pilot or caboose. A dispatcher at any point, wishing to send a consignment of cases to any car or building, consults a chart for proper pin settings, and places his pins; for example, short No. 2, long No. 6, short No. 7. This pilot, passing through the system with cases following, will contact all electrical lock-out interferences with the high pin and prevent other trains on branch conveyors from entering the system and colliding with the cases that follow. (See Fig. 26.) If the train-load is about to approach another section of the conveyor that is already conveying cases, the belt conveying the train stops at the instant the high pin contacts the interference switch; the passing of the caboose of that train instantly starts the waiting train. (See Fig. 27.) At a certain point in the system, short pin No. 2 contacts a tab that no other pin setting could operate, and electrically moves the proper deflector to divert the train to the proper route. Short pin No. 7 may operate to throw another deflector and further direct the train properly. Arriving at the destined building, long pin No. 6 contacts a tab and throws a deflector between the pilot and the cases following to divert these into the proper car. Meanwhile the pilot continues straight ahead and automatically comes to rest on a reserve section of conveyor, ready to be used on another mission. (See Fig. 28.) The caboose, with a long pin at No. 16, follows the train of cases and operates tabs to replace all interferences and deflectors at neutral; it operates the car-loading deflector before arriving at the deflector and after the last case had passed to the car, so that the caboose may pass to the reserve conveyor.

Simultaneous loading can be carried on at the four main units of the plant, where a total of 29 cars may receive cases via conveyor, during half of the 24-hour day, then to be hauled away and replaced with a similar number of cars for the last half of the day. When 58 conveyor-loaded cars cannot handle the day's shipping requirements, there are additional car-loading points that can be made available to meet the emergency.

The loading procedure by conveyor (see Fig. 29) is as follows:

Cars are cleaned and lined with paper.

Heavier products, Grape-Nuts and Postum, are always loaded at the bottom or ends of the cars; lighter foods, Post Toasties and Bran Flakes, are loaded on top of the heavier products. For example, a typical car may contain 500 cases Post Toasties, 50 cases Post's Whole Bran, 100 cases Post's Bran Flakes, 200 cases Grape-Nuts, 150 cases Instant Postum.

It is readily seen that this car will be placed for loading at the Post Toasties department. The loading foreman tele-

phones his orders to the respective departments for delivery to car at No. 59 door. Grape-Nuts are given the right of way for they must be placed in the bottom of the car. These are loaded to the conveyor at the Grape-Nuts department and dispatched to No. 29 building (Post Toasties department). The load of cases may be temporarily held to await a consignment of Bran Flakes that is finishing a car at No. 58 door. Cases are handled at rates as high as 2000 per hour; hence the delay is comparatively brief. As the "caboose" of the Bran Flakes cases passes the junction point the "pilot" for Grape-Nuts cases automatically follows, and leads into the Post Toasties department. At No. 59 door the "pilot" operates a deflector to send cases over portable conveyor sections into any one of three cars at this door.

Meanwhile, Instant Postum cases have been loaded to the conveyor; these arrive at the junction to find Grape-Nuts already passing. Postum cases automatically halt until the Grape-Nuts have passed, then automatically start up and follow into the Post Toasties department, where they are diverted into the proper car. Bran products, having been dispatched from a third section of the plant, arrive outside of the Post Toasties department to find Grape-Nuts and Postum occupying the right of way. Likewise this train of cases automatically awaits the passing of the "caboose," then follows into the Post Toasties building. Thus there are assembled all required cases with a count both at the dispatching point and at the car. Our consignment of Postum cases may have been a mixture of several different sized cases; similarly with Grape-Nuts and Bran Flakes or Whole Bran; but a double check is always forthcoming and no confusion results. During the time Grape-Nuts and Instant Postum cases are flowing to the Post Toasties shipping point, Post Toasties may also be moving to cars at other buildings.

Portable conveyors are changed and miscellaneous loading is carried on at one of the other cars at No. 59 door, or portables are quickly rolled to cars at one of the five other loading doors. Post Toasties cases are then loaded into the typical car, from an adjacent area, with platform trucks. There is no economy in handling cases from the immediate shipping floor into nearby cars by conveyor, except in a very few instances; moreover, the conveyor is usually occupied in bringing miscellaneous cases into the loading department or in conveying Post Toasties to other loading points.

In event that the bulk of the load is Grape-Nuts, Postum, or Bran products, the car is located at the department representing the least handling, and other cases are conveyed to the department, or loaded direct from reserve stocks if any are available within the department.

Within recent years a considerable amount of autotruck hauling for local distribution within a hundred-mile radius has been built up. These trucks often move in trains of two or more trailers. The conveyor has made it possible to assign these truck trains to a convenient loading point within the plant to which all products may be conveyed; thus no confusion arises from operating these truck trains through the busiest parts of the works. Without the conveyor it is questionable if these trucks could be loaded economically.

Mechanically, the conveyor loading system comprises some two miles of belting. High-friction rubber belting is used for inclines, none of which exceeds 22½ deg. pitch. For level runs a heavy sewed canvas, oil-impregnated belt is used. All supporting structure is guarded to prevent injury to cases in transit.

Operation is accomplished by means of 46 alternating-current motors, varying in size from 1 to 10 horsepower. These may be manually operated, or if the system is occupied by a train of cases, control is automatic in accordance with the pin setting of the "pilot" car.

Both mechanically and electrically, the automatic conveyors operate with comparatively little trouble; an experienced maintenance man is assigned to the system for purposes of inspection, adjustment, and lubrication.

Discussion

R. K. Merrill.[2] One who has gone through this plant, as has the writer, could observe the orderly and cleanly appearance of the layout. Not only does this result in a reduction of cost under that which would result with other methods of handling, but the hand trucking of materials would certainly be the cause of an enormous amount of dirt and dust, which in turn would increase the cleaning expense in proportion. The handling of foods by mechanical methods is almost a necessity in this day when dietitians and medical authorities are insisting on careful attention to these details to prevent contamination and spoilage. In the recent past there have been numerous outcries against the cost of packaged foods as against the cheapness which seemed to obtain in the old cracker-barrel days when the grocer lifted out of the barrel a scoopful of crackers, assisting the scoop with hands which had probably been engaged in sorting potatoes or pouring out a gallon of kerosene. It is probably true that the Postum Company had no choice in the competitive situation which exists today but to completely conveyorize their operations.

Where the shipping containers of a product are fairly uniform in size and shape, as in the case of the Postum Company, the system described seems to fit very well. However, it should be pointed out that mixed carloads of other classes of material, such as furniture composed of wood and metal parts, are best handled by tractor and trailer system or by means of electric lift trucks handling skids, since the odd-shaped crates and multiplicity of sizes do not lend themselves so readily to handling by belts, elevating conveyors, and transfers. The quantity of boxed material handled also has some effect on the type of handling equipment to be selected for this work.

The mechanical engineering fraternity is somewhat familiar with the enormous amount of experiment and thought necessary to produce such a layout as the author has perfected and which is described in this paper. It is unfortunate that the average layman can have no conception of this phase of the matter.

George H. Dettling.[3] The writer would ask these questions: What saving has been effected by the use of the selective conveying system for handling the cartons to various loading points? Has the author made any saving study, and is the system producing definite results as regards to saving? How much lost time in conveyor operation is caused by electrical trouble due to switches, pilot cars, and cabooses getting out of order? What provision is made for taking care of the loading of cars when the conveyor system is out of order? Does the Postum Company maintain a trucking system to replace the conveyor system when, due to electrical trouble or other causes, the conveyor system is out of order? Are there any cost figures on operation of the conveyor system. The author mentions that there is no economy in handling cases from immediate shipping floor into cars by conveyor except in a very few instances. The writer would like to learn something more in connection with this. It is noted that he specifies the use of platform trucks for this type of conveying. The paper indicates that the Postum Company has

[2] Mechanical Engineer, American Seating Company, Grand Rapids, Mich. Mem. A.S.M.E.

[3] Material Handling Engineer, Grand Rapids, Mich. Assoc-Mem. A.S.M.E.

made a very thorough study of their conveying problems, and it should be complimented on the system worked out.

C. M. Bonnell, Jr.[4] The paper indicates that, by the application of proper materials-handling equipment, costs of production can be very materially reduced in an industry such as the Postum Company, where the receiving of materials, packing of same, and the arrangement for shipping constitute the principal part of production and marketing.

Exception is taken to that statement which might be construed to classify such machines as two-color presses, cutters and creasers for shipping containers, gluing machines, etc., under the classification of materials handling.

It is interesting to note the statement that when cars are loaded such heavier products as Grape-Nuts and Postum are always placed at the bottom or ends of the cars. This is interesting, for the reason that a few shippers give consideration to this point, but the majority, it is believed, do not. Some contend that, if the fiber container is certified by the railroads to carry a certain weight, then it should be satisfactory if placed in any part of the car. Perhaps this position is so taken because some shippers do not wish to be bothered by what they consider a trivial matter. Others claim that it would be difficult always to load the heavier containers in the bottom.

Another statement is made in reference to distribution to the effect that in recent years a considerable amount of motor-truck hauling for local distribution within a 100-mile radius has been built up. The use of motor trucks for short hauls undoubtedly is increasing, and it is presumed that the Postum Company has adopted this method because it is cheaper and quicker than by the use of l.c.l. freight service of the railroads. It is not stated whether the company owns its own trucks or whether it employs the services of local trucking companies.

[4] President, *Packing and Shipping*, Bonnell Publication, Inc., New York. Assoc-Mem. A.S.M.E.

Author's Closure

The regularity and uniformity of established shipping cases lend every advantage to the possibility of mechanical handling. As for conveyor operation, the loading costs have been lowered and the loading speed increased. While the conveyor is not free of interruptions, it is reasonably in line with other automatic equipment with which we are experienced. It has not been necessary to resort to previous methods of intra-plant hauling and transferring. The conveyor as now installed is primarily to transfer cases between unit buildings; thus it is usually occupied with these duties and should not be interrupted by lesser handling costs.

MH-53-5

Mold-Handling Methods in Foundries

By WILLIAM L. HARTLEY,[1] CHICAGO, ILL.

This paper analyzes the mold-handling problem in foundries, first listing the important features to be considered in a study of the application of mold-handling devices. Present-day practice in intermittent and semi-continuous foundries is reviewed. The numerous advantages and reasons for lower cost production in continuous mold-handling operations as compared with floor methods are given. The design and application of continuous power-operated mold conveyors are discussed, with illustrations of several types.

THE handling of molds in the foundry covers a very broad field when consideration is taken of grey-iron, malleable, steel, bronze, and aluminum foundries, each having a great variety of products and range of production. The importance of the mold-handling phase of foundry production will be appreciated when it is realized that it generally represents between 20 and 40 per cent of the total materials-handling effort in the average foundry production work. As foundrymen and foundry managers have become more and more mechanically minded, the mold-handling operations have been given a great deal of consideration, along with handling equipment for sand, castings, cores, metal, etc.

In all types of foundries certain fundamental factors apply to their problem of mold handling as regards method, arrangement, and type of equipment, all of which have a direct influence on production costs.

The following is a tabulation of these important fundamentals:

1 *Molding Method and Arrangement of Machines.* It is of major importance to obtain maximum production from molding machines, patterns, and molding operators. Every thought should be given to relieving molders from all duties but making molds. To illustrate this point, numerous cases can be cited in high-production repetitive work where relieving the molder even of setting cores, a helper doing this work instead, has brought about a marked increase in production per man and machine, and thereby lower production costs.

2 *Size and Variety of Molds.* Any means of mold handling must provide sufficient flexibility and be suited to production requirements. Where a wide variety of work must be handled or when a shop does not have full control of its own products and is likely to encounter frequent changes in classes of work, flexibility is of major importance in the successful application of mechanical devices.

3 *Quantity of Production.* Careful planning must guard against too elaborate or expensive equipment for material or tonnage to be handled. Coordination of plans with production requirements is of vital importance, as equipment mu t justify itself from a cost standpoint and tonnage basis, as well as for its operating features. An unusual illustration of the point in question was a case where a complete mold-handling unit was installed for a particular job to handle a two-year production contract and, because of circumstances, was of no further use on completion of it, yet the unit well justified itself from a cost standpoint, for the one contract alone.

4 *Setting Cores, Finishing, Drying, and Closing.* Each of these operations must be given its proper consideration in every mold-handling layout. On many installations efficient handling and delivery of cores is a vital factor to the successful operation of the molding unit.

5 *Foundry Layout and Available Floor Space.* Quite often volume of production can be more than doubled from existing floor space by the addition of mechanical equipment costing less than half of what new buildings would cost to obtain an equivalent increase in production.

Because of the tremendous saving in floor space by the use of mold-handling equipment, as compared with floor methods, it is nearly always found possible to provide an effective arrangement of mechanical devices for old foundries, with minor building alterations.

6 *Flow of Material.* Proper relation of pouring zones to melting furnaces, shakeout and delivery of castings to cleaning room, and delivery of cores to molders are of prime importance. To establish the most economical and effective arrangement it is sometimes necessary to make a most thorough analysis of comparative material-handling costs. For example, it is quite generally a fact that hot metal can be conveyed in ladles some distance to molds at a lower cost than molds can be conveyed to the hot metal.

7 *Intermittent or Continuous Molding, Pouring, and Shakeout.* There is no doubt that continuous operations most nearly approach the ultimate in efficient and low-cost production when continuous power-operated mold conveyors are utilized. For intermittent operation more careful planning is necessary in estimating cost of equipment and returns on investment, for, strange as it may seem, the cost of proper mold-handling equipment for batch operation will often be more than the cost of continuous conveyors.

8 *Handling Jackets, Weight Shifting, and Clamping.* These operations in their proper order, with provision for reclaiming and convenient storage of the parts, are most essential. On several jobs handling molds on gravity rolls where it was possible to standardize flask sizes, weights are suspended above and are placed on the molds merely by shifting a lever; thus a considerable saving in time and labor is realized.

9 *Storage of Molds and Proper Cooling Time.* An even balance between mold production and melting capacity is most essential to avoid waste, yet it must be kept in mind that excess mold storage, beyond that necessary for flexibility of operations, is also a waste that will reflect itself in production costs. With regard to capacity of continuous mold conveyors, 25 per cent over the estimated mold production, to take care of peak periods and equalize for missed trays, has proved in practice as quite generally a conservative basis for figuring.

The pouring operation deserves careful attention in regard to handling of metal and method of pouring, and particularly

[1] Engineer, Foundry Division, Link-Belt Company. Mr. Hartley has been connected with the Link-Belt Company in engineering and sales since 1916. He has specialized on foundry-equipment sales for the past five years.

Contributed by the Materials Handling Division and presented at the Semi-Annual Meeting of The American Society of Mechanical Engineers, Birmingham, Ala., April 20 to 23, 1931.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

as to the size of molds and length of time necessary to pour. The mold-handling problem is often complicated where numerous molds are poured through two or more gates.

Because of its effect on quality of castings and the size and capacity of the mold-handling unit, proper length of cooling time deserves very careful study, particularly in the continuous grey-iron and malleable foundries.

10 *Method and Arrangement of Shakeout.* Every effort should be made to reduce manual labor at the shakeout, particular attention being given to speed and ease of operation of mold-handling devices. A very marked improvement in mold-handling and shakeout arrangement has been made on several continuous snap-mold units where simple and effective devices have been developed that automatically dump the mold at the shakeout without manual control, thus eliminating one of the most laborious tasks in the foundry.

11 *Flask and Bottom-Board Return.* The importance of this item should not be overlooked, particularly where high-speed production of molds is to be considered. This feature accounted for a difference in production of 15 molds per hour on a green-sand mold made on jolt-squeeze machines. This was not an unusual job except in the high production obtained, but it is cases of this kind that bring such facts to light.

Mold-Handling Method in Semi-Continuous Foundries

Under this classification would come practically all steel foundries, non-ferrous (with a few exceptions), and small production grey-iron and malleable foundries.

Manual. Where the molder carries out the molds he makes or has a helper to do this work. It would seem unnecessary to mention a method so well known and common in practice, yet it is just to the foundries still using this method that knowledge on the subject may be of most interest and value. For reasons apparent to all, it is difficult to establish hard and fast rules that will show with accuracy at just what point in production volume the carry-out method becomes uneconomical. However, for light and medium work, that is, molds weighing up to 250 lb., it can be stated with confidence that mechanical mold-handling equipment will be well justified where a production of 3000 or more molds per day is involved. For heavier work, mechanical devices become a necessity, and it is a question of the speediest and most economical.

Crank, Jib, or Hoist. Operated manually, electrically, or by air; where the crane operator takes the mold from the closing station and places it on the floor or where the jib and hoist assist the molder or helper in the carrying out; also, where a number of molds are placed on a long frame or skids, being taken from the molding station by the crane. When a single crane is depended upon to serve a number of molding stations, frequently delays occur that penalize operations to the extent that individual hoists for each molding station prove a profitable investment.

Skids and Trucks. Electric or gasoline. Where the molds are loaded on skids by the molders, with a lift truck for moving the skids to the pouring zone, and then to the shakeout station, returning the skids and flasks to the molders.

Gravity Roll Conveyor. Where the molder places the molds on gravity roll lines, which conveys them by gravity or hand power to the pouring zone, then to the cooling zone, and then to the shakeout station. Empty flasks and bottom boards are returned to the molder on a second run of conveyor. In some cases air cylinders have been used to push the molds along the conveyor, particularly for large flasks on production jobs, such as bathtubs, truck side frames, etc.

The roller conveyors provide a mobile storage of molds, and can be arranged to enable the molding operator to load his finished section or mold directly at the molding machine. Many effective layouts handling molds on roller conveyor are so arranged as to concentrate the pouring in comparatively small areas and to deliver the poured molds to a central shakeout point.

To move the great weight with ease, the roller conveyor must provide a minimum of friction, and this under the most adverse conditions. As the greater amount of molding is done in green sands, and demands are being made for closer specifications and finer detail and finish in castings, mold-carrying conveyors must operate smoothly, avoid destructive vibration, and be continuously maintained in this condition. They must withstand sand and metal spillage and provide an effective method of bearing preservation by preventing entrance of abrasive matter and moisture to the bearing elements. Development of roller-conveyor equipment specifically for foundry use has now reached a stage where any green-sand mold that will stand pouring can be rolled safely.

Mold-carrying systems using floor gravity-roll conveyors have the advantage of flexibility, selective directional movement to suit the day's work, and provide an easy means of access to a central shakeout point. They may be fitted to premises of peculiar shape and may be operated either longitudinally or latitudinally, or both, with molding points arranged in line for economy in sand-handling and other equipment.

Such systems may be altered easily in arrangement from time to time to suit changing conditions. This is readily accomplished, as no power applications are concerned, and the equipment, being above the floor level, is quickly shifted.

There are of course numerous modifications and combinations of the several methods mentioned in successful practice in many of the intermittent and semi-continuous foundries. Also, for certain conditions and requirements, very special devices offer the only mechanical means for effective handling of the molds, such as cast-iron pipe production, dry-sand molding, and stack molding, but a description of these is of little value in general.

Much has been written of the advantage that continuous molding and continuous pouring offer over intermittent operation, and there is no longer any question that continuous operation does bring about startling economies. There are many foundries today operating on a continuous basis that considered the idea impossible and foolhardy a few years ago. In numerous cases these foundries modified their production schedule, and even adjusted the design of their products so that they would lend themselves to continuous operation.

A national authority on foundry practice stated, "Any foundry manager who is interested in reducing labor costs and decreasing his foundry floor space at least 50 per cent, thereby substantially lowering the cost of castings, should fully investigate continuous melting and pouring operations."

Present-day melting methods in steel, and in most non-ferrous foundries, preclude the use of continuous mold conveyors in those fields, but it seems very likely that as steel-foundry production increases, metallurgists in that field may solve the melting phase of the problem in time not far distant, as was done in the malleable field where metal-control methods centuries old were changed to bring about a supply of hot metal for continuous pouring.

Mold-Handling Methods in Continuous-Process Foundries

The most general application of continuous-power type mold conveyors has been in the grey-iron and malleable foundries. As it is necessary to have a sand-handling system in conjunction with the mold conveyors to get their full benefit, it is almost im-

possible to give the exact savings chargeable to the mold conveyors alone. Therefore, to some extent, the following items cover the combined advantages of sand- and mold-handling devices, and apply most generally to continuous grey-iron and malleable foundries:

1 *Production Methods in the Foundry.* Continuous operation results in a steady flow of materials and products. Cleaning rooms, machine shops, and all finishing departments benefit by a systematic, orderly foundry. Continuous inspection is made possible, thereby reducing losses. It is possible to work two or three shifts during rush periods, which results in more than double saving, as it is accomplished on original investment. High-speed production lowers inventories of work in process.

2 *Floor Space.* Value of floor space is multiplied in accordance with increase in production, and thereby a saving is realized by lower taxes, insurance, maintenance, and depreciation of buildings per ton of castings produced.

3 *Saving in Flask and Molding Equipment.* A reduction of at least 75 per cent in flask equipment is generally obtained on a continuous system as compared with the old floor method; at the same time production of molds is increased. In shops having a large production of tight flask work, the saving in flask equipment alone will generally more than cover the cost of power-operated mold conveyors. In one foundry producing cylinder molds on a continuous basis, a production of 1200 molds a day was obtained with 100 flasks, the one set of flasks going through the operation of molding, pouring, and shaking out twelve times a day.

4 *Increase in Efficiency of Molders.* Conveying molds directly from the molding machine eliminates walking and bending to place molds on the floor, thus relieving the molders of their most laborious task. There is less danger of damage to molds in placing them on a mold conveyor than when the molders carry out and set them on the floor. This is true particularly when it is necessary to stack snap-flask molds on account of lack of floor space. The molder's time previously used for pouring and shakeout is used for molding, which results in continuous molding all day, with no less of molder's time waiting for iron when his floor is filled. This method gives the good and speedy molders a chance for high production, their energy not being used up in shoveling and long carry-outs; also as a result of continually performing one operation, the molders find short-cuts and become experts in their part of the system. The benefit of all-round better working conditions should not be overlooked.

5 *Systematic Pouring Reduces Costs.* Continuous pouring requires the minimum number of men working the entire day on the pouring gang, as it does away with the extra labor required when a large tonnage of metal is poured in a comparatively short time. It is generally possible to locate the pouring zone of the conveyors adjacent to or near the melting furnaces, thereby obtaining the shortest possible carry for the hot metal. Pouring at one central point simplifies pouring equipment, supervision, and metal control.

6 *Centralized Shakeout.* After pouring, molds are cooled on the conveyor and delivered to a central shakeout point, thus eliminating collecting and carrying the castings around the foundry area. Likewise the shakeout sand is delivered to one point for rehandling, establishing ideal conditions for economical continuous sand-handling equipment. The speed of the mold conveyors can be adjusted to suit production requirements, and regulated so that the molds are shaken out in the shortest safe cooling time, thereby reducing burning out of the molding sand.

7 *Pace Setter.* Continuous operation tends to speed up production and set a pace that can be maintained, because of the elimination of fatigue and back-breaking operations. With careful design, equipment can be arranged for waist-high operations all along the line.

Early Design and Development of Continuous Power Mold Conveyors

Fig. 1 is an illustration of what was perhaps the first continuous power mold conveyor installation in the country, having been in successful operation more than 40 years ago. The general design of this early mold conveyor consisted of successive carriages about 2 ft. above the floor, which formed the propelling medium

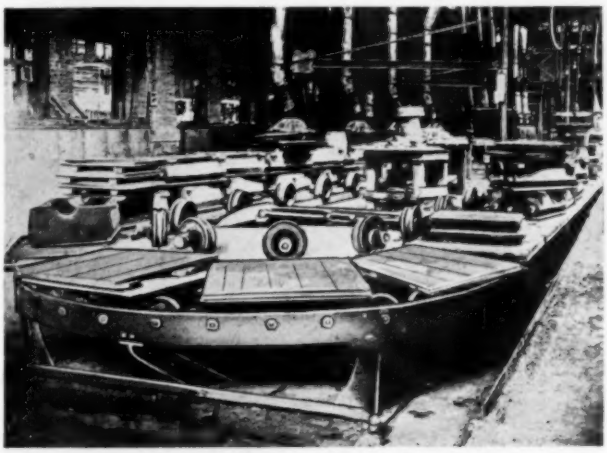

Fig. 1 An Early Power Mold Conveyor

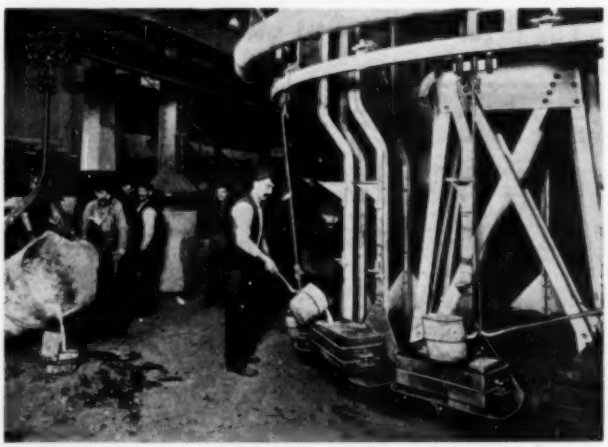

Fig. 2 Suspended Trolley-Type Mold Conveyor

and the molding, pouring, and shakeout operations were performed in much the same manner as at present.

Trolley-Type Mold Conveyors

Some years later the pendulum or trolley-type mold conveyor was developed and used quite extensively, and with much success. This design, one of which is illustrated in Fig. 2, consisted of long hangers made of pipes or structural steel, to the bottom of which were attached trays for carrying the molds. Flanged rollers are attached to the hangers at the upper end, which in turn travel on a flat steel-bar track. The chain is attached adjacent to the rollers to provide motion to the trolleys and to keep them properly spaced.

An electric motor drive, with the necessary gear reductions

and end sprockets, is used most generally on this type of mold conveyor, although a few have been built that are propelled by a wire cable and an air cylinder. The advantage of the trolley type was that the rollers, track, and chain, together with all driving machinery, were overhead and safe from falling sand or hot metal, which resulted in smooth travel and minimum wear, but required rather expensive construction, because of the necessary heavy overhead supporting structure.

Although the trolley-type mold conveyor still remains in favor with some foundry operators, it seems principally because of the impression that the trolley conveyors operate more smoothly than the floor types. However, close observation of the various designs of mold conveyors in operation does not indicate any particular advantage for the trolley conveyors in so far as smooth action is concerned.

FIG. 3 SLIDING-TYPE MOLD CONVEYOR

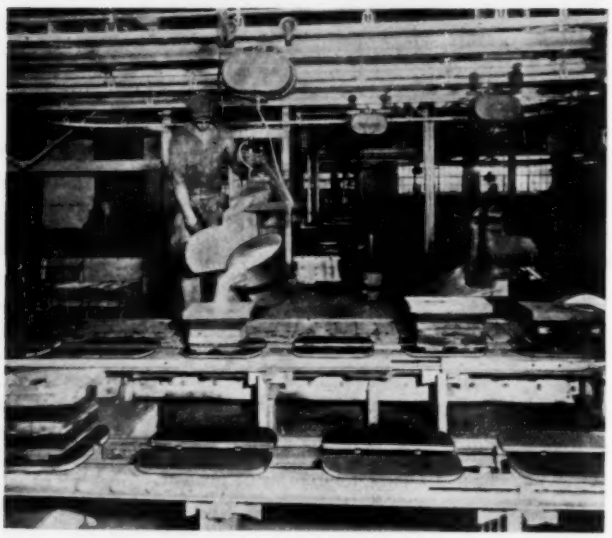

FIG. 4 POURING OPERATION ON A SLIDE-TYPE MOLD CONVEYOR

FLOOR-TYPE MOLD CONVEYOR

In the course of time a heavy, rugged chain was developed that would stand the wear and tear of sand and hot metal and which therefore did not need to be placed overhead. This did away with the costly overhead steel work, and also made it possible to locate the motors and driving machinery at the floor level.

What is commonly referred to as the slide type, illustrated in Figs. 3 and 4, is perhaps the most widely used of all the different designs. It has been in general use for a number of years and is still popular, being economical in first cost and very effective for handling light molds not weighing more than 150 lb.

Various designs of this machine have been made, all of which use the two T-rail tracks for supporting the mold tray. On the early slide-type conveyors the chain was carried on a separate pair of rails and was equipped with dogs or attachments for pushing trays along the tracks. On later designs the chain is attached directly to the trays and is carried by them, eliminating the extra rails. While in most cases the tray slides directly on the rails, a few have been made in which the trays are fitted with rollers. The smoothest travel is obtained with the sliding trays, as these keep the tracks cleared, while the rollers on the truck trays tend to ride over any obstructions of metal or sand, causing jolts, or will slide, due to shot on the rails, resulting in flat spots on the rollers.

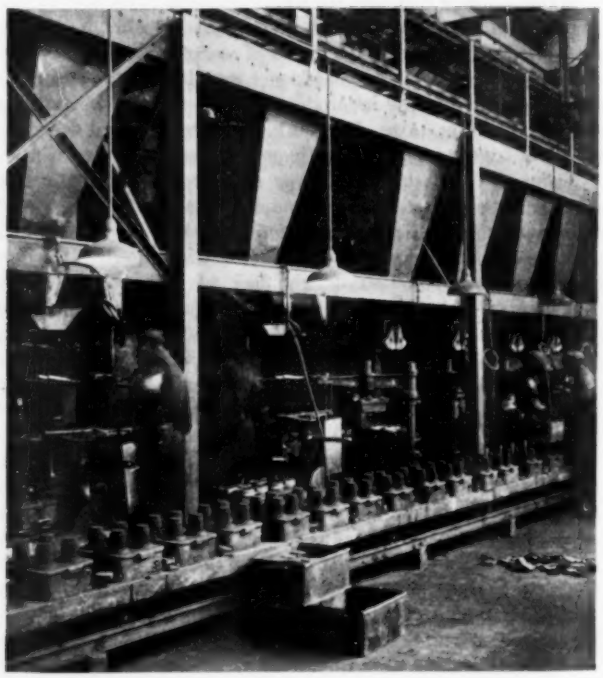

FIG. 5 CONTINUOUS TRAY-TOP "ANTI-FRICTION" CAR-TYPE POWER MOLD CONVEYOR

The most general application of the sliding-type conveyor is for the handling of snap-flask and the smaller tight-flask molds, although quite a few are handling molds weighing 300 to 400 lb.

To eliminate a crane or hoist handling from the molding station to the conveyor for these heavier molds, the cope and drag are built on a stationary section of gravity conveyor placed at right angles to the power-driven mold unit. The tray tops of the power mold conveyor also consist of gravity rolls, which permit rolling the molds on to the conveyor tray from the stationary gravity conveyor as it passes the molding station.

For long conveyors handling molds weighing more than 200 lb., experience and study have shown the advisability and economy of utilizing "anti-friction" roller design.

MODERN ROLLER AND CAR-TYPE DESIGNS

In the last few years several durable and effective designs

of "anti-friction" roller and car-type mold conveyors have come into general use. Figs. 5, 6, and 7 illustrate two such designs used extensively, both of which present a continuous series of tray tops that fully protect the conveyor chain and supporting structure. Fig. 5 is a development of the earlier car type, which can be equipped with "anti-friction" rollers and is so designed

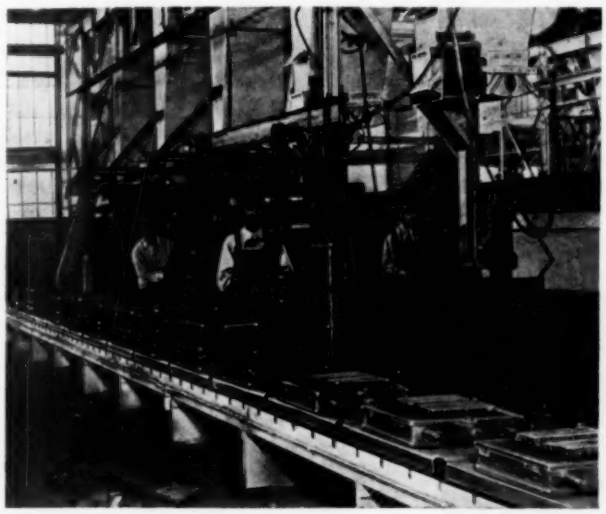

FIG. 6 CONTINUOUS TRAY-TOP "ANTI-FRICTION" ROLLER-TYPE POWER MOLD CONVEYOR

that the trucks will operate around short turns without excessive roller or track wear.

The conveyor illustrated in Fig. 6 is known as the "anti-friction" type because of the liberal use of high-grade tapered roller bearings. The tracks of the conveyor are attached to the under side of the trays, making it impossible for metal or sand to fall on them, as, besides being inverted, they are always under the tray. The chain is likewise protected in its position under the inside edge of the tray flange. The inverted tracks ride on large diameter rollers, having pressure grease-lubricating attachments for the roller bearings on which they revolve. The continuous overlap trays completely cover the rollers, making a continuous moving platform, and thus protecting the rollers from sand and metal.

A number of modified designs of car-type mold conveyors are in use to suit special conditions. One of these consists of trays, fitted with swivel casters and traveling through a rectangular path. Propulsion is provided by air cylinders mounted at the corners giving motion to each horizontal line of trays, the corner turn being accomplished by the nature of the joint between adjacent trays.

Standardization of mold-handling devices has been carried on in so far as it is possible to do so, and for most problems it

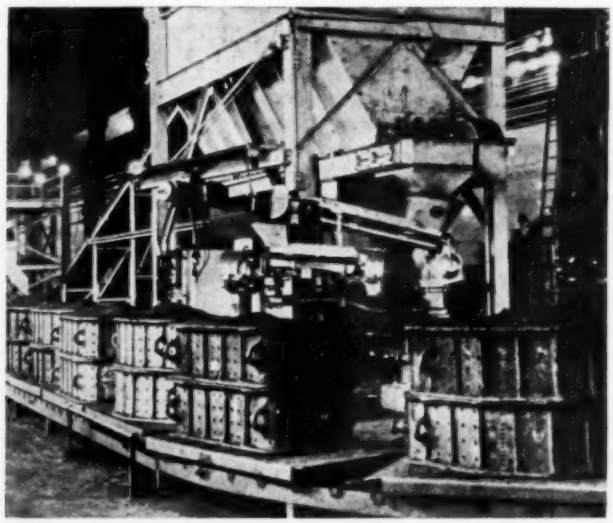

FIG. 7 CONTINUOUS POWER MOLD CONVEYOR HANDLING LARGE MOLDS WEIGHING 5500 LB.

will be found possible to purchase suitable standard conveyors, cranes, hoists, or trucks at reasonable cost.

All too often tremendous expenditures are made for special and expensive equipment when actually standardized designs would prove much more effective and economical.

Discussion

H. L. MCKINNON.[2] The author makes the statement that gravity conveyors have been developed to such an extent that molds of all characters may be handled safely thereon.

It is the writer's judgment that this is scarcely a correct statement inasmuch as we have found that short molds, and especially when stacked, unless they are put on long bottom boards, cannot be safely handled on gravity conveyors. It seems to be almost impossible to get gravity conveyors to handle the molds without high and low rollers, and if the bottom boards are less than covering four rollers, difficulty is usually experienced.

Synchronization of Production Control With Conveyorization

By E. M. OLIN[1] and W. C. BEATTIE,[2] MANSFIELD, OHIO

Mass-production methods are applied to a plant making a variety of things by concentrating for a definite period on one thing, making a supply for distribution over a certain length of time, and then turning the plant's efforts to producing another type of product. This paper deals with the production control of a partly conveyorized plant of the Westinghouse Company where 1500 operators produce certain domestic and commercial heating devices.

E. M. Olin

W. C. Beattie

MASS-production methods, first utilized in a large way in the automotive industry toward the end of the second decade of this century, have revolutionized industrial practices in this country and indeed throughout the world.

These methods have been introduced and are being employed in mining, transportation, the oil and gas industries, agriculture—in fact, in every walk of life.

They have resulted in tremendous economic changes affecting the living conditions and social status of the peoples of the entire civilized world.

The higher standards of living which we have been enjoying during the past ten years must in large measure be due to the reduced costs brought about by mass-production methods. These reduced costs mean that the average output of each individual worker per unit of time has been greatly increased. In some cases this increase is as high as 200 per cent; that is, the same number of workers, with modern facilities, will turn out three times what they did before the introduction of mass-production methods. To the uninitiated this seems almost unbelievable, but it is true nevertheless.

To some of us, at least, these methods have brought a change in our thinking as it applies to almost every problem of our daily lives.

No doubt there has been a certain loss in cultural and esthetic values because of our so-called mechanized existence, but, on the other hand, tremendous wastes have been eliminated which in the long run must result in great benefit to the human race.

Hundreds of magazine and newspaper articles have been written about mass production and its influence on our economic and social life. The authors of these articles for the most part have little or no knowledge of the technique of mass production. They form their opinions without full knowledge of the facts, and in many instances draw erroneous conclusions. For example, nearly all of them lament the disappearance of the old-time, all-around mechanic, the jack-of-all-trades, the artizan who took such joy in his craftsmanship. They deplore the robot who is simply a cog in the machine, doing the same monotonous task hour after hour, day after day on a production assembly line, let us say.

There is plenty of evidence that there is very little foundation for this feeling of sorrow on the part of the uplifters, and that the American workman in a modern factory using mass-production methods is today better housed, better paid, better satisfied than ever before.

While the average output per man in a modern factory may be from two to three times what it was under the former method of operation, this does not mean that the worker himself does in physical labor what two or three men formerly did. On the contrary, due to labor-saving devices and better handling facilities in general, he has it easier now than ever before. The huge savings made are owing to the use of automatic machinery, the elimination of effort due to better handling by means of conveyors, and other mechanical aids to better coordination all along the line.

This paper deals with the production control of a partially conveyorized plant of the Westinghouse Electric and Manufacturing Company at Mansfield, Ohio, where 1500 operators produce the domestic and commercial heating devices marketed by that company, such as electric ranges, flatirons, toasters, grills, bread ovens, and the like. There are other items made, such as industrial heating equipment, icing units for refrigerators, safety switches, etc.—in all some 300 different devices. One of these, the flatiron, runs into hundreds of thousands annually. Others have a yearly production of but 200 to 300 units, or even less. Obviously where the volume is small there would be no economy in using conveyors. Their first cost and installation expense could not be justified. On the other hand, flatirons and electric ranges are made in volume sufficiently great to justify mass-production methods. In fact, any other plan of manufacture would be uneconomical. In a great many instances items of relatively small volume are partially conveyorized as it is often found that considerable savings can be effected by a moderate use of this method.

Several years ago when we first began to study modern mass-production methods in the automotive plants with a view to using this principle or method in our own works, we believed that the conveyor must be the heart of the matter. Of course, none of the equipment which we studied was designed for flatirons or ranges. We therefore had to ask ourselves, "What is the function of the conveyor? What does it do?" Our simplest definition was that a conveyor transports material at a definite

---

[1] Works Manager, Westinghouse Elec. & Mfg. Co. Following his graduation from the electrical engineering course at Purdue University in 1894, Mr. Olin became a student apprentice with the Westinghouse Electric & Mfg. Co. He served as superintendent of commercial testing at the East Pittsburgh Works from 1900 to 1905, and then became design engineer on turbo-generators and rotary converters. He has held his present position since 1917.

[2] Director of Production, Westinghouse Elec. & Mfg. Co. For six years after being graduated from the Mansfield, Ohio, High School, Mr. Beattie was estimator and later manager of a general contracting company. For the past thirteen years he has been with Westinghouse Electric & Mfg. Co., in its works engineering, production-planning, and stores-control departments.

Presented at the "Three-M" (Management, Materials, Maintenance) Congress held in Cleveland, Ohio, April 13 to 17, 1931, under the auspices of the A.S.M.E. and the S.I.E.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

speed over a definite route. Therefore, it provides for three things:

1 Transportation
2 Definite speed or time
3 Definite routing.

The value of any conveyor may depend on any one of these things, or on a combination of any two or all three of these things.

It was to perform the first function that conveyors were first used—mainly for handling bulk materials. Many conveyors are still installed for this purpose.

The bulk-material conveyor has been followed by package conveyors of various kinds. Many of these are designed with very intricate deflecting arrangements which permit selective routing of packaged materials.

About four years ago we installed a complete conveyor system of this nature in a new warehouse. This is primarily a transportation unit, although we have gained a number of benefits from the definite routing feature also.

One of the first conveyors which we installed at our works was a cord-assembly conveyor. We had seen a conveyor of this kind in one of our competitors' plants. We adopted the basic idea and improved on its application. All are familiar with the common appliance cord with attachment plug on each end. For assembling this cord we constructed a conveyor 36 ft. long, having in addition a cutting and stripping table about 10 ft. long, the overall width being 30 in.

The conveyor is equipped with a number of lugs for carrying the cord along and is driven by a variable-speed motor.

Various tools are used at intervals along the length of the conveyor, such as cutting and stripping fixtures, eyelet machines, drill presses, arranged with friction screwdrivers, testing devices, etc.

Six girls work nine hours a day turning out 1500 flatiron cords. Each operator has a particular operation to perform—one cutting and stripping the wires, another putting on the eyelets, still another the attachment plugs, etc. It is in reality a Ford assembly line in miniature. By means of this conveyor we reduced our assembly time from 13 hours per 100 cords to $7^1/_2$ hours, a reduction of 45 per cent. In money, this would amount to a 2-cent saving per cord. We make at Mansfield well over 500,000 cords per year, so here we have a clear saving of $10,000 or better.

This unit was the first of a number of pace-setting conveyors. Now let me say something about this pace-setting feature of a conveyor.

I know of several shops where they are using conveyors for transportation only, ignoring or neglecting the pace-making or time feature. The managers of these plants are overlooking one of the most important features of the conveyor, and one which can be made productive of large returns.

Another type of conveyor in which the definite time element is all-important is the process conveyor, used for painting, baking, drying, vitreous enameling, heat treating, etc. The human element is almost entirely eliminated, and the same results are produced day after day. This results in lower rejects and lower costs.

Even if no direct labor savings are made, the reduction in rejects alone often returns the whole investment in a very short time.

We have at the Mansfield works one conveyor application which is unique and which it is believed is original with us.

A study of a certain department which assembles a considerable variety of the smaller appliances, such as toasters, waffle irons, hot plates, bowl-type radiant heaters, and the like, showed that there was a great similarity in the fundamental assembly operations in each of them. For example, all had wire-wound heating elements of similar design. All of them had frameworks or bodies consisting of sheet-metal parts held together by hollow rivets. All of the devices were electrically tested in about the same way and were afterward packed in cartons of about the same size and design.

Now, while no one of these devices had enough volume to justify a conveyor set-up, we conceived the idea of using one conveyor for all of them and running the different devices consecutively at different times during each monthly production period. For example, we would run toasters at the rate of 1000 a day for ten days, then waffle irons at 500 a day for ten days, then hot plates or bowl-type radiant heaters at 500 a day for ten days, thus gaining the advantage of conveyor economies although we would not have been justified in conveyorizing for any one of the devices because of lack of volume.

Of course this is an entirely special condition with us, and it is mentioned merely to indicate that conveyors can be employed advantageously in many cases which at first glance do not appear to be susceptible to conveyor treatment. We were able in this case to reduce our assembly labor about 35 per cent on each of these devices.

In the foregoing paragraphs we have outlined briefly the manufacturing set-up in our Mansfield plant and have touched upon mass-production methods in a rather superficial way in order to get a background for an understanding of the methods used for production.

Any engineer who has been thrown in intimate contact with manufacturing operations in a factory operating under old-fashioned methods knows that there is a tremendous loss of time due to lack of coordination. Outwardly this may not be apparent. The operators seem busy. There is the whir of machinery. Loads are being trucked to and fro in an endless stream. Clerks are flying about checking materials and operations. There is no loafing, and yet 50 per cent of this activity may be superfluous. One of the greatest advantages of the conveyor treatment in manufacturing operations is that it brings this superfluous activity to light, and forces the correction of the myriad abuses of the former method of haphazard manufacture.

This means that with the conveyor there must be production control of a very high order. Work must flow from operation to operation or from process to process in an orderly way, without delay and in a predetermined order.

When layout engineers plan a conveyorized system of manufacture, each separate operation must be studied minutely and scrutinized as never before.

Not only must each individual operation be time-studied, but the different operations all along the line must be tied together or balanced out in such a way that there will be absolutely no lost motion, and this requires expert planning.

When we installed the place-setting conveyors and began to manufacture according to modern methods, we found immediately that we had to have better production control. We soon found that if we started material at the right time, it would be at the proper place on the assembly line at the proper time. We therefore centered our production control on getting started at the right time. If parts are started too soon, congestion and extra handling result; if started too late, the assembly line is held up. So a production-control system of the highest order must go hand in hand with every conveyor layout.

We use a graphic control plan that starts with a definite graphic plan for each assembly conveyor. From this chart a plan is made for each component part back through the finishing departments, fabricating departments, etc., to the raw-material requirements. Every part is checked monthly, and each day's

performance is indicated on the feeder and assembly charts so that we know at all times exactly where we stand.

The definite routing plan also results in less supervision, as the foreman does not have to spend a large part of his time chasing jobs through the department. This has tended to raise the standard of our foremen, and they have been very active in cost-reduction work, which was not possible when their time was taken up with the daily routine of following work to see that schedules were met.

The reduction in work in process inventories is one of the greatest advantages of a conveyor system, and usually it can be shown that conveyorizing is justified from the money saving thus made, if for no other reason.

Under the old scheme of manufacture it was customary to build parts for assembly anywhere from one to three months ahead of the time of actual assembly. These parts were stored until used. Many extra handlings were required, not to mention the additional space used for stocking. Then, there was always a loss due to bookkeeping errors, and many times, due to changes in schedules and design, the stored parts became obsolete and would eventually go into the scrap pile.

Now, with the conveyor plan, the idea is to keep the material moving all the time. The stocking of parts is reduced to as near zero as possible. "A rapid assembly and a quick turnover" is the slogan of a conveyorized factory.

Since conveyorizing we have been able to reduce our inventories of raw materials and work in process more than 25 per cent, and we would be able to make far greater reductions if we had not so many articles in the line on which the volume is very small, but which must be carried for commercial reasons.

We shall now describe the graphic control plan in a more detailed way.

The first step is an order or schedule to make a specified number of certain complete devices. We shall use electric ranges for the sake of illustration.

Some one must determine the quantities and types to be built and the time deliveries are required. In our company a department known as the stock-control section sets up these schedules. This department works between the sales and manufacturing branches of the organization and has accurate data at all times relating to sales, stocks, and manufacturing schedules.

The delivery date is determined by the time required to secure raw materials, fabricate and finish those materials, and finally assemble them.

It is our practice to provide just enough raw materials to cover this period of time.

Sales are forecast four months in advance, and materials are provided against that forecast depending upon the time required to secure them.

Production planning starts when the stock-control schedule is received.

Graphic load charts are built up for the entire schedule for all types of ranges. These load charts are built up two weeks in advance of the time final assembly is to start and cover a four weeks' assembly period, the first two weeks repeated, the second two weeks new.

Three major factors determine the load-chart values:

1 The commercial requirements
2 The facilities and materials available as reflected by individual tooling for each type of range
3 Operator efficiency.

We find the dates the completed ranges are wanted, the possibility of meeting these dates, and the gross loads on the different manufacturing sections.

These loads are then plotted graphically, using figures and "blue bar" for load and "red bar" for performance against load. Opposite each range under the working day or portion of working day in the month, the bars and figures indicate the time for assembly and later the performance against the load.

Requirements for the complete schedule of ranges are estimated with respect to parts, raw material, expense material, and labor from permanent manufacturing information. These are nothing more or less than bills of material showing parts and multiples thereof, to make one range of each style.

DESCRIPTION	L OR R	QUANTITY	1 2 3 4 5	6	7	8	9 10 11 12	13	14	15	16 17 18 19	20	21	22	23 24 25 26	27	28	29

FIG. 2 ASSEMBLY CHART FOR JANUARY, 1931

written on the 14th day of each month and on the last day of each month. Each chart shows the load for four weeks, the first two weeks being a repetition of the previous chart, the second two weeks added.

Space is provided on these charts to tabulate the following values on one line for each part:

Identifying number of part
Description of part
Routing through departments

Available quantities in process
Required quantity
Working days of ensuing assembly period.

A comparison of these values with the vertical bars which show the time the parts are required for assembly indicates the different quantities of parts to be provided and when needed.

Let us emphasize that with fabrication starting only two weeks before assembly, for those parts on which production is small and for specialized equipment, the longest investment turnover is two weeks. Later we shall explain the much more rapid turnover accomplished on that portion of the range schedule where quantities are large, which justifies the specialized facilities which have been provided.

Part orders are written up on still another graphic chart (departmental chart, Fig. 3), which becomes the order to the department to do the work. This chart shows the following values:

Identifying number of the part
Identifying description of the part
Routing through departments
Quantity to be made.

A red dot under the date indicates when delivery must start. This is graphed by extension of the red bar showing performance against requirement.

Perhaps the greatest obstacle to successful conveyorized control is a sudden change-over from one type of device to another to meet some commercial demand.

We can revise our control set-up for the entire plant in 12

FIG. 3 DEPARTMENTAL CHART FOR JANUARY, 1931

hours by means of our chart system, and can produce any type of range wanted in two weeks.

No part production is started more than two weeks before assembly begins, and many parts are made and finished as used.

With part fabricating and finishing synchronized with the assembly requirements, the entire manufacture is in tune and rapid revisions of schedules are simple; also obsolescence of material is avoided.

We shall now explain our method of providing purchased parts and material. Again we have developed a plan which permits rapid turnover and guards against obsolescence.

We advise our suppliers monthly of our expected requirements during the third and fourth months from that date. At the same time we give them an order for the second month's requirements.

Since we have indicated our February requirements on two previous estimates—namely, those of November 1 and December 1—our suppliers have their facilities and material available to furnish February requirements during January just a short time before assembly starts.

Certain classes of material, such as porcelains, castings, and cartons, are handled on weekly, semi-monthly, and monthly schedules.

Cartons, for example, are particularly adaptable to schedule

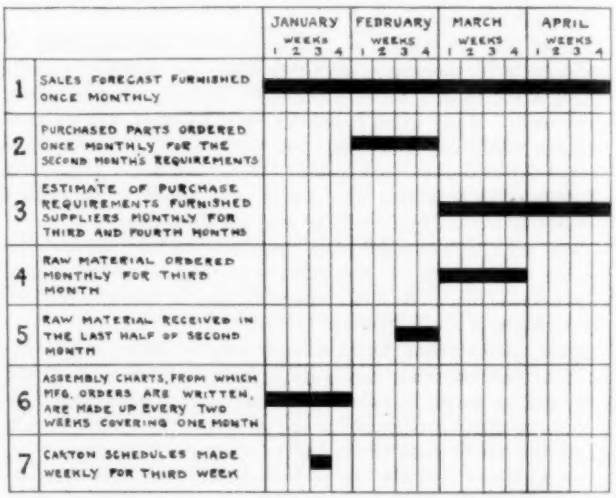

FIG. 4 CHART SHOWING REQUIREMENTS OVER A LONG PERIOD

purchases. However, their variety and changing requirements, together with storage and handling problems, present considerable difficulties.

We have worked out a plan whereby we secure a four days' turnover, and we purchase every carton we use.

On Monday morning of each week we provide our suppliers with a schedule of our third week's requirements. Once monthly we furnish our suppliers an estimate of our next three months' requirements, with which they fortify themselves with board and manufacturing facilities.

The suppliers consume the first and most of the second week to make our cartons and ship to us via motor trucks, so that we receive on Friday or Saturday of each week all requirements for assembly in the next week.

Other purchase schedules are similar.

Raw-material control presents a different and more difficult problem because it frequently happens with us that one kind and size of material is used to make many different items. This is particularly true of steel sheets.

From the breakdown of the complete schedule previously described, we post the four months' advance requirement to a "raw material card" (see Fig. 5), which we use to accumulate requirements and availables of raw material from which replenishing supplies are ordered.

These cards are serially numbered and are headed with the name of the material, purchasing specifications, and ordering size, one for each item of raw material which we purchase.

Each part requiring material on any card is shown with a cross-reference of the card serial number back to the "permanent manufacturing information." Requirements are posted opposite each part for each of the following four months. The available amount in process is also posted on the card.

The number of pieces of each part that can be obtained from one ordering unit of raw material is divided into the requirement, and totals for each month are added and multiplied by the weight or measurement of the ordering unit. The quantity thus obtained is reduced by the available number or amount in process and in raw stock. A replenishing supply is then ordered.

The turnover of raw material accomplished with this method never exceeds four weeks and averages three weeks. When we consider that extra supplies must be carried to permit flexibility of schedules, this turnover is extremely good.

We have talked about the paper control with no mention of the conveyor control. However, the paper control is essential, otherwise the conveyors cannot function. We shall now trace the fabricating and finishing operations.

Our limited schedules do not permit of punch presses and dies specialized for each part we use.

The departmental charts indicate the sequence of operations for the different parts to be made on each press in order that

delivery dates may be met and assembly continued without interruption, also so that no surplus stock will be accumulated.

Control is accomplished by a master punch-press board which has three pockets for each press (see Fig. 6): first, one for parts to be made (called the load-ahead pocket); second, one for parts in work, and third, one for parts which are delayed. This board indicates the sequence of operations for each part.

A work ticket for each operation for each part to be made in a two weeks' period is filed in the "load ahead" pocket of the planning board. It is a simple matter to file all of these work tickets for each press in the sequence required, as indicated by the delivery dates on the "departmental charts."

Delivery is made via gravity conveyors to stores in standard containers, which have no definite individual locations in the store rooms and are controlled by balance tags. These containers are handled in stores with automatic elevators.

Storage of fabricated parts is ordinarily not necessary, but sometimes becomes so for one of the following four reasons:

1 When the volume required is insufficient to justify specialized equipment to make as used
2 When the volume required is insufficient to justify suppliers of purchased material furnishing as required
3 When impossible to finish as fast as fabricated, because of volume not justifying more finishing equipment; it is impossible also to run the small quantities to match finish facilities, because of set-up costs to manufacture
4 When it becomes impossible to assemble the part or parts as soon as finished; again volume is the determining factor.

When storage of material is necessary, we have eliminated the usual bookkeeping and its attendant evils by means of the following coupon system.

A ticket serially numbered, consisting of three coupons, is attached to each container as the parts are received in stores, showing the identifying style and quantity on each of the three coupons. The bottom coupon is detached and returned to the delivering department and serves as a memorandum for paying the operator.

The second coupon is detached after the section and bin number (one of 2000 for sheet-metal parts) are noted thereon and is filed in identifying number order, the oldest container first in the file. The third coupon remains attached to a piece of material in the container. To find the total quantity of any part available it is only necessary to add all of the quantities shown on the coupons for any one style.

Because of the varying requirements for each part, it is impossible to assign definite bins in which the same kind of part will always be stored.

The location of the parts by the serially numbered coupon-control method is indispensable for conveyorized manufacture.

To obtain the best turnover for parts painted and vitreous enameled, a daily schedule is provided. A one-day bank of such parts is stored on conveyors on the assembly floors.

Each day, parts for the second day's assembly are sent out of stores to the painting or enameling departments by the gravity and mechanical conveyors.

When during finishing or assembling operations defective parts are found which cannot be salvaged at once, additional pieces are started immediately to balance out the run with no shortage or surplus.

Through the burn-off (cleaning) operation, paint, inspection,

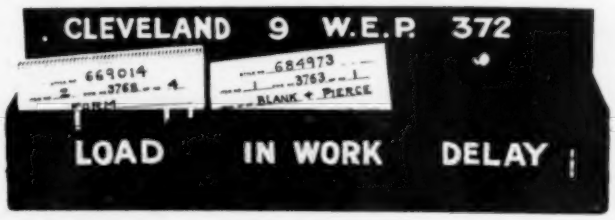

Fig. 6 Section of Planning Board, Machine-Tool Control

and assembly, the parts are handled entirely by conveyors placed by assembly requirements.

Through the vitreous-enamel department the parts are progressively handled by conveyors, delivering from stores through pickling, ground-coat dip or spray, ground-coat burn, finish-coat spray, dry, rim, burn, inspection, second coat (if necessary), and delivery to the assembly department.

Lack of volume and multiplicity of parts require closely coordinated control of nickel, chromium-plated, and lacquered parts. A schedule made daily with conveyorized transportation as in the case of the painted and enameled parts provides the right quantity required for assembly.

A coupon system of control for the stores or handling conveyors which feed the assembly conveyor again eliminates bookkeeping.

As in the case of unfinished-part stores, a coupon is detached upon delivery of the part to the conveyor servicing the assemblers. This is filed in identifying-number sequence. As the container is sent to the assemblers, another coupon is detached and clears the corresponding coupon in the file.

Part assemblies are never stored, but are synchronized on the feeder lines to the final-assembly conveyors, thus eliminating stores. Here again the time element is paramount. These part assemblies are serviced by conveyors to the final-assembly conveyor.

In the case of a range, the bottom of the crate is started first on the assembly conveyor and the proper parts added successively at various stations along the conveyor until the range is completed and ready for final inspection, after which it is crated on the conveyor and conveyed to the warehouse, where it is stored under cranes serviced by conveyors. It is then available for miscellaneous shipment.

In a modern conveyorized factory, the old-time production chaser has been replaced by a much higher type of man.

Production control has become a fine art, one which is worthy of any man's talents. In no other branch of industry is there greater need of resourcefulness and imagination. A mistake or oversight on the part of the production-planning department may wreck a season's output.

Once under way, a production line must be kept going. No price is too great to pay to accomplish this. Truly an efficient production department is one of the most indispensable factors in this great modern development which we call mass production.

MH-53-7

Material Handling in Mass Production at the General Electric Plant

By H. C. RUNDLE,[1] SCHENECTADY, N. Y.

In this paper the author describes the conveyor system used throughout the various buildings where refrigerators are made at the General Electric Company. Before this installation material was handled by tractor-and-trailer trains, lift trucks, and gas and electric trucks. The new system has eliminated congestion, retracing of material routes, delays in schedule, spoilage of material, and maintenance and replacement of the industrial trucks. The conveyor serves as a traveling stockroom, thus releasing floor space for use in manufacturing operations. The conveyor system has linked together four different sections located in 12 separate buildings and maintains a uniform flow of material.

THE General Electric Company started to build electric refrigerators at the Schenectady plant in 1926, at which time it was decided to use the existing buildings that were available. As in most cases, these buildings were not adapted to this type of manufacturing, so it was necessary to fit the equipment to the buildings in order to meet the requirements of refrigerator manufacture. In 1927, the refrigerator department occupied a single three-story building. During the next two years, electric-refrigerator manufacture increased at such a rapid rate that the processing of parts spread into nearby buildings formerly occupied by the switch-gear department. In 1930, the refrigerator-unit department, not including the manufacture of cabinets, occupied 12 buildings spread over a ground area of approximately 10 acres.

During this time the material distribution from building to building throughout the department was handled by means of tractor-and-trailer trains, lift trucks and skids, gas and electric trucks. This method of material handling resulted in congestion on the avenues, courtyards, and in buildings, the retracing of material routes, delays in schedule, spoilage of material due to rough handling and exposure to weather, and maintenance and replacement of equipment. Material-handling costs were excessive. This condition brought up the question of a better method of handling material, and resulted in the installation of an overhead chain conveyor.

To justify the installation of such a system, advantages have been derived which otherwise could never have been accomplished. They include (1) decreased handling cost, (2) reduced spoilage, (3) released floor space, and (4) reduced inventories.

Handling costs have been decreased by a saving in direct labor, the elimination of 624 hr. of porter labor per week, which was formerly necessary for the handling of material throughout the department. In conjunction with this, approximately 90 per cent of the spoilage and waste from the former handling method, due to rough handling and weather exposure, has been eliminated. Also 140 trailers, one tractor, and one electric lift truck were released for use elsewhere in the plant, and the necessary maintenance cost of keeping this equipment in working condition was done away with. By eliminating the use of this equipment, congestion from trucking within the buildings, on the works avenue, and in courtyards has been relieved, all of which helps to improve working conditions and outside appearance.

Because of the increased speed and uniform flow of material and its storage on the conveyor which serves as a traveling stockroom, the buffer storages before and after the lines of processing have been reduced. This releases floor space that can be used for manufacturing purposes and at the same time reduces inventory.

In addition to these, the production department in charge of the material handled by this conveyor can control the work in process by regulating the speed of the chain. By governing the inflow of material to the assembly line, the contributing section can produce no more than what the conveyor can absorb. Thus, the production department can automatically regulate the output of the contributing section to conform with the requirements of the assembly line, maintaining the same production schedule throughout the whole department, with a uniform flow of material, which reduces the inventory, and at the same time eliminate any change of over-production in any one section.

Course and Type of Material Handled

The department is divided into four sections, namely: (1) DR-1 section located in building No. 28 (see Fig. 1), where the DR-1 unit, used on the 4-cu. ft. cabinet, is assembled; (2) DR-2 section located in buildings Nos. 24 and 26, where the D-2 unit, used on the 6-cu. ft. cabinet, is assembled; (3) the water-cooler section located in building No. 12; and (4) the contributing section located in buildings Nos. 8-A and 10, where all punch-pressed parts are processed for the assembly lines of the other three sections. Fig. 1 shows the outline of the conveyor path as it winds its way through these four sections.

Throughout this system there are 12 loading and unloading stations where the various material parts are received from or loaded for other points on the system. To become familiar with the course of the conveyor and the type of material handled, for further reference, the path will be followed through which it travels in one complete cycle. Assuming that the endless chain has a starting point at the drives in building No. 8-A, one can follow the path of the conveyor, in the direction indicated by the arrow, as it travels toward building No. 26. In building No. 8-A, small parts such as check valves and float bulbs, handled by means of small tote boxes, are loaded on the tote-box carriers, routed for building No. 28. Also evaporators are hooked on at this point which is within 3 ft. of the last operation in the line

---

[1] Planning Engineer, General Electric Company. The author, as student engineer to the Chain Belt Company, worked as assistant to the plant engineer during the summer of 1928. He was graduated from Washington State College in 1929 with the Bachelor of Science degree in Mechanical Engineering, and entered the General Electric Company in July, 1929. He is now engaged as planning engineer in the General Planning Department.

Presented at the "Three-M" (Management, Materials, Maintenance) Congress, held in Cleveland, Ohio, April 13 to 17, 1931, under the auspices of the A.S.M.E. and the S.I.E.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

of processing. The style of carriers, hooks, and type of material handled is shown in Fig. 2. After leaving building No. 8-A, the conveyor enters a steam-heated, corrugated-steel covered housing, lined with $^1/_2$-in. celotex, where it rises to an elevation of 30 ft. along the side of building No. 8-A. (See Fig. 2.) From this point it passes over the tops of buildings Nos. 20, 27, and 25 to where it enters the second floor of building No. 26.

In building No. 26 the conveyor travels in a straight line near the ceiling (see Fig. 4) to building No. 24, where the D-2 compressor cases are unloaded during the night shift, and stored

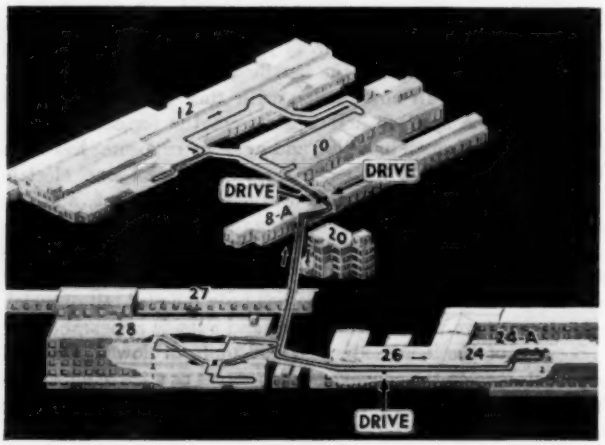

FIG. 1 PATH OF CONVEYOR SYSTEM THROUGH THE DIFFERENT BUILDINGS

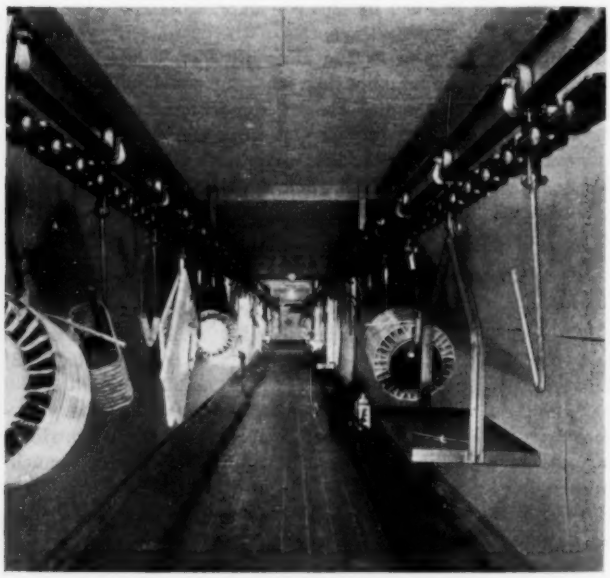

FIG. 2 INTERIOR OF BUILDING 8-A SHOWING INTRADEPARTMENTAL-CONVEYOR HOUSING

for steam cleaning in building No. 24-A during the day shift. Also miscellaneous stock parts from the general stock room, located in building No. 28, first floor, are unloaded at this point and distributed to the various points on the assembly line where needed. From the second floor of building No. 24 the conveyor drops to the first floor of building No. 24-A, where the D-2 compressor cases are unloaded for steam cleaning, after which they are carried to the assembly line by means of a secondary conveyor. From this point the conveyor rises again to the second floor of building No. 24, where it parallels the incoming path to building No. 26, where a second drive is encountered.

In building No. 26, cabinet tops, float valves, and miscellaneous-stock parts are unloaded at the operation on the assembly line where they are used. Leaving the second floor of building No. 26, the conveyor rises to the third floor, where it enters building No. 28. In this building the conveyor dips to a convenient workable height for a length of approximately 30 ft., where DR-1 cabinet tops, float bulbs, and stock parts are unloaded at the operations where they are used on the assembly line. Also the completed DR-1 unit is loaded on the unit carrier (see Fig. 2), routed for the water-cooler section, where it is assembled to the water cooler. Leaving the third floor the conveyor descends in the inclosed housing along the outside of the building, to the first floor, the general stockroom for all four sections, where there are two stations. One is for receiving and loading for distribution all miscellaneous stock parts, and the other is for the transferring

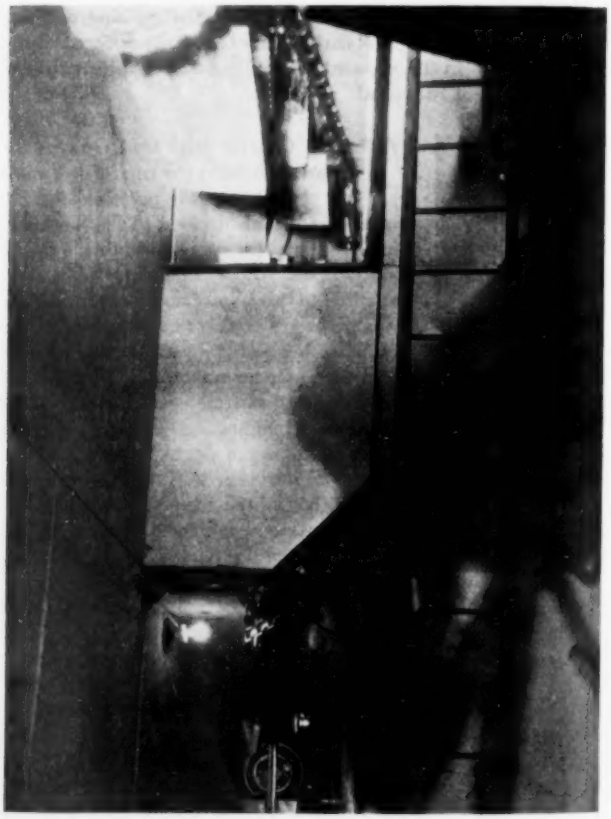

FIG. 3 CONVEYOR AS IT ENTERS THE THIRD FLOOR FROM THE FIRST FLOOR OF BUILDING 28

of evaporators, to a secondary conveyor on which they are carried directly to the sandblast machines in building No. 25. Also the DR-1 compressor cases are unloaded, at this station, for steam cleaning, after which they are carried to the assembly line, on the third floor, by means of a vertical elevator. After serving these two stations, the conveyor leaves building No. 28, where it again enters an enclosed housing, outside of the building, which rises to the third floor, where it connects with the housing of the incoming line. From this point the return line parallels the incoming line (see Fig. 3) to building No. 8-A, where a third drive is encountered. As the conveyor leaves building No. 8-A it enters another housing which it follows along the rear of building No. 10 to where it enters the rear of building No. 12. Here

the DR-1 and D-2 cabinet tops are unhooked from a secondary conveyor, used in the paint line, inspected and then transferred to the main conveyor, for distribution to buildings Nos. 26 and 28. From here the conveyor travels toward the front of the building, where it passes through a subsidiary stockroom, where the stock parts for the assembly of the water cooler are received from the general stock room in building No. 28 and redistributed to the assembly line. In the front end of building No. 12 the DR-1 compressor unit is unloaded at the operation on the assembly line, where it is assembled to the water-cooler cabinet. From building No. 12 the conveyor passes through another housing to where it enters the front end of building No. 10, at which point the DR-1 compressor case is loaded for distribution to building No. 28. From here the conveyor follows the wall, inside the building near the roof, to the rear of the building, where the D-2 compressor case is loaded for distribution to building No. 24. From this point the conveyor leaves building No. 10 and enters building No. 8-A, where it encounters the first drive at the starting point, thus completing one cycle through which the conveyor travels. At no point is this system a part of the assembly lines. Its function is purely one of transportation among the four sections within the department, no operations being performed on the conveyor.

Throughout the course of the entire system just described, approximately 50 different parts are handled daily. These parts range in size from a small wood screw to the compressor unit which is mounted on top of the refrigerator, and in weight from one ounce to 75 lb. On the present production schedule the chain is traveling at a speed of 26.6 ft. per min., completing one cycle in 2 hr. 18 min., carrying approximately 85,000 pieces per day, a total load of approximately 85 tons.

The care with which this material must be handled, involving temperature changes, humidity, dust, grit, and marring and scratching, was carefully considered in the design of this system. Proper clearances and spacing of hooks were maintained to insure against any possibility of marring and scratching of material. The hooks used for carrying the compressor cases are rubber covered to prevent the burring of machined edges when loading or unloading. To prevent the collecting of dust and grit on the material as it passes through the housing located directly above the sand blast building, between buildings Nos. 26 and 28, a dust-proof enclosure was necessary. One of the largest spoilage losses which had to be overcome by this system was that from rust due to weather exposure. In order to maintain the same temperature in the housings as that in the buildings, all of the outside housings, totaling 1000 linear feet, were lined with $\frac{1}{2}$-in. thick celotex and equipped with a steam-heating system. Approximately 90 per cent of the losses which occurred in the former handling method have been eliminated; all of which cuts down the cost of rehandling, reworking, and loss of material.

The outstanding features in the design of this system are the multiple drives and the signal system, which are as follows:

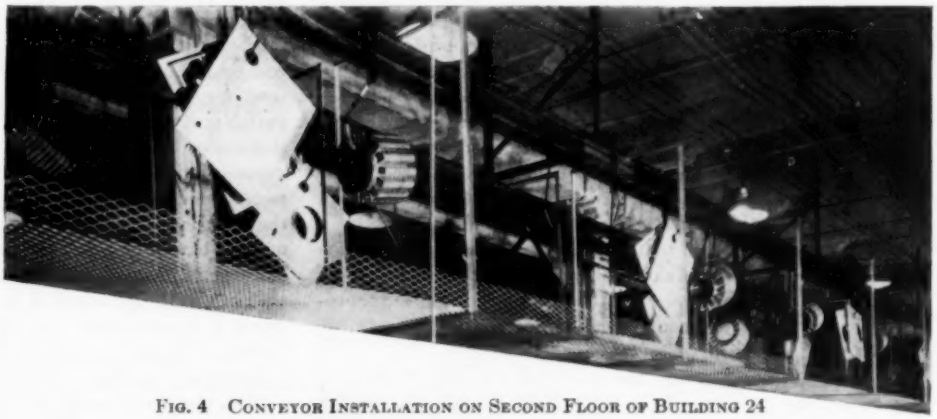

FIG. 4 CONVEYOR INSTALLATION ON SECOND FLOOR OF BUILDING 24

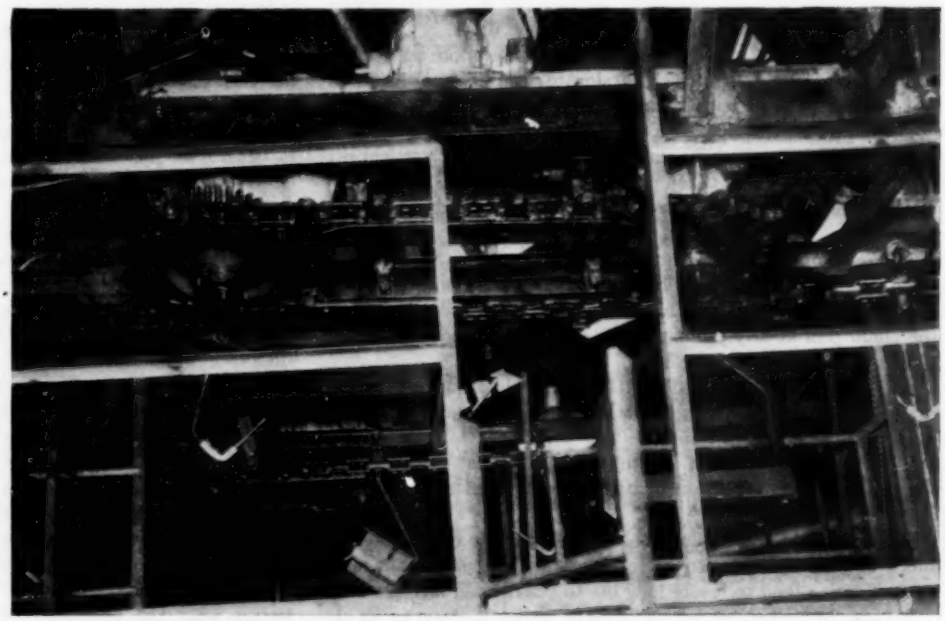

FIG. 5 FULL-FLOATING DUAL CATERPILLAR DRIVES WITH REEVES AUTOMATIC ADJUSTMENT

MULTIPLE DRIVES

The automatically synchronized caterpillar drives used on this overhead chain conveyor installation consist of:

A standard caterpillar drive mounted on a cast-iron base with Reeves speed variator. All are mounted on a structural frame floating on four heavy-duty ball-bearing rollers, with vertical ball-bearing rollers to take the side thrust. A special shaft extension is provided for the Reeves adjustment shaft. A pinion on the end of this shaft engages a rack attached to a fixed support, so that when the drive floats in either direction a resultant turning of the Reeves adjustment shaft occurs. When

the floating drive moves ahead or in the direction of travel of the conveyor chain, the Reeves adjustment shaft turns so as to speed up the drive. Conversely when the floating drive moves back or in a direction opposite to the direction of travel of the conveyor chain, the Reeves adjustment shaft turns so as to slow down the drive.

A limit switch is placed behind the floating drive frame. Should a sudden overload be put on the drive due to fouling of the conveyor chain, the floating frame moves back until contact is made with a limit switch which stops all drives.

The maximum allowable travel of the floating frame is 6 in., but in actual practice the travel is about $1^1/_2$ in. The amount of pull the drive is to take is predetermined and compression springs are placed behind the floating drive frame calibrated to withstand a reaction equal to this pull.

In application of the above principles, let a conveyor be assumed with three drives driven by independent motors of the same nominal speed. (No special winding of motors is required.) Suppose each drive is intended to take $^1/_3$ of a total chain pull of 3000 lb. The three drives are started instantaneously by a common switch, but due to difference in motor windings one of the drives runs slow and does not pick up its share of the load. This drive will move ahead with the conveyor chain, automatically turning the adjustment screw on the Reeves adjustment shaft to speed up the drive.

On the other hand should the drive run too fast, tending to take more than its share of the load (1000 lb. pull), the springs behind the floating drive frame will compress, allowing the drive to move backward, automatically turning the adjustment screw of the Reeves adjustment to slow down the drive.

In using two or more (the conveyor in question has three) drives of this type it is advisable to locate drives so that an equal distribution of load will occur. Elements to be considered in determining distribution of load are (1) length of loaded conveyor pulled by each drive, and (2) uncompensated vertical lift of the loaded conveyor taken care of by each drive.

Advantages of the automatically synchronized drive are as follows:

1 Conveyors of extreme length may be constructed using the same standard chain and trolley equipment as is commonly used for conveyors of short length. This is accomplished by keeping the chain pull at any point within the limits of good design for conveyors of ordinary length.

2 Drives may be placed at the most advantageous points, it not being necessary to group them around a countershaft or other medium of power.

3 Variation in pitch of conveyor chain is not important as the floating type drive automatically overcomes this variation by variation in speed.

4 The compression springs behind the floating drive take the shock of starting and also act as a cushion in case of a wreck, both of which tend to insure long life to the driving mechanism.

5 Limit switches behind each drive make it easy to locate trouble in case of a wreck on the conveyor. In connection with this feature, it is possible to install signal lights at a central location which will tell the operator in charge when a limit switch kicks out, and also in what zone the trouble is to be looked for. This will save considerable delay in getting the conveyor into operation again.

Safety

Safety plays an important role in the design of all conveyor installations, as well as other equipment in the plant of the General Electric Company. All proposed layouts must be approved by the safety engineers before the proposals are submitted to outside companies for propositions. After the conveyor has been installed, a final inspection is made to see that the safety appliances conform with the safety rules of the General Electric Company.

Throughout this entire system, guarding for safety has been carried out to the most minute detail; no expense has been spared. Control switches, guards, and signal horns have been supplied to insure safety to those working in the vicinity through which it travels.

At each loading and unloading station, a safety switch is located directly above the conveyor rail within easy reaching distance from the floor. The switches are of the push-button type, equipped with a locking device, so that when the button is pushed the locking device must be unlocked before the switch makes contact. The switches are so connected that they can only be used for stopping the conveyor. The one and only starting switch is at the control station, located in building No. 8-A, which is operated by an officially appointed operator. In case the conveyor is stopped by a safety switch, the control-station operator must receive word, from the station where the switch was used, that the line is cleared before starting. Also a switch is located on the drive frame of each drive, so that the conveyor can be stopped in case of accident while making speed adjustments, the only work permitted to be done on the drives while the conveyor is in operation. At all places on the system where the material on the conveyor is below 7 ft. from the floor, safety switches are installed within reaching distance.

To prevent any accident which might occur when starting the conveyor, a horn-signaling system was installed whose function is to give warning to those near the conveyor. Each station is equipped with a siren horn, connected to the starting switch, so that for approximately 10 sec. before the conveyor starts the horns throughout the system sound warning that the conveyor is going to start. Also a horn is located near each drive. From a safety standpoint, this announcing system has proved very satisfactory. To eliminate any possibility of a hazard while oiling, each drive has been equipped with a one-shot lubricating system.

One of the difficulties which arose in having such a large number of stop switches, located at points in eight different buildings, was the lost time in locating a locked switch, after the conveyor had been stopped. In order to overcome this a tell-tale lighting system was installed which has reduced lost time to a minimum. It is very important that the system be put into operation as soon as possible after a shutdown, as all three assembly lines depend upon this installation for their source of incoming material. Each stop switch is connected to two lights, hooked in multiple, placed on a panel board, located near the starting station. The stations are numbered in rotation, corresponding to those stations numbered on the panel. When the conveyor is stopped, the operator at the control panel is able to tell instantly which stop button was pushed. He can then communicate, finding out whether or not the line is cleared, so that he can start the conveyor. For example; when the switch at station No. 1 is opened, the two lights No. 1, on the panel board, which are connected to station No. 1, will be switched off, while the remaining lights designated by the numbers corresponding with the station number to which they are connected will remain lighted. The control operator then knows that the switch at station No. 1 stopped the conveyor. This light system is also very effective in stopping practical jokers from meddling with the stop switches.

Metal guarding has been used extensively; the entire length of the conveyor through buildings is guarded with expanded metal and sheet iron. Wherever the conveyor runs overhead, an expanded-metal guard is fastened from the rail so that it hangs below the material being conveyed. (See Fig. 4.) The

guards are made with the metal turned up on the sides to prevent the material from falling in case it becomes disengaged from a hook or carrier. The only points at which the conveyor runs near the floor are at the unloading and loading stations. At these points the track is guarded with an umbrella sheet-iron guard, completely inclosing all moving parts. The driving and idler sprocket and caterpillar chain on the drives are inclosed in a sheet-metal guard. Every precaution has been made to make this system safe.

Scheduling of Material

The scheduling of material plays an important part in the operation of the conveyor. The material movement of parts from the contributing section and DR-1 section must be synchronized with the operations of the assembly line. Miscellaneous stock parts must be scheduled in accordance to production requirements. Rework parts and other material must be scheduled as fast as they are repaired.

The scheduling of stock parts is routed by a numbering system. Those parts which are common to both DR-1 and D-2 units are routed to the different sections in different quantities, which makes it necessary to have some system whereby the person at the station where they are to be unloaded will know which allotment is to be unloaded. By a numbering system, for example, a tote-box container filled with stock parts scheduled for station No. 1 is numbered by means of a clip with a corresponding number, so that the material is conveyed directly to the station where it is unloaded.

The synchronizing of material movement between two sections is maintained by painting the hooks for one section a different color than those used for another section. These colored hooks are spaced so that the inflow of material at the assembly line is at the same rate as the outgoing. To take care of any fluctuation in the assembly line or conveyor delivery, a space has been allowed at each station for a small buffer stock.

The installation of this conveyor system has resulted in linking together four different sections located in 12 separate buildings and in maintaining a uniform flow of material.

Discussion

Jervis B. Webb.[2] For a number of years the problem of driving long conveyors with multiple drives had not been entirely satisfactorily worked out. The Webb Company had worked out problems of this nature from many angles, but a considerable amount of care and attention and adjustment had always been necessary on the methods heretofore used.

One of the first types of multiple drive was used at the Ford Motor Company in Toronto, where three individual drives using the alternating-current type of motors, having as nearly as possible the same characteristics, were connected to one conveyor chain at convenient points, so located as to balance the load as nearly as possible. The system was worked out on the basis that an ordinary a.-c. squirrel-cage motor has a slight variation in full-load and no-load speed—that is, no-load speed would be around 1200 r.p.m. and full-load speed around 1140 r.p.m. As the motors were selected to have practically identical characteristics and the load was fairly evenly balanced, any discrepancy in speed would be taken care of by this slight slippage.

This installation proved to be very satisfactory, but when adopted, in a number of instances, due to the inability to get equal loading and accurate similar characteristics of motors, much difficulty was experienced. One drive was found to take all the load, or even to try to pull through the other drive; and of course this type of system was of constant speed. This system also had its limitations in that, on a slow-speed conveyor, where the reduction in speed from the motor involved a considerable amount of gearing or a large ratio, it did take a tremendous pull on the driven chain to have any appreciable effect upon the lag in the motor, so that on slow-moving jobs the difficulty was even greater. On fast-moving jobs it was easier to get proper distribution of load per drives.

Another form of multiple-drive application is one where all drives are driven from a single motor with possibly a Reeves for varying the speed and the power being transmitted by means of a shaft to several drive units. The first obvious limitation of this is that the drives must be reasonably close together, in order to be able to connect them mechanically. The second objection to it is that in a long conveyor any 1000 pitches of chain will vary in its total length quite a little from any other 1000 ft. of chain in the conveyor. This is due to wear, strain, or general conditions, and it inevitably works out that certain lengths of the chain, which correspond to the same number of pitches in another part of the chain, will be shorter or longer. Inasmuch as the individual drives turn the chain, pitch for pitch, being mechanically connected, when a certain part of the conveyor chain is between two certain drives, it may have a very slack or loose condition of the chain, while this same section of the conveyor, when it has passed by one drive and is now between another set of two drives, may be tight. In long conveyors this slack frequently amounts to several feet. If the slack is taken out at the point where it occurs between two certain drives, when the conveyor is started up and that conveyor chain passes beyond one of those drives, there being so many less pitches in that section than there was before, the system tightens up and breaks the chain.

The only safe solution when such a condition occurs in a conveyor is to break up the main conveyor chain into small units, and redistribute them, so that any 500 or 1000 ft. of it equals any other 500 or 1000 ft. in length. This is a difficult job and requires considerable expense, and has to be done from time to time. Also careful adjustment of the drives has to be made frequently.

Another type of drive for handling this problem is the synchronous-motor type of drive which electrically holds the drives together, much in the same manner as when they are mechanically connected, and much of the same problem is presented. The difference in pitches of chain frequently causes one drive to pull against the other or introduces very heavy initial tensions between drives, due to shortness in pitch. Actual tests with a dynamometer chain-pull measuring device have been made on such drive constructions and have proved this point.

With the floating type of drive, which has been described in the paper, and which we designed to meet this particular problem, when the strain occurs on an individual drive, due to any condition, the drive pulls back against the springs, which slows up its speed and relieves its tension, and as it were "passes the buck" on to the next drive that otherwise would try to take it off. It thus operates to even up the pull on the chain at any one point. One of its most important factors, however, is that the pull is always against springs, which give under shock, particularly in connection with long systems where possibilities of foreign obstacles may occur. Sudden stoppages of a conveyor while in motion put great strains on drives, even though shear pins are present. While coming up against the spring the shock is cushioned. All of this makes for longer life of the system.

Then there is the additional factor of safety of the limit switch which operates when the spring is fully compressed, shutting off the power on all drives. The system described also has the advantage of making it possible to vary the speed of the whole

[2] President, Jervis B. Webb Company, Detroit, Mich. Mem. A.S.M.E.

system. Also, the drive, being of the caterpillar type, permits of placement at practically any advantageous spot on the conveyor system.

In other words, a boost or a pull can be introduced at any desirable spot on a conveyor by the use of such a system. One interesting use of this is on long inclines. One of these floating-booster type of drives is inserted part way up the incline, and the springs are adjusted to take a certain amount of the pull, thus operating to reduce the total strain of the chain by one-half, or whatever amount is desired at this point.

Handling Bulk Materials Mechanically

By WILLIAM W. SAYERS,[1] CHICAGO, ILL.

The paper outlines the general characteristics and fields of applicability of the numerous types of mechanical handling and conveying equipment. It also covers the types commonly used for handling such bulk materials as coal, coke, sand and gravel, crushed stone, lime, cement, phosphate and fertilizer, grain, cottonseed, sugar, earth, foundry sand, etc. No attempt has been made to cover overhead cranes and hoists, crawler and locomotive cranes, and such dock handling equipment as bridge tramways, unloading towers, lift-type car dumpers, etc., all of which are also used for handling bulk materials mechanically.

HOW can the average purchaser intelligently select, from the many types and sizes of conveyors, the one type that is the best and the most economical under the worst conditions of service? The answer is that no two plants are alike and neither are the handling conditions, and that the buyer should seek the expert counsel of the conveyor manufacturer or of a consulting engineer who has had a wide experience in the application of equipment of this character.

The manufacture and satisfactory application of conveyors is a business in which the owners of the business gain valuable engineering experience with the years. The longer they have been in the business and the more applications they have made and the more conditions they have met, with perhaps resulting grief, that much better should they be fitted to engineer and install a conveying system that will be a credit to all concerned, with everything considered, such as efficiency, dependability, and ultimate economy.

Seemingly expensive engineering usually means work by more experienced engineers and a good general design based on a real study of the requirements. This is important because there is often a question at first as to whether, for a specific installation, a bucket elevator is better than a skip hoist or whether the horizontal movement should be by drag or by apron, by belt, or by a screw conveyor, or whether one conveyor can be made to serve the purpose better, within the space available, than separate vertical and horizontal units.

Good engineering will insure rigid and dependable supports to carry the machinery so that it will stay in line and so that it will be safe and accessible for painting and for cleaning and oiling, all of which means less ultimate cost and longer life. There should be paths of travel that are economical, chutes that will not clog, and clearances that are safe.

Good engineering extends to every detail of a conveying system, and especially considers the nature and size of the material to be handled, whether it is sticky or abrasive, and the manner in which the material is to be fed to the system.

The selection of the proper types and combinations of conveyors is an engineering problem that cannot be solved by the use of any set formulas; but data are given farther on which it is hoped will be of some help and guidance to those who are seeking to obtain reliable information on the subject or who have occasion to design, operate, supervise, or maintain equipment of this kind.

The commonly known bulk materials and other materials that some may not realize are mechanically conveyed to the extent indicated are treated under individual sections of the text, such as grain, sugar, etc., in an attempt to give specific information or concrete examples of handling, along with the necessarily more or less general statements made in the section immediately following.

Types of Conveyors and Their Application

Under this heading will be covered (1) belt conveyors, (2) skip hoists, (3) trolley bucket conveyors, (4) screw conveyors, (5) apron conveyors, (6) flight conveyors, (7) drag conveyors, (8) chain and bucket conveyors, and (9) power hoes.

Belt Conveyor. The belt conveyor is especially well suited to the conveying of large quantities of bulk materials, such as coal, sand, ores, clay, coke, chemicals, pulpwood chips, etc., at a low cost per ton, due to its small power consumption and to the large capacity that results from its continuous delivery of material at a relatively high belt speed.

The principal elements are the rubber-covered conveying belt, the troughed multi-roll idlers over which the belt moves in the carrying run, the straight rolls over which the belt returns in the bottom run, the end pulleys, and the driving machinery.

When the material is not to be discharged over the end or when it is to be delivered into bins or bunkers at various points along the conveyor's travel, a traveling tripper is used. This tripper supports the belt and raises it sufficiently for the material to be discharged through the tripper's one-way or two-way chute to the storage or to floor below.

Belt conveyors are installed horizontally or at inclinations up to 18 or 20 deg. therefrom, or both horizontally and inclined, but it should be borne in mind that steep inclines are to be avoided, as the material will start to roll back and the belt-carrying capacity is reduced. Therefore, when the material must be elevated to a considerable height, the belt conveyor may be out of the question due to insufficient space or length being available within which to make the grade, and because of the first cost resulting from the additional length and height of framework needed. Trippers are used only on horizontal sections.

The conveying belt may be from 12 in. up to 60 in. wide, may operate at 300 ft. to 600 ft. per min. (or faster when handling grain), and have its carrying-run supporting idlers spaced 3 ft. to 5 ft. apart, depending upon the capacity required, the size of lumps, and the weight of the material per cubic foot. The return idlers may be 9 to 10 ft. apart.

---

[1] Chief Engineer, Link-Belt Company. Mem. A.S.M.E. Mr. Sayers is a graduate of the University of Illinois, with the degree of B.S. in Mechanical Engineering. His experience includes the apprenticeship course in the shop drafting room of the Chicago & Alton Railroad, Bloomington, Ill.; heating and ventilating draftsman, Treasury Department, Washington, D. C.; heating and ventilating draftsman, D. H. Burnham & Co., architects, Chicago, Ill.; Link-Belt Company from 1903 to date, in the following capacities of draftsman, one year; superintendent of construction, erecting, and operating the various types of equipment manufactured by this company, six years; sales engineer, twelve years; chief engineer, Philadelphia, three years; chief engineer, all Link-Belt plants and subsidiaries for the past five years.

Presented at the "Three-M" (Management, Materials, Maintenance) Congress held in Cleveland, Ohio, April 13 to 17, 1931, under the auspices of the A.S.M.E. and the S.I.E.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The use of the belt conveyor has advanced very rapidly during the past five years due to the perfection of anti-friction idler rolls, thus prolonging the life of both the rolls and the belt and further reducing the amount of power required per ton of material handled.

Today's idler is equipped with tapered roller bearings and with grease reservoirs that need to be recharged at but very infrequent intervals by a grease gun. Attention to maintenance is reduced to a minimum. Accurately made, well-balanced, well-lubricated, free-turning rolls result in long life of the whole equipment.

FIG. 1 ANTI-FRICTION BELT CONVEYOR HANDLING SAND OR GRAVEL

Grease seals are important, to keep the grease in the reservoir and the dirt and grit out and away from moving parts.

Skip Hoists. In its simplest form, the skip hoist consists of a rectangular bucket running on vertical or inclined tracks, a hoisting cable, and a hoisting machine. It has few moving parts, is easy to operate, and is very dependable.

The skip hoist plays an important part in the handling of materials, and has been used extensively in mining operations for generations. It has always been the standard means for feeding blast furnaces, a service for which it is peculiarly adapted, not only because it delivers accurately measured charges at definite intervals of time, but by reason of its reliability.

The skip hoist is well adapted in general for high lifts and to such uses as these:

(1) Storage of coal in high bins
(2) Elevation of ashes in boiler plants where large clinkers are produced
(3) Handling any large or coarsely broken material, as well as fines
(4) Lifting abrasive or corrosive materials, since only the loader and bucket are in contact with the material handled.

The skip hoist may be classified in three ways: (1) Single bucket with no traveling counterweight to offset the dead weight of bucket; (2) single bucket, counterweighted; and (3) two buckets, one balancing the other and ascending while the other is descending.

The electrical control is either entirely automatic, semi-automatic, or non-automatic, depending on the requirements.

The loading of the bucket or skip may be accomplished by hand shoveling or by dumping material into a hopper fitted with a hand-operated discharge-regulating gate or through an entirely automatic loader attached to the bottom of a storage hopper.

The automatic loader may be of (1) the damming type, the bucket continuing to be hoisted and lowered whether or not there is material in the hopper; (2) the full-bucket-control type, causing the bucket to be hoisted when filled, and to remain inoperative when empty or only partially filled; (3) the weight-of-load-in-bucket type, permitting a certain predetermined weight of material to flow into the bucket; or (4) the measuring type, loading the bucket with a fixed volume. In all cases the ascent of the skip closes the discharge gate of the automatic loader, the loader's counterweights holding it in the closed position until contact of the bucket in its descent has again moved the loader into the automatically discharging position.

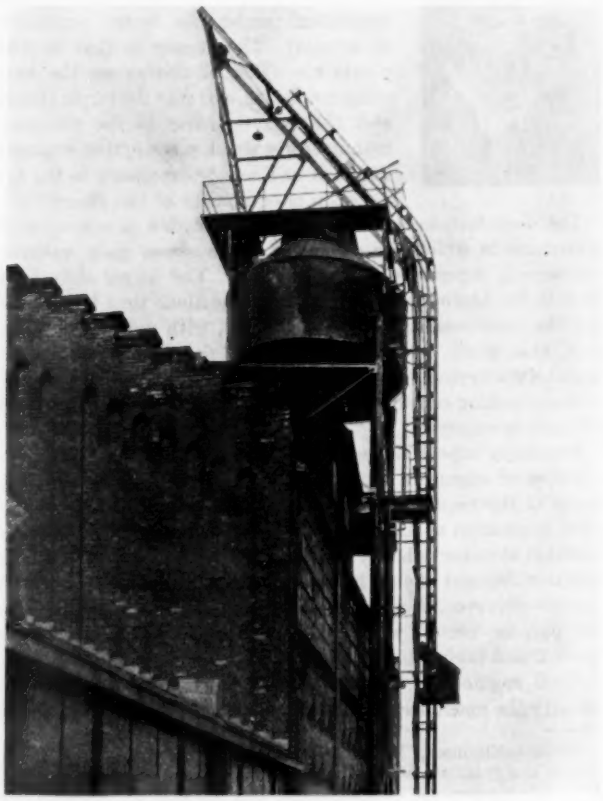

FIG. 2 SKIP HOIST

The machine's electrical control prevents overtravel of the bucket and is arranged to shut off the power when excessive slack has accumulated in the hoisting cable. The bucket may have a holding capacity of 20 cu. ft. up to 150 cu. ft. or more. The normal cable speed may run from 40 ft. to 450 ft. per min. or more, in the handling of such materials as coal, coke, ashes, limestone, gravel, etc.

Trolley Bucket Conveyor. The trolley bucket conveyor is a form of skip hoist, and since it has thus far been used primarily in retail coal yards, it is further discussed under the section, "Retail Coal Yards."

Screw Conveyor. The screw conveyor is used to excellent advantage in the conveying of such small-sized material as grain, cement, cottonseed, and its by-products, pulverized coal, sand, salt, starch, rice, sawdust, sugar, etc.

Screw conveyors are low in first cost, being exceedingly simple in construction and requiring very little head room. The conveyor consists of a spiral mounted on a central shaft or pipe and serves to "screw" or push the material ahead in the all-steel or wooden steel-lined trough in which the spiral is rotated by suitable driving machinery, and from the top of which trough the ends of the 8-, 10-, or 12-ft. sections of standard conveyor are supported at intermediate points by means of hanger bearings.

The diameter of the conveyor or spiral may be as small as 3 in. and as large as 24 in. in diameter. The material is discharged either over the end of the conveyor trough or through gates fitted in the trough's bottom where desired. Sometimes there are simply discharge holes, with no gates, with the result that the coal, for example, discharges through the first opening until the height of pile reaches and closes up the hole. Then the

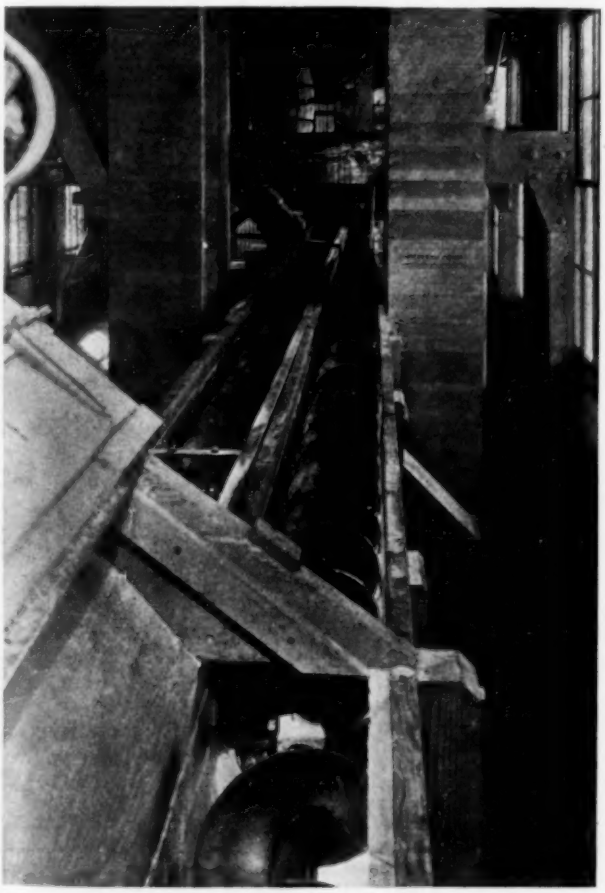

FIG. 3 SCREW CONVEYOR

discharge will be through the next hole in the trough, and so on until the storage is full.

Screw conveyors are used for moving materials horizontally or at slight inclines not exceeding about 10 deg. As a rule their use is confined to the lighter classes of service; and when employed for conveying ashes or other abrasive materials tending to cause rapid wear, the screw and the trough ought to be constructed of cast iron, manganese steel, or heat-treated steel.

The screw conveyor is used quite often at sand- and gravel-washing plants as a dewatering device. The screw has a scrubbing action on the sand and keeps the loam and other foreign matter in suspension, to be carried away in the overflow. Thus a clean and dry sand is secured for use where the specifications and inspection are rigid.

The screw conveyor can often be placed in close quarters where other forms of conveyors could not work.

Apron Conveyors. Apron conveyors for handling bulk materials, such as coal, sand, crushed stone, etc., are usually con-

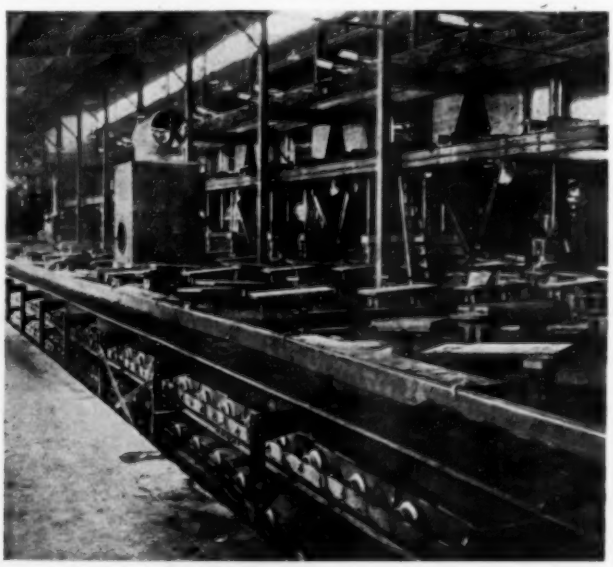

FIG. 4 STEEL APRON CONVEYOR IN THE FOUNDRY

structed with two strands of roller chain traveling on suitable tracks in both the top and bottom runs—overlapping steel pans tying the two chains together and serving as the apron on which the materials are conveyed. Stationary retaining sides or skirt boards are used to permit a greater depth of material to be carried.

Apron conveyors make excellent feeders from coal-track dump hoppers to other conveying media or to a crusher if it is a case of receiving run-of-mine coal and reducing the large lumps in size before the coal is delivered to the main boiler-house conveyor.

Apron conveyors may be installed either horizontally or at inclines up to 26 deg. Owing to their substantial steel construction, the pans will withstand the shock of dumping heavy masses of material on them. As the conveyor operates at a slow speed, usually from 20 to 100 ft. per min., the maintenance cost is low.

In the metal-mining field especially, a very rugged and different form of apron feeder has, of necessity, come into use, as lumps up to 6 ft. in dimension and weighing a ton are sometimes dropped to the pans from a relatively considerable height. To meet such conditions, the pans, the chains, the supporting rollers, and the sprocket wheels, all are made of manganese steel and of a very rugged design. This heavy-duty ore feeder is further discussed under the section, "Ores," in the subdivisions, "Iron Ore" and "Copper Ore."

Flight Conveyors. The flight or pusher type of conveyor was developed as a means for distributing coal and other non-abrasive materials horizontally or elevating at angles from 0 deg. to approximately 45 deg. The material is received in a trough, pushed along by flights attached to the chain at intervals, and usually discharged through openings in the bottom of the trough, being provided with gates to be opened or closed as the conditions

require. In the early days the flight conveyor was made only with a single strand of chain, the flights being fastened to it centrally, and usually made of malleable iron with a thickened scraping edge, as well as with wearing pads for sliding the flights on steel tracks on the return run. In the flight conveyor, the bottom run does the conveying.

The need for greater capacity was met by providing two strands of chain attached to the ends of the flights. A further improvement is the use of rollers suspending the chains and flights, instead of permitting the latter to drag on the bottom of the

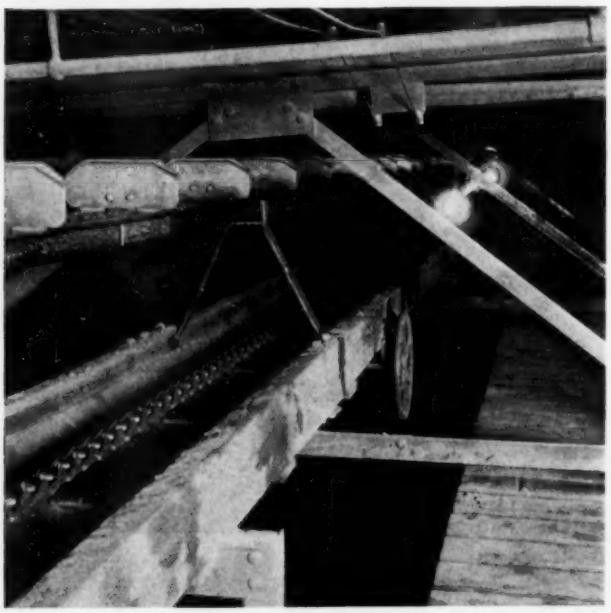

FIG. 5 SINGLE-STRAND SCRAPER FLIGHT CONVEYOR

trough; also the use of double strands of chain with rollers at the articulation points, to carry the chains and flights.

The flight conveyor is a useful type that has been much used in retail coal pockets over the bins; and at the smaller power plants for receiving coal from track dump hopper and stocking it out alongside, and for distributing coal throughout the length of overhead bunkers.

It is used a great deal where the conveying must be done at greater inclinations than 20 deg., the maximum inclination at which a belt conveyor ordinarily can be used. The height of a belt tripper might also preclude the use of a belt conveyor and make the flight conveyor the best suited where the available height is limited and where it is desired to discharge the material at various points.

The flight conveyor is not expensive in first cost, but should be avoided for handling abrasive materials, such as ashes and sand, as the sliding or scraping action rapidly wears the trough lining. The conveyor operates at speeds up to 150 ft. per min., and is suitable for either lumpy or small materials.

Drag Conveyors. Drag chain conveyors are nothing more than one or more strands of chain of suitable type, sliding along in a trough and carrying the material along. Such conveyors are used a great deal for conveying sawdust.

The cast-steel drag chain often used in conveying hot or cold cement clinker, a very abrasive product, has broad wearing surfaces on upper and lower sides. When worn on one side, the chain's useful life can be renewed by turning it over in the trough and using the other side. The head of each link acts as a pusher for conveying the material.

Drag-chain conveyors should be operated slowly to keep the wear to a minimum.

Chain and Bucket Conveyors. Under this caption will be considered the centrifugal-discharge, perfect-discharge, continuous bucket, gravity-discharge, and pivoted bucket carrier types.

Centrifugal-Discharge Bucket Elevator. This usually consists of malleable-iron buckets spaced at intervals on a strand of chain, and operates at a speed of 200 to 300 ft. per min. The material (coal, ashes, etc.) is delivered into a boot, from which it is scooped up by the buckets, elevated, and discharged or thrown by centrifugal force, while passing over the head sprocket, into a chute usually leading to a bin or a distributing conveyor. Although one of the earliest types, it is still an ideal bucket elevator for nominal capacity, for handling material that does not have very large lumps, and where the operation is intermittent.

Perfect-Discharge Bucket Elevator. This uses two strands of chain and has its buckets attached thereto at intervals. This type operates more slowly than the centrifugal type and has a pair of idler sprockets on the return side just below the head wheels, to deflect the chains and completely invert the buckets, thereby effecting a perfect discharge. Because of its slower

FIG. 6 DRAG-CHAIN CONVEYOR CARRYING SAWDUST

pick-up and discharge, the perfect-discharge elevator results in less breakage of friable lumps in the material elevated. When used on an incline, the deflector sprockets may be omitted.

Continuous Bucket Elevator. This is made up with steel buckets fastened continuously and very close together, on one or two strands of chain or on a rubber or canvas belt.

The flanged front of each bucket forms a chute for the discharge from the succeeding bucket, thus effecting a clean discharge at slow speed. This slow speed, with the use of a feeding leg, permits feeding the material directly into the buckets, thus avoid-

ing the wear and strain of digging through an accumulation of crushed stone, ore, coal, or other material of a bulky or gritty character, in an elevator boot, besides reducing breakage of the material elevated and prolonging the elevator's life.

The bucket speed is usually about 100 ft. per min. and up to 200 ft. per min. The continuous bucket elevator is more expensive, but has greater capacity at slower speed than either the centrifugal or the perfect discharge types. It is more expensive because more buckets are required, and the chain and driving machinery must be heavier to carry the greater load and to handle the same quantity in a given time.

The continuous bucket elevator was developed to fill the need for a better elevating unit than the centrifugal-discharge type, and is popularly used in stone quarries for elevating crushed stone into bins.

As the discharge is by gravity and not by centrifugal force, the efficiency or effectiveness of discharge is not particularly dependent upon the speed of the elevator and the speed of discharge.

Gravity-Discharge Bucket Elevator. As the conveying and elevating art progressed to the point where the foregoing types of bucket elevators had been developed for elevating and the flight conveyor for distributing materials horizontally or at inclinations up to 45 deg., engineers appreciated the desirability of a single unit for accomplishing both the elevating and distributing operations. The gravity-discharge elevator was designed and built to accomplish this purpose and has come into wide use.

It consists of steel buckets, approximately V-shaped in cross-section, attached at intervals between two strands of chain. Coal or other material is received in a boot, from which it is scooped up by the buckets in passing around the foot wheels, and is elevated to the desired height, where the buckets turn around wheels from a vertical to a horizontal position. The buckets then push the coal along a steel trough and discharge it through gates or openings to an overhead bunker, storage, or other conveyor, as conditions require.

Frequently, coal is discharged or withdrawn from bunkers or storage into the lower horizontal run of the conveyor, pushed along and picked up by the buckets as their travel changes from horizontal to the vertical direction, then elevated, diverted, and then shoved along the upper horizontal run for distribution to desired points.

An advantage of this type of equipment is that the material can be carried at any inclination, varying from horizontal to vertical, as the buckets will carry and convey the material at angles too steep for flight or belt conveyors.

The buckets may be spaced from 18 to 48 in. apart and vary in size from 12 in. by 12 in. to 48 in. long by 24 in. wide, a normal conveyor speed being 100 ft. per min. Malleable chains are used for the smaller sizes of buckets and heavy steel chains for large capacity installations.

This type is not adapted for handling ashes or abrasive materials, which cause rapid wear of the steel trough linings, but is admirably suited for the handling of hard coal as the pick-up in the boot is slow, and in discharging, the material is allowed to slide gently down a chute, instead of being thrown or dropped. This lessens breakage of the material handled. The machine is flexible in its applications, with special reference to the paths of travel that can be arranged, and it is very reliable in operation.

It is used in retail coal pockets, locomotive coaling stations, power houses, etc.

Pivoted Bucket Carrier. This is so called because each bucket is pivotally suspended between two strands of chain, and maintained in the carrying position by gravity, thus permitting a single carrier to transport material horizontally, vertically, and again horizontally, or in any desired path within a vertical plane of travel.

The advantages of the pivoted bucket carrier may be named briefly, as follows:

(1) The material is carried and the bucket line is supported by rollers of large diameter. Destructive friction and the power required for operation are reduced to a minimum.

(2) Using one machine to both elevate and convey avoids transfers which are often troublesome, take up valuable space, and necessitate deep pits. In addition, only one driving unit is required.

FIG. 7 UPPER HORIZONTAL RUNS OF TWO GRAVITY-DISCHARGE BUCKET-ELEVATOR CONVEYORS

(3) The material handled is automatically discharged on the horizontal runs at any desired point, by a mechanical dumper, and it is only at the dumper that the position of the bucket changes from its original upright position during the entire cycle of operation.

(4) The buckets are overlapping in the horizontal runs, and either right themselves or are righted by a separate device, after having been turned by the mechanical dumper and discharged of their contents. The manner of righting the buckets depends upon the make of the carrier.

(5) Slow speed, quiet operation, with practically no vibration. This results in long life of the conveyor.

Long pitch chains having links made of malleable iron for ordinary installations and of forged steel for very high lifts are used. The chain pitch may be either 18, 24, 30, or 36 in. The buckets have the same pitch as the chain and are from 15 to 36 in. wide, depending upon the capacity required. The chain joint is usually constructed with case-hardened steel pins and bushings and large-diameter enclosed-oiling rollers with chilled or flint-rim treads. The conveyor speed may be 40 ft. per min. and up to 80 ft. per min.

Portable Loaders. Conveyors may be further classified according to whether they are portable or stationary.

The portable loader is very popular for the loading of trucks with bulk materials, such as coal, sand, coke, borings, etc., and is made with either a belt, chain and flight, or chain and bucket elevating medium. Each type has its uses. The belt and flight types are also employed for unloading hopper bottom cars of coal, sand, etc., piling the material alongside the track or delivering it to trucks.

The majority of these portable loaders are hand moved on their

four wheels, while for the larger capacities the moving mechanism is a power-operated crawler of regular crane or tank type. This larger-capacity loader has a platform on one side, on which the operator stands, and from this position he controls the various functions of the machine by the convenient manipulation of hand levers.

The hand-propelled machines are pushed close to pile, and require that the material either be shoveled on the foot end or if the machine has been pushed hard enough into the material, it may merely be necessary to assist the flow of the material with the aid of a shovel. In this latter case no actual shoveling is required. The crawler loader has a self-feeder, and crawls under power as it digs and as it loads.

Power Hoe. The power hoe, or drag scraper, is a simple conveyor which has proved its ability to save time and money in the handling and reclaiming of various bulk materials into and out of storage piles.

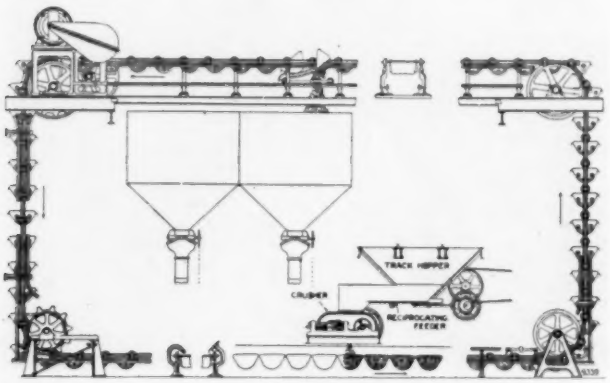

FIG. 8 PRINCIPLE OF OPERATION OF PIVOTED BUCKET CARRIER

The hoe or scoop is operated to and fro by means of a double-drum-friction or geared engine, a wire rope, and properly designed sheaves supported on posts or other form of anchorage. With it one man can store or reclaim most bulk materials at any normal capacity per hour. Used in conjunction with an elevator or loader to trucks or cars, large areas of storage can be reclaimed, and at a very small cost per ton. The system lends itself especially well to irregularly shaped property.

A man in an operator's house operates the engine by hand lever, thus working the full or empty scoop back and forth.

ROTARY RAILROAD-CAR DUMPER

Unloading a flat bottom car of coal or other bulk material by hand shoveling is slow and expensive work at any time, and much more so in winter, when laborious use of a pick is often necessary in breaking up frozen masses.

Unloading hopper-bottom cars through their doors to track hopper is less expensive than unloading flat-bottom cars, but when the car gates are not working properly, as often happens, or when the car is in bad order, and gates have been nailed up to prevent leaking, there is considerable delay, expense, and loss in the normal unloading capacity rate.

A crane with grab bucket may reduce unloading expense and delays, but will require cleaning up by hand, at the corners and sides, and where crossrods are used in hopper cars, they cause much inconvenience and delay. Of course the crane has its application, but under conditions where the capacities are great enough to justify a car dumper, it is obviously more economical to employ a dumper.

Various types of car dumpers have been used successfully for many years on the principal loading docks, both on the Great Lakes and the Atlantic Seaboard, where the rapid loading of vessels is of paramount importance. For the most part these installations have been costly. One reason for this is that in most cases vertical lifting was required. The handling of a large volume of material continuously was necessary, in order to effect economies.

With the development of the rotary dumper the economies of the lifting type of dumper have been brought within the reach of those whose unloading requirements are fairly low.

It turns the car of coal, ore, or stone practically upside down, and the discharge is orderly and immediate, winter or summer, for all types of open-top cars from the smallest to the largest.

The number of cars this dumper can handle per hour or per day depends principally on the switching and track facilities for supplying loaded cars and removing empties. The full cycle of dumping and return to normal position is accomplished in $1^1/_4$ min. The whole operation is so simple, automatic, and foolproof that unskilled labor can perform it readily; it is completely under control and observation at all times, and can be stopped instantly at any point of the cycle.

An interesting marine coal-loading plant is that operated by the Louisville & Nashville Railroad at Pensacola, Fla. While designed primarily to handle cargoes of coal, doing so at a high rate of speed from railroad cars direct to ship without provision for intermediate storage, this dumper and ship-loading elevator have also handled cargoes of other bulk material, such as gravel, stone, and bulk pitch.

The large or super power houses must unload their coal quickly and cheaply. There dare be no delay due to shortage or to freezing of coal in cars. An interesting example is the rotary dumper in use at the Cahokia Station, St. Louis. Placed in service on Nov. 22, 1923, it was taken out of use for its first major repair on July 23, 1928, after having dumped 1,822,360 tons, or approximately 36,450 cars of coal of 50 tons each.

In order to get the 1700 tons of coal per day into the plant for a period of eight days, it was necessary to use the special emergency hoppers for unloading drop-bottom cars. A crew of eight men and the car dumper can handle the 1700 tons per day in one 8-hour shift; but with the dumper out of service for eight days, it required two extra shifts of ten men each, in addition to the regular crew of eight men, working three 8-hour shifts per day to do the same work. Thus we get a good idea of the efficiency and the money- and time-saving characteristics of equipment of this type.

SELF-UNLOADING SHIPS

A number of self-unloading ships are in use on the Great Lakes for transporting and discharging large quantities of raw materials in bulk, such as sand, gravel, cement, limestone, and coal.

The economy of this handling unit lies not only in the efficiency and dependability of its conveying and discharging equipment, but also in the fact that these vessels usually carry a full cargo going and returning, and their use makes it unnecessary for the receiver of the cargo to invest in expensive dock unloading equipment, such as a grab-bucket unloading tower or bridge tramway, since the vessel itself contains the necessary unloading machinery. The cargo may be limestone from the Northwest to the steel-mill district, and coal on the return trip.

The records on one of these vessels show that in the year 1930 its average unloading rate was 1374 tons of stone per hour and 964 tons of coal, this including all the delays and being figured practically from the time the vessel tied up at the dock until it cast off.

Each side of the ship is equipped with a steel pan conveyor under the cargo holds, with hand-operated slide gates at suitable intervals. The desired gates are opened wide, and beyond seeing

that the cargo is flowing to the conveyors, the handling system requires no further attention once it has been started. The two pan conveyors operate slowly, and up an incline at one end, sufficiently steep to discharge the material sidewise to a centrally located continuous bucket elevator, which in turn delivers to a belt conveyor mounted on the vessel's hinged, power-swung unloading boom. This boom conveyor delivers the material direct to the customer's dock or yard, the boom usually being swung out over the side of the boat in time to start unloading the ship's cargo the moment the vessel gets to the shore. A maximum of only about 200 hp. is required for driving all conveyors.

The discharge rate of another of these vessels is said to be in excess of 2000 tons of stone per hour. Belt conveyors and power-operated regulating gates are used under the cargo holds. To keep the belts fully loaded and attain the large handling capacity mentioned, it is necessary to handle the gates constantly.

The apron conveyor moves slowly, carries a deep load, and serves as its own feeder. The belt conveyor operates fast, carries a thin stream, and requires regulation of the feed of material to it.

Quite a number of old boats have been converted into self-unloaders by building two or more tunnels into the bottom of the regular hold, and operating a drag scraper or power hoe back and forth in each tunnel. The scraper may deliver through a hopper, to an inclined belt conveyor delivering to the belt conveyor on the boom.

Self-unloading ships can serve economically the docks which, through lack of adequate and fast enough unloading facilities, have been unable to attract the large ships with low freight rates.

The self-unloading ship keeps its rates down by carrying cargoes going and returning, and by its ability to receive and discharge cargoes at intermediate points or points beyond the regular course that a vessel, not self-unloaded, would be obliged to follow in order to take advantage of the use of dock unloaders.

Terminal Handling of Grain

Today's modern terminal grain elevator, with holding capacities up to 11,600,000 bushels of grain, is equipped with machinery of large capacity to insure rapid handling. There are elevator legs handling as much as 25,000 bushels an hour and scale hoppers weighing 2500 bushels of grain at a time.

At the smaller grain elevators, box cars are unloaded by power shovels into a receiving hopper feeding the elevator.

The large elevators employ the automatic tilting type of grain-car unloader, which is capable of unloading any size car of wheat, oats, or corn in 6 or 7 minutes.

This machine, besides doing the unloading much faster and at a greatly reduced labor and operating cost, effects a further saving by automatically removing the grain doors without destroying them, so that they can be used over and over again, thus avoiding the usual delay for this operation and the expense of repairing damaged doors.

As one unloader will do the work of seven hand pits, there is a substantial saving, due to the use of the former requiring less property, a less expensive trackage layout, a smaller track shed, and a simpler and less costly work house.

The loaded grain car is spotted on the platform of the unloader, with the outer door of the car open on the dumping side. As the disappearing end clamps are brought into position in contact with the car couplers, the car is automatically centered, and two platform locks are disengaged to permit tipping the car sidewise.

The door opener automatically removes the grain door as the car is tipped sidewise 15 deg. The platform is then tipped endwise to a maximum angle of 40 deg. in both directions, and the car load is discharged into a suitable receiving hopper.

After the car has been emptied, the unloader is returned to its normal position, the empty car is removed, and another car is brought on for unloading.

From the track receiving hopper the grain is fed either direct or over a short belt to the boot of the elevator leg, which consists of a centrifugal-discharge belt-and-bucket elevator traveling at a high speed—from 400 to 800 ft. per min., depending upon the type of buckets and the size of pulleys used.

The elevator leg discharges into a garner, or large concrete storage hopper, equipped with a number of gates for rapid dis-

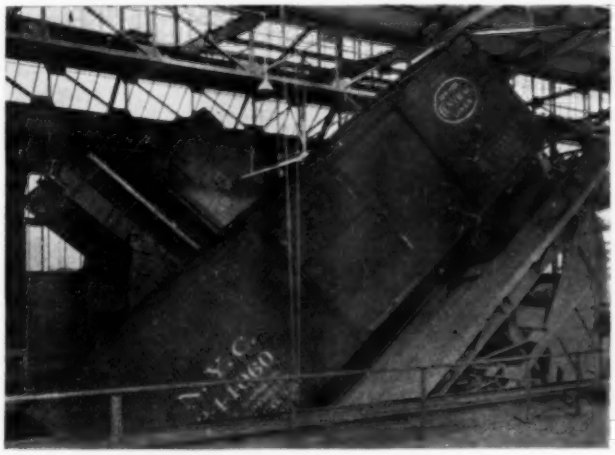

Fig. 9 Grain-Car Unloader

charge into the scale hopper. A car can be unloaded and its contents passed to the scale. Then while it is being weighed and discharged, another carload can be unloaded and elevated to the garner.

If the grain is to be cleaned, it is spouted to the headhouse bin and from there to the cleaner, or direct to cleaner from the scale hopper. After cleaning, it is elevated, weighed, and passed to storage. Grain is delivered to storage by means of a gallery belt conveyor, with a traveling tripper, which runs the length of the tanks.

Grain-handling belt conveyors operate with the belt flat or very nearly so; i.e., there is very little troughing of the belt. A flat belt has a good contact with the horizontal idler pulleys and will run straight, empty, or loaded, or even loaded to one side of the center. Grain carefully fed to a flat belt will not tend to shift toward the edges and spill, but to prevent scattering at the loading points and to increase the carrying capacity moderately, it is customary to use inclined concentrator pulleys at the loading points only, or at 10- or 12-ft. intervals along the length of the conveyor.[2]

In modern practice, wheat and corn are carried at speeds up to 800 ft. per min. on belts 36 in. and wider, but on belts less than 20 in. wide the speed should be less than 500 ft. per min.[3] The main reason for this is that in chutes suited to wide belts the flow of grain is rapid and regular, and the belt can be loaded full, but in narrow chutes the flow is not so fast and even, and the narrow belt running faster than 500 ft. per min. will not take a full load nor will the loading be uniform along the run of the belt. Oats, bran, and flour have to be conveyed more slowly to keep from being blown off the belt by air resistance.

The capacities of grain belts with concentrator pulleys at intervals are given by three manufacturers, in bushels per hour, at 100

[2] Hetzel's book, "Belt Conveyors and Belt Elevators," p. 9.
[3] Ibid., p. 155.

ft. per min., as 1.75 W^2, 2.2 W^2, and 2.5 W^2, in which W is the belt width in inches.

Grain is drawn out on a lower belt conveyor, elevated, weighed, and then spouted to cars. Generally, the large houses load in on one side and reload on the other for shipment. The car-loading capacity of most elevators today is approximately 25,000 bu. per hour per spout. Two spouts are generally used.

Often grain is received with a high moisture content. To keep this grain from getting hot or burned, it must be turned over, so the grain is drawn from bin, handled on the lower conveyor, elevated, and discharged back to the gallery conveyor for delivery to storage. Frequently an extra leg, known as the "turning leg," is installed to handle this work, so that the process of loading and unloading will not be disturbed.

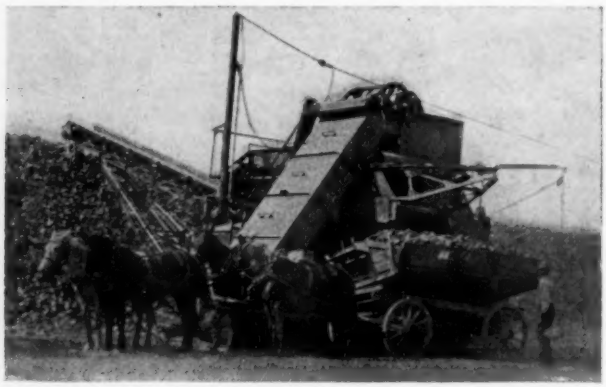

FIG. 10 PORTABLE BEET PILER

When grain is unloaded from boats to elevators, the "marine leg" is employed. This is mounted adjustably so that the foot of the elevator can always reach the grain to be unloaded.

The screw conveyor also is well adapted to the handling of grain, and finds many ideal uses in grain elevators of all sizes.

The 1,000,000-bu. capacity wooden-construction grain elevator of 25 years ago, with its maximum continuous unloading capacity of approximately two cars per hour per unloading pit, with three men and one bucket elevator per pit, required a ground area of approximately 20,000 sq. ft., as compared with only about 15,000 sq. ft. needed for today's fireproof concrete-construction elevator of similar holding capacity, unloading eight cars per hour per unloader, with two men to operate the unloader, a third man to attend to moving of the cars, and the use of only one bucket elevator.

The old house of 1,000,000-bu. capacity usually had at least three tracks, with three but sometimes four pits per track. This compares with two tracks (one for unloading and one for shipping) required for a modern elevator of similar capacity, equipped with an automatic unloader and one unloading pit.

HANDLING SUGAR BEETS AND SUGAR CANE

The chief sources of sugar are sugar cane and the sugar beet. The sugar beet is a native of various sections of the United States. Cane is grown most extensively in the West Indies, Hawaiian Islands, Philippines, State of Louisiana, and now to a limited extent in Florida. First, let us consider the beet.

Sugar beets are dug out of the ground before cold weather sets in, the tops are chopped off with a heavy knife, and the beets are thrown in rows paralleling the furrows. They are then forked into wagons or trucks and are transported to a conveniently located beet dump. The beet-slicing season generally lasts 90 to 120 days, and on account of insufficient storage space at the factory, farmers have to unload a good portion of the crop alongside or near the dump.

A caterpillar-mounted portable beet piler and reloader has been developed, consisting of a hoist for dumping trucks or wagons, a hopper for receiving the beets, a very unusual type of conveyor, a rotating-disk grizzly screen, a stacking belt conveyor for delivering the beets to the pile, and a dirt conveyor for loading the dirt back to the farmer's truck. The use of this machine has resulted in the forming of larger storage piles at the dumps than ever before. The reloading into cars is done by means of a grab bucket which operates over the boom that supports the stacking belt conveyor, this conveyor being removed when it is desired to recover the piles.

The advantages claimed for this machine are that there are no elevated structures to drive upon (in other words, a ground-level dump), large capacity, no bruising of beets, good screening and dirt return, higher piling, compactness, portability without loss of time, and minimum number of operators.

One of the latest factories receives the beets through a flume direct from railroad dump hopper. Beets grown nearby and received in trucks are stored in piles by a portable stacking unit as already described, but regardless of whether factory yards store the beets by this method, by a track dump hopper and belt conveyor system, or from parallel elevated railroad trestles, they are stored over concrete flumes covered with boards which are removed when a supply of beets is to be washed into the factory for use.

The beets have to pass through a trash catcher, consisting of two strands of chain with sawtooth bars hanging down into the flume. From there they go over a stone catcher into a beet wheel, consisting of a large-diameter vertical plate with buckets on its outer edge dipping into the flume, to pick up the beets and dump them into a screw paddle washer, called a "beet washer." Now the beets pass over a roller-type screen into the beet elevator, the newest type of which employs two strands of drop-forged rivetless chain with gravity-discharge buckets fastened thereto at intervals by swiveling attachments.

The elevator discharges to a double-strand-chain wood-slat picking-table conveyor. Here any rotten beets, leaves, or refuse remaining are picked off by hand. From the end of the picking table the beets drop through a weighing device and to the knives which slice them into cossettes, or maybe they are sliced first and then weighed.

The sliced beets are carried either by flat belt conveyors or fingered-type flight-conveyors to the diffusion tanks, where the sugar is dissolved under pressure.

The beet pulp, at a number of factories, is pumped to a big outside pond and fed to livestock. Other factories now make it into a pressed pulp. This pressed pulp is handled by screw conveyors and centrifugal-discharge bucket elevators.

The wet sugar from the centrifugals drops into a ribbon conveyor which delivers to a centrifugal-discharge belt and bucket elevator. The sugar then passes to a granulator or rotary-kiln type of drier with lifting vanes to a dry-sugar bucket elevator, to a screen for taking out lumps, to bins, and to the automatic weighing and sacking machines. Portable bag pilers and conveyors are used for piling the filled bags in the warehouse.

As much sugar has hardened in the bags, necessitating reprocessing, the newer factory handles the finished sugar from the screens by screw conveyors either to the sacking bins or to the boot of an elevator which delivers the sugar into a distributing screw conveyor system over immense concrete silos in which the loose sugar is stored, and from which it is withdrawn by screw conveyors underneath the silos to an elevator delivering to the sacking bins.

Let us now see how sugar cane is handled in Cuba, for instance.

The cane is chopped down by hand and stripped of leaves with a long, broad knife, and then loaded into ox carts, many of which are now equipped with caterpillar treads, or tractors. The cane is hauled to the mill if nearby or to a conveniently located bridge-mounted cane hoist and transfer which lifts the entire load after slings have been passed around it, trolleys it over the railroad track alongside, and dumps the cane into side-dump cane cars, usually of about 30 tons capacity, for transportation in train to the mill.

At the mill a side-tilting hydraulically operated dumper serves to discharge the cars to a large hopper over the foot end of a slow-moving feeder carrier of the apron type, which has to carry a tremendous load of criss-crossed cane stalks, sometimes 8 ft. deep. The feeder carrier delivers the cane to the inclined cane conductor, which feeds it to the initial crushing rolls. Cane kickers or levelers are used in some mills, near the head end of the feeder carrier, to help level the cane and provide a more uniform feed to the cane conductor. The leveler shaft has arms fastened to it in staggered positions, extends across the width of the carrier, and is rotated at a slow speed. Power-operated revolving knives, also used in some mills, are very effective in preparing the cane for more effective crushing. There is no appreciable loss of juice due to this cutting operation.

The cane carriers are as wide as the mills, which measure up to 7 ft. wide. The sugar juice is squeezed out by passing the cane through a series of mills, perhaps consisting of one initial two-roll crusher and six three-roll mills in one tandem, totaling 20 rolls.

The cane is carried from one mill to another on intermediate carriers, which are mostly of the steel-apron type. Sometimes a carrier is used consisting of two strands of chain with angle-iron cross flights for pushing the cane along a juice-tight trough over into the next mill.

From underneath the mills a combined juice straining and trash elevator, of specially constructed chain and flight type, scrapes any trash in the juice up an incline and disposes of it through a screw conveyor to the blanket of crushed cane on one of the intermediate carriers. The juice drains back through perforated trough linings and is delivered to the juice tanks by pipes or canals.

The bagasse, or what is left of the cane after the juice has been crushed out, is carried by double-strand chain and flight conveyor to the boiler room where, through rack-and-pinion type slide discharge gates in the conveyor trough and through specially designed feeders the bagasse is fed to the furnaces and burned as fuel. More recent developments, however, are resulting in the use of bagasse as a by-product for the manufacture of cellulose and fiber board.

The juice and sugar are handled through processes similar to those used in the production of beet sugar, excepting that another form of conveyor, called the grasshopper conveyor, named after its hopping, reciprocating motion, is frequently used in the cane-sugar field, under the centrifugals. It has a steel trough (flexibly supported on a series of hickory sticks) along which the operation of its drive serves to jiggle the sugar without crushing or grinding the crystals. It has large capacity, the trough is self-cleaning, and there is no danger of wrecking the conveyor by broken paddles falling into the trough from the centrifugals.

In the warehouse the bags of raw sugar, weighing 325 lb., are usually handled by portable conveyors and stacked to a height of not over 25 ft. by means of self-propelled portable bag pilers of the double-boom type, the discharge height of the upper boom being adjustable by power.

Much of the bagged raw sugar is refined in plants located in the United States. Here more mechanical handling equipment is used.

Methods of Handling Cottonseed

In the South and Southwest the cottonseed-crushing industry is one of the largest fields for the use of bulk handling equipment; in fact, there are far more cottonseed-oil mills than the North has cement, lime, and gypsum plants.

Bulk cottonseed is received largely in box cars from cotton gins, although all mills have facilities for receiving shipments by truck and some of the smaller plants receive all seed by truck, or wagon.

The modern mill may employ a double automatic power shovel for unloading the seed from box cars and discharging it on an inclined belt to the elevator shaft. The belt may operate at a speed of about 450 ft. per min. over anti-friction troughing-type idlers in the carrying run. Along the unloading track a collector screw receives seed which is "broken out" as the car doors are opened, but the bulk of the unloading is done by the shovel at the unloading hopper. A screw conveyor collects the seed received by truck or wagon and feeds it by one of the track screws to the track-unloading hopper.

The inclined unloading belt discharges into a large double-row bucket elevator in the elevator shaft. This elevator in the particular mill in mind has two rows of 12-in. by $6^1/_2$-in. seamless steel buckets bolted staggeredly to a canvas elevating belt, which is driven by a 40-hp. motor. This motor also drives a 20-in. wide canvas, anti-friction troughing-type distributing belt conveyor at a speed of about 500 ft. per min., through the conveyor's tail pulley. A light steel-frame self-propelled cotton-seed tripper, with three-way discharge spout, distributes the seed in the seed storehouse.

One feature of these plants is that all motors are kept out of the storage house proper. For this reason, distributing belts are driven from the foot pulley, and provided at the far end with long-travel horizontal gravity take-ups, weighted sufficiently to accommodate the belt pull and to take up any belt stretch due to wear, tear, and moisture.

The unloading and distributing equipment in the average fair-sized mill is designed to handle at least 50 tons of bulk cottonseed per hour, weight 20 lb. per cu. ft. It is essential that the unloading equipment be dependable and of adequate capacity, since practically all the seed is delivered to storage by the source of supply between the months of September and December.

The larger unloading elevators have belt speeds of around 400 to 450 ft. per min., with head pulleys 36 in. to 42 in. in diameter. The casings in the newer plants are mostly of steel and of single-leg construction. The elevating speed is slower than that of grain elevators, as cottonseed is lighter, bulkier, and not so free-flowing.

The seed unloaded contains quite a little trash and sand, and it is for this reason that belt elevators and belt conveyors are preferred, although screw conveyors are used in plants of smaller capacity or those with comparatively short distributing conveyors.

The seed storage houses as a rule have capacities of from 5000 to 15,000 tons and are built with fire walls dividing the main body of storage into two, three, or more compartments. The distributing belt conveyor and tripper operate through special firedoors which are arranged to accommodate the conveying equipment in the monitor.

For reclaiming seed from storage, an A-shaped structural-steel tunnel is usually provided down the center of the house. On the floor of this tunnel a drag belt conveyor, of 10-in. or 12-in. wide canvas, operates at a speed of around 500 ft. per min. in a 4-in. or 5-in. deep steel trough to which the seed is fed through doors in the tunnel structure, the belt dragging in the loaded run and returning usually over anti-friction flat rollers. The capacities in this operation are less, usually not more than 5 to 10 tons per hour, in line with the capacity of the mill to lint, separate, and crush the seed.

The reclaiming drag belt delivers to a second elevator provided in the tower for discharging the seed to the proper point in the seed-cleaning room or the mill. Here the trash, sand, and bolls are removed from the seed by rotary reels, and by a secondary screening operation over flat, inclined shaker screens, thus assuring longer life of the linter saws and the knives in the processing equipment through which the seed is later passed.

Some of the more modern mills preclean the seed, meaning that they clean it before storing instead of after entering the storehouse—a practice that probably will grow, for it is safer to store clean seed in large volume than wet, trashy seed, which often may generate heat and catch fire. The mill operator also protects himself by cleaning the seed on arrival, since it is possible to weigh the seed as it is unloaded and cleaned, after trash and sand have been screened out. Some seed is very dirty.

The cleaned seed passes on to the linter room in screw conveyors. Here the first-cut and second-cut linters remove practically all cotton lint from the seed, the lint being handled pneumatically to a baling room, while the seed passes through the linters to more screw conveyors, and then to elevators to the hulling and separating room.

In special processing machines the seed is now slit open, and by a series of shaking trays the hulls are separated from the meat or nuts. Here some inclined drag elevators are used.

Screw conveyors carry the hulls to a separate storage building, for use as an ingredient in cattle food. A small feed-mixing plant usually adjoins the hulls-storage building.

The cottonseed meats pass to the roll and press room. The rolls grind the meats to a form suitable for cooking and compressing. From here the meal is elevated and conveyed to the cookers, comprising a series of three or four steam-jacketed kettles, and serving to bring the meal to the temperature required for properly separating the oil from the body of the meal.

The cooked meal passes from the bottom of the lowest kettle to a hydraulic former, which shapes the material into cakes about 12 in. wide by $1^1/_4$ in. deep by 18 in. long, to fit the press boxes. When all the compartments of the presses have been filled, pressure is exerted, and as the box frames are contracted, the oil is extracted—the oil running down the edges of the inclined back side into a large storage tank. Continuous oil expellers have come into use, but the box presses still seem to be the more popular.

After the oil is extracted by the press, the residue of the meal (a hard cake) is broken up in a cake breaker and elevated to a distributing screw conveyor over storage bins. This conveyor is provided with screen discharge chutes, and a rough separation of several sizes of cracked cake is made in the bin compartments.

This cake also is used as an ingredient in the mixed feeds for cattle and as sheep food. For grinding the cake an attrition mill is usually provided in the meal room, together with an elevator and a batching and sacking unit.

For the mill operations screw conveyors and bucket elevators serve very nicely, since the hourly capacity as governed by the presses is not large as a rule.

In the lint and separating rooms vertical screw conveyors have recently been applied with considerable success. However, in the seed-unloading layout bucket elevators will undoubtedly continue to be favored because the capacities are necessarily rather large.

Phosphate and Fertilizer

Phosphate forms a large percentage of the bulk of most prepared fertilizer and most of it comes from Florida. These prehistoric animal remains exist there in vast areas, being of the variety known as pebble phosphate.

It is mined hydraulically, the formations, consisting of sand, clay, and phosphate, being broken down by powerful water jets. The material so broken down is sluiced to a sump, from which it is pumped by centrifugal pumps to an inclined sluiceway 3 or 4 ft. wide and about 40 ft. long, the bottom of which is a plate with longitudinal slots about $^1/_2$ in. long by $^3/_{64}$ in. wide throughout its area. Sand, clay, phosphate, and dirty water pass through the slots to a second sump. The material carried over goes to a revolving scalper screen provided with holes of approximately $1^1/_2$ in. diameter. The grass, lumps of clay, and rock are discharged at the end of the screen and are rejected.

Fig. 11 Portable Bucket Loader Handling Super-Phosphate to Motor-Driven Buggy

The material which has passed through the screens now goes to a log washer, consisting of two cylindrical logs side by side, with projections, and revolving upwardly in the center. The log washer is inclined similarly to a sand washer and breaks up and disintegrates the clay balls which have passed through the scalper screen, the dirty overflow water discharging to the second sump, previously mentioned.

The wet material from the log washer is discharged to a vibrating screen, where fresh water is added. The water with fine material goes to the second sump, while the material passing over the screen goes to a second log washer where the washing process is repeated. The material discharged from the second log washer goes to a finishing vibrating screen of 20 mesh. The material passing over this screen is the commercial phosphate, which is now loaded on small cars and generally run over a trestle about 20 ft. above the ground and dumped to storage below.

There are generally two tunnels under the trestle, containing belt conveyors for reclaiming the stored phosphate and carrying it to the drying plant. The material is dried, and later ground to a fineness about equal to that of cement.

Today's modern plant reclaims enough of the fine phosphate from the clay and dirty water that pass to the second sump from all washing and screening operations to justify the installation of the added equipment—a classifier and another centrifugal pump.

To make the ground phosphate rock more quickly available as a plant food, it is treated with sulphuric acid, forming what is known as super-phosphate. This treatment, at the fertilizer plant, produces a material which if kneaded or rubbed becomes the consistency of putty. Therefore conveyors for its handling are used

as little as possible, the material being preferably carried in cars or carts in bulk.

The various ingredients composing the finished fertilizer, with the exception of the super-phosphate, are stored in bins. The super-phosphate generally is stored in the center of the building in a high pile, and this, as well as the other materials used in lesser amounts, are all trucked by buggies or wheelbarrows to the mixing point. Here the proper proportions are weighed out, and the batch, consisting of the various materials, is dumped to a bucket elevator which discharges to a vibrating screen. The material going through the screen discharges through a hopper and gate to a batch mixer. The lumps in the mixture which do not go through the screen are bypassed back to the elevator and are broken down in this way.

A small-capacity, hand-propelled portable bucket loader, specially constructed to meet the conditions, is used very successfully in certain sections of the large fertilizer plants, as well as in the smaller dry-mixing plants, for loading super-phosphate and other fertilizer materials into buggies which are either hand-pushed or motor-propelled. Its use saves from five to seven laborers; besides, the loading is done faster.

Portable bag pilers and conveyors are used for storing and for handling the filled bags to cars.

Power shovels are employed for unloading the raw materials from the box cars in which they are received.

Sand and Gravel

The handling of sand and gravel from pit to cars usually follows a certain general flow sheet, and consists of an excavator and some means of getting the material to a washing and sizing plant. The material can then be loaded direct into cars or trucks from the bin or delivered to storage for future loading. The type of excavator and conveying equipment is usually determined by the nature of the deposit or by the shape or contour of the property.

For a small plant, handling up to 50 or 60 tons per hour, with a fairly deep deposit either above or below water, or both, a slack-line cableway excavator is sometimes used. This machine consists of a track cable which can be raised, lowered, and shifted. One end of the track cable is anchored at ground level, and the other is attached to a high mast. The mast is usually high enough to permit the bucket to dump into a hopper over the washing screens. The track cable is slacked, and the bucket, carried on a trolley, runs down by gravity to the digging point. The drag line is then pulled forward, loading the bucket. When the bucket is filled, the track line is raised, and the bucket is pulled up along the track cable to the dumping point. This machine serves as both excavator and conveyor.

Where deposits are below water, or both above and below water, and capacities are over 100 tons per hour, a pump may be used to dig the material. If the distance to the plant and the lift to the top of the plant are not too great, the pump may be used to force the material through a pipe line to the top of the washing plant. It then acts as both excavator and conveyor. Where the lift is too great for economical pumping (perhaps over 30 ft.), the pipe line may be carried on a horizontal line at ground level to a sump at the foot of the plant.

A special digging elevator may then be used to dig the material out of the sump and elevate it to the washing screens.

When the deposit is located quite some distance from the washing plant, the sump may be located at a convenient point and a comparatively short digging elevator used, provided with perforated buckets. This special bucket elevator would dig the material from the sump and drain out the water through the perforations in the buckets. This elevator would then discharge on a belt conveyor leading to the top of the washing plant.

In cases where material is all above water, a gasoline or steam shovel is used to dig the material and place it in dump cars. A locomotive then hauls the cars to a track hopper near the plant. From the hopper the material is discharged by a feeder to a belt conveyor or bucket elevator. Usually the first conveyor discharges the material to a scalping screen which removes the oversize stone.

This large stone is then crushed to proper size and mixed with the other material, and is carried by belt conveyor or bucket elevator to the top of the washing plant.

Whether a belt conveyor or bucket elevator should be employed depends on the lay of the ground and the space available. In most cases where sufficient space is available, the belt conveyor is preferable for handling sand and gravel. It is simple and economical and requires a minimum of attention.

In some deposits with material both above and below water, a boom drag line is used to load the material into cars for transfer to the washing and sizing plant.

In some cases where space is limited, a skip hoist has been installed to take material from a track hopper and elevate it to the screens. The use of the skip hoist is also desirable when gravel contains many boulders above 12 or 14 in. in diameter.

In handling screened and washed material from plant to storage, several systems are used, depending on the amount of storage required and on the shape and location of the space available.

For a moderate amount of storage, the product may be drawn from the bins into railroad cars and handled along the track to a convenient point. Here a crawler or locomotive crane will unload the car into stock piles along the track, as well as reclaim the material from piles to cars or trucks.

Where large storage is needed, a belt conveyor system may be used. A conveyor from the bins is carried on a trestle 50 or 60 ft. high and arranged with a tripper or shuttle conveyor to discharge at any desired point along the trestle.

This stock pile may then be recovered and loaded with a crane. In other cases a tunnel is located under the conveyor trestle, the material being drawn through gates to a belt conveyor in the tunnel. This belt conveys and elevates the material to a loading point along the railroad track or into truck loading bins.

There is no single type of handling equipment that is best or suitable for every condition. Each installation should be studied as an individual problem and a type of conveyor chosen to meet the requirements at that particular location.

Foundry Sand Handling and Preparation

It has been computed that foundries have to handle as much as 150 to 200 tons of material per ton of castings produced. This includes pig iron, coke, limestone, scrap, molding sand, core sand, flasks, patterns, cores, bottom boards, gaggers, the hot metal, sprues, castings to the tumblers, sand to be shaken out and reconditioned, and the returning of the flasks and patterns to follow the same cycle over again if it be a foundry producing a repetitive product, such as automobile parts, sanitary ware, etc.

This industry consequently has great need for mechanical-handling equipment, and there is no denying that within the past 10 years it has made big strides in the economical, production-expediting application of such devices, especially for the handling, preparation, and reconditioning of the sand, and for the handling of molds on slow-moving horizontal tray conveyors to permit continuous molding and pouring.

Instantaneous delivery of prepared sand from overhead hoppers located along the molding zone of the mold conveyor, and pouring "on the move" along the metal-pouring zone, are doing much to speed production methodically and efficiently and to keep the handling costs down to a minimum. Give a molder his conditioned sand ready to drop into a flask, a molding machine, a

mechanical metal carrier, and a shake-out grate, and he can produce for himself in wages and for his employer in profits much more than any molder can by the old shovel and muscle method, provided the right type of machinery has been installed and in the right way for the purpose.

It is true that the foundry sand-handling machinery originally did not accomplish what was expected of it, but time and added experience bring many changes and today the foundryman can get a system for handling his sand just as satisfactorily as for the handling of other materials.

Proper sand conditioning is essential to economical foundry operation. Today mechanical sand conditioners deliver a uniformity and excellence of sand unheard of in the day of the sprinkling can and shovel.

Bucket elevators, belt conveyors, flight conveyors, apron conveyors, rotary screens, paddle mixers, sand-revivifying machines, vibrating shake-out screens—all have found their place in the foundry in the process of handling and preparing molding sand and in conditioning it for re-use.

It should be borne in mind, however, that not all foundries lend themselves to the application of conveying equipment or to the introduction of such complete handling systems. For example, a "jobbing foundry" may profitably employ a simple sand-handling unit, but have no use for mold conveyors. The matter of the producing capacity required or desired, nature of the work, whether many or only a few molds are to be made from the same pattern at a time, and other conditions all enter into determining whether a foundry should install mechanical-handling equipment and also how much or how little.

Crushed Stone, Lime, Cement, Gypsum

An enormous tonnage of crushed stone is quarried annually for the manufacture of chemicals, cement, lime, gypsum, steel, etc., and the building of highways and concrete structures. One plant alone, located in Michigan, has a producing capacity of 10,000,000 tons of crushed limestone per season of seven to eight months.

Normally, about a third of this plant's output is flux stone. Gigantic dipper shovels load the rock into 30- and 40-yd. side-dump air-operated steel cars, which a steam locomotive hauls to a 60-in. gyratory primary crusher in 15-car trains.

The crushed rock is conveyed to the top of the screen house on a 54-in. wide belt conveyor, 700 ft. between centers, which probably employs the heaviest and thickest belt ever installed anywhere. The belt weighs approximately 30 tons, and is about $1^1/_2$ in. thick, being of 14 by 16 step-ply construction, using 42-oz. duck, with $^{13}/_{32}$ in. rubber cover. Anti-friction tapered-roller-bearing heavy-duty belt idlers are used. The drive is of the dual-motor type using 250-hp. motors. This conveyor and the primary crusher are installed in duplicate.

The belt conveyor discharges to a large roll grizzly at the top of screen house, the oversize going to roll crushers and the "throughs" to roll grizzlies below, followed by another set of two roll grizzlies below that, spray-jet washing having started on this third set of grizzlies. At this point the flow of stone is divided to 12 vibrating screens, and continues on down over three more sets of 12 vibrating screens, making 48 of these screens on the four levels.

Open-hearth, flux, and commercial sizes of stone are carried off on belt conveyors at the several floors, and are conveyed and then discharged over belt trippers to their respective storage piles. Belt conveyors operating in tunnels underneath these storage piles serve to reclaim any size of stone that may be wanted. These conveyors deliver to other belt conveyors, and through this medium it is possible to load a 10,000-ton capacity vessel in about five hours or less.

This Michigan plant employs about 21 miles of belt conveyors of widths ranging from 30 to 54 in.

A 50-ton-per-hour stone crushing plant for making, say, four sizes of stone besides dust, may require nothing more than the crusher, a cylindrical rotary screen with dust jacket, and a continuous bucket elevator, with its buckets carried either on chain or a flat belt, for feeding the crushed stone to the screen.

On a 100-ton-capacity plant several crushers may be required, with an apron feeder delivering the quarry-run stone uniformly from a dump-car receiving hopper to the primary crusher, a rotary scalping screen between primary and secondary crushers, a continuous bucket elevator or two, a rotary finishing screen with dust jacket, and a single deck vibrating screen to further "size" the material passing through the meshes of the dust jacket.

The multiple revolving roll grizzly is being widely used now instead of the cylinder type of revolving screen. When the material to be elevated is of large size, such as the product of a primary jaw crusher, an all-steel pan or apron conveyor may be preferable to the use of a bucket elevator.

Each plant is an individual engineering study in the matter of determining the proper type and size of crushing, handling, and screening equipment for accomplishing the desired results—depending to a great extent upon whether quarry cars are loaded by hand or by dipper shovel and, if the latter, on the size of stone the dipper will conveniently handle.

At a modern chemical lime-producing plant we find a dipper shovel reclaiming the raw limestone from storage pile to industrial cars hauled by gasoline engine to the feed hopper of a fully automatic skip hoist which employs a 60 cu. ft. skip bucket, elevates the $2^1/_2$ tons of stone 130 ft. to two 400-ton storage tanks at a speed of 180 ft. per min., making a complete trip every two minutes and delivering 75 to 80 tons an hour.

From these tanks the stone is fed by belt conveyor over a weighing device to a rotary kiln delivering to a cooling kiln, from which belt conveyors receive the lime and feed it to a continuous-bucket elevator discharging to a vibrating screen which makes three separations. The tailings, or pebble lime, and the screenings are fed to their respective bins through screw conveyors. Steel-encased centrifugal-discharge chain and bucket elevators and more screw conveyors form important links in the mechanical handling system from here on through the hydrate building.

A portable-belt-type box-car loader loads pebble lime into box cars which are "spotted" on the plant siding by an electric capstan-type car spotter.

At many of the Eastern lime plants we find the hot lime being drawn from a series of vertical kilns on to steel pan conveyors. The lime may be delivered to a cooling bin by a car system and reclaimed from underneath by a steel-pan conveyor delivering over a shaking screen, the "fines" being taken by a belt conveyor to the hydrating plant and the lumps delivered over a second pan conveyor to a pivotally mounted adjustable-boom conveyor-type box-car loader which, with the aid of an attendant, serves to fill both ends of car to the desired height.

The core may be picked from the second pan conveyor by hand.

The arrangement and type of handling equipment employed necessarily differ according to the local plant conditions and the nature of the lime.

At the cement mill the mechanical handling processes will vary somewhat according to whether cement is being produced by the dry or the wet process and whether limestone or marl is being used as a raw material.

An apron conveyor usually feeds the rock from dump hopper to crusher. From the crusher the material is elevated to the mill

storage bins or the marl to a washing plant by an inclined belt conveyor. Continuous steel bucket elevators, when employed, must be of rugged design and construction to withstand this service. The belt conveyor should be used wherever space permits.

The product of the ball mills, Hercules mills, and other granulators can be conveyed very readily by means of screw conveyors or belt conveyors.

From the cooler the cement clinker may be handled by a pivoted bucket carrier, a belt conveyor, or a cast-steel drag-chain conveyor, or perhaps the hot clinker falls into a pit from which an overhead grab bucket crane takes it to outside storage, returning with a bucketful of seasoned clinker for grinding.

The finished cement may be delivered to silo storage bins by screw conveyors, by a belt conveyor, or by bucket elevator. Screw conveyors are ideally suited for conveying finished cement, and usually handle it from underneath storage bins to packing house. Finished-cement conveyors and elevators should be fully housed and made dust-tight.

In the wet-process plant the limestone and other raw materials are drawn from storage bins and fed to the grinders of the various types, with a sufficient quantity of water to make a thin slurry when the mixture is ground.

Before cement clinker is ground, the proper amount of gypsum is added to regulate the setting time of the finished cement. Gypsum lends itself to mechanical conveying in about the same way as the limestone or marl and the shale or clay.

The kilns may be fired by oil, gas, or coal, and when the fuel is coal, this coal must be crushed, dried, and pulverized. The finely pulverized coal is delivered to storage bins by bucket elevator, and later fed into kilns with the proper amount of air pressure.

Coal Mining and Preparation

Where a seam of coal is close to the surface, the overburden is removed by dipper shovels and the coal is mined from an open pit. When the seam is a considerable distance below ground level, the coal may be hoisted to the surface from a shaft. For example, a certain Illinois bituminous mine employs a balanced-bucket skip hoist, using buckets of 9½ tons' capacity each and automatic loaders to fill them. The coal is hoisted a distance of 525 ft. at the rate of 1400 tons an hour, or 11,200 tons per day of 8 hours, the buckets, in portions of their travel, attaining a speed of 3000 ft. per min.

In other mines the coal is brought to the surface on conveyors, either apron, flight, or belt conveyors being used. This is an economical system in cases where the depths below surface are not very great.

The Colonial Mine of the H. C. Frick Coke Company employs 20 belt conveyors placed end to end, running 500 ft. per min. and carrying 10,000 tons of coal per 8 hours a distance of 4½ miles to the surface.

Their Palmer Dock Mine employs 11 belt conveyors placed end to end, also operating at 500 ft. per min. and handling 10,000 tons of coal or more per 8 hours a distance of 3½ miles from mine-car dump in the mine up to the tipple bin for loading into barges. Particularly impressive is the noiseless conveying of such a large tonnage, with so little degradation and manual attendance. Special attention was of course given to the design of the chutes for transferring the coal from one belt conveyor to the next.

Where mine openings are on mountainsides, the mine cars are brought to the surface, hauled to a power-driven dumper, and dumped into a hopper from which the run-of-mine coal is fed to a retarding conveyor for lowering it to the screening and preparation plant. Apron, belt, and flight types of retarding conveyors are in use, including the rope-and-button style of flight conveyor.

Down in the mine one will see conveyors used as loaders for carrying coal from the faces to pit cars.

Certain types of caterpillar or track-mounted loading machines are provided with gathering mechanisms which pull coal, shot down at the faces, on to inclined conveyors lifting it into cars for transportation to the tipple. A loader of this type, with a crew of three men, will handle 200 tons per 8 hours, whereas the best miners will average no more than 10 tons per man. And while the miner, besides loading 10 tons, also does other work, such as drilling coal, laying track, and timbering, the loader-equipped mine shows a big saving, even though a separate crew is hired to perform the supplementary work just mentioned.

In other mines, inexpensive conveyors, mounted on light flanged wheels and without coal-gathering mechanism, are used. Their handling capacity is limited, since the miners must shovel the coal on the lower ends of these units. These pit-car loaders do have the advantage that rock and bone can be removed by hand before loading and can be left in the mine, whereas this is difficult of accomplishment with loaders of the digging or self-gathering type. These smaller machines can be used where roof conditions are bad and the timbers close together. Like the self-gathering loader, they are of the flight-conveyor type, being made up with two parallel strands of roller chain connected by bars at intervals, to serve as the conveying medium for dragging the coal along the conveyor trough.

Where coal is mined from long faces, one also will find "face conveyors" in use for carrying the coal shoveled into them to pit cars at loading points which may be several hundred feet away. Thus the conveyor is made to serve as an efficient mine-transportation unit. Apron conveyors, mat conveyors, and belt-and flight-type conveyors have all been used, but the drag-chain conveyor has been found to be the simplest and most satisfactory. This consists simply of a rugged chain, with wings at intervals, sliding in a trough.

Shaking or jigging conveyors also are used in the mine. These consist of steel troughs, roller-supported, to which a quick return stroke is imparted by the drive units.

The idea was imported from Europe, but American inventive genius improved it by developing a shovel end, which is pushed into the "shot" coal and serves to load the shaking conveyor. The shovel has a telescoping end to permit its being advanced as the coal is loaded. These conveyors are made in 10-ft. to 13-ft. sections, the shovel end having an extension equal to the length of one section of conveyor. When the conveyor has been extended its full length, an additional section of trough is inserted, and the advance is again begun.

Let us now pass to the preparation plant, tipple, or washery, the function of which is to clean and properly size the coal for the market. Mechanical loading in the mine, while a step in the right direction, has on the other hand served to increase the amount of impurities to be taken out of the coal. This means that in some plants additional equipment is needed for adequate preparation.

The sizing is done over screens, usually of the shaking and vibrating types. The cleaning is accomplished by either of three methods, the method that should be selected depending upon the nature of the coal and its impurities. The three methods are:

(1) Manual inspection and picking on picking-table conveyors.

(2) Separation of free impurities by dry-cleaning mechanical methods.

(3) Wet concentration, or "the washery process."

The washing process is the most effective method of separating the impurities or refuse from the coal. The difference in specific gravity of coal and refuse is utilized to effect a separation in the

water, by means of pulsations which lift the coal into the upper current, while the refuse drops on the sieves and passes out through refuse gates.

The cleaned and sized coal may be loaded into open-top railroad cars by means of a pan-type loading-boom conveyor, the discharge end of which is adjustable by an overhead hoist arrangement, to permit placing the coal in the car gently, with practically no drop to cause degradation. When coal is loaded into box cars, the pivoted-boom conveyor-type box-car loader is used, the discharge height of this loader also being adjustable to minimize breakage of coal in the loading process.

Coal and Ashes Handling at the Power Plant

Coal is delivered to its destination by water or by rail.

Ordinarily, water-borne coal, arriving in vessels, is removed by clamshell buckets which are hoisted and dumped direct into storage or into a hopper, whence it is conveyed to a bunker located in front of and above the boilers. The buckets are operated from hoisting towers, or bridges, of either stationary or traveling type.

At power houses which receive their coal in railroad cars, the coal may be shoveled by hand over the side of the car, but it seldom is, as this method is too slow and expensive, demurrage is high, and it is wasteful to use man power which can be employed to better advantage for other purposes. This method of unloading cars is in the same category as the hand firing of boilers.

Car Unloading. It is customary to dump part or all of a car's contents into a hopper, located under the coal supply track—a satisfactory method when bottom dump cars are available, when adequate trackage and switching facilities are provided, when the coal is not partially frozen in the cars, and when not more than 300 to 400 tons of coal are to be unloaded during a period of 8 hours. The dump car and track hopper are by no means an altogether satisfactory combination, hence are generally used only by plants which consume too little fuel to warrant the larger investment required to install better methods.

The large or super-power house must unload its coal quickly and cheaply. There dare be no shortage of fuel, even though shipments be delayed, coal be partially frozen in the cars, or bottom dump cars unobtainable. To meet all these troublesome conditions the rotary railroad-car dumper was developed, which overturns and discharges the contents of the smallest or largest open-top car of any type within two minutes when desired.

Coal Elevating and Conveying. Since coal-crushing and pulverizing equipment is heavy and requires substantial foundations, it is, in practically every case, located at or near the ground level. Therefore the crushed product must be elevated and conveyed to the overhead storage bunker to be drawn off as required by the stokers, by the direct-fired pulverized-firing system or by the central pulverizing system when pulverized coal is stored.

For the quite small plant, which can support only a small investment in equipment, the centrifugal discharge bucket elevator fulfils well the purpose of elevating and discharging the coal into the storage bin.

When the coal-handling requirements are fairly moderate, the continuous bucket elevator is preferable to the centrifugal type, and if the overhead storage bin extends in front of several batteries of boilers, the elevator is supplemented by a scraper flight conveyor overhead, which distributes the coal along the length of the bin.

Medium-sized boiler houses may be provided with several types of handling equipment, the selection of which depends largely upon the surrounding conditions, such as location of track upon which coal is received, location available or desirable for storage bunker, and whether the coal and ashes may be advantageously conveyed and dumped into their respective storage bins by the same system. The leading types are: pivoted bucket carrier, gravity-discharge elevator-conveyor, belt conveyor, and skip hoist.

Pivoted-Bucket Carrier. Probably the overlapping pivoted-bucket carrier is the most generally used and applicable type of conveying equipment for serving the medium-sized plant, as it performs the several functions of receiving both the coal and ashes, separately of course, in its lower run, conveying the material to one end of the boiler house, elevating it, and then conveying it to the overhead coal or ash bunker, where the contents of the buckets are dumped and distributed. After 30 years of use, it is still a leading type for handling coal and ashes within its range of capacity and height. Its maintenance cost is low and its dependability high.

Gravity-Discharge Elevator Conveyor. The development of this combined elevator and conveyor preceded the pivoted bucket carrier, but it still is used widely for handling just the coal, in power plants of moderate capacity. In fact, it is this type of conveyor that is in use in the boiler house of the world's largest building, the Merchandise Mart in Chicago. Their conveyor follows a rectangular path of approximately 203-ft. horizontal centers by 30-ft. vertical centers, travels at a bucket speed of 50 ft. per min., and handles 30 tons of coal per hour. The ashes are discharged direct into tunnel cars and hauled away by an electric engine.

Belt Conveyors. Large and super-power houses require large capacity and high lifts. The belt conveyor and skip hoist types of coal-handling equipment are generally used to meet these exacting requirements.

When the coal-supply track is located so as to permit a belt conveyor to attain sufficient height before reaching the boiler house to enable it to pass over the storage bunker and distribute its load to that bunker by means of a tripper, the belt conveyor makes an excellent selection. For distributing the coal to the large overhead bunker, which should contain a supply for at least a 24-hr. maximum boiler demand, the belt conveyor is provided with a traveling tripper of the automatic or semi-automatic type. Preferably, the tripper should have anti-friction bearings, large shafts, and pulleys, and its traveling mechanism should be driven by an independent motor direct-connected to an efficient speed reducer mounted on the tripper frame. This type of drive is superior to the type driven from the conveyor belt, which requires troublesome gearing, clutches, and reversing mechanism.

Should the supply track be located alongside or at one end of the boiler house, the skip hoist is well adapted to elevate coal from the crusher and dump it into the overhead bin direct or into a hopper feeding a belt or flight conveyor for distribution to a long overhead bunker. As the skip is hoisted vertically or at a slight inclination, it requires but a minimum of space. It has the additional advantages of being adapted to high lifts and to large or small tonnage capacities per hour.

Overhead and Reserve Storage. Few designers have made the mistake of providing too much overhead storage for coal ready to be delivered to the stokers, but many have erred by having insufficient storage capacity to allow for delays in receipt of shipments, thus necessitating urgent messages by the operating department.

For the quite small plant, requiring a few tons a day, accommodations should be for at least two days' consumption, plus a full carload. The reason is obvious.

The medium-sized plant should have two days' maximum supply overhead storage and an auxiliary ground storage supply for one or two weeks' requirements adjacent to the boiler house, which can be drawn upon immediately in case of delayed shipments or bad weather. If it is impossible to provide an auxiliary storage, the overhead bunker capacity should hold at least one full week's supply.

The large or super-boiler plant burns such enormous amounts of coal that it seldom is practicable to provide more than 24-hr. overhead storage. These plants, however, always provide a secondary storage adjacent to the boiler house, from which they can quickly and economically draw enough coal for their daily requirements to insure uninterrupted operation. This ground storage, sufficient to take care of operation for one or more months, is usually equipped with cranes, bridge tramways, or drag scrapers, for economically storing and reclaiming large tonnages per hour. A large auxiliary storage permits purchasing coal at favorable prices, in addition to insuring a desirable quality and quantity of coal at all times.

Ordinarily, the overhead storage is located in front of the boilers, but there are conditions where it is desirable to place it centrally with or at one end of the boiler house and to distribute the coal to the stokers as needed by means of a traveling weigh larry. This latter arrangement is necessary where stokers, overhead storage, and coal-handling equipment are installed in an existing boiler plant, to avoid remodeling the boiler-house building and roof.

Coal-Weighing Tools. Track scales serve to weigh and check carload shipments as they are received for unloading to either overhead or ground storage.

Weightometers are used to weigh and record automatically the weight of coal passing over the conveyors on which they are installed, before the coal is discharged to the bunker. The weightometer provides an accurate record of all coal delivered to the bunkers, practically eliminating the human element.

Weigh larries are located under the overhead storage bunker to permit drawing the coal from storage into the larry hopper, for weighing and transferring to the stokers as needed, the larry traveling on overhead tracks in front of the boilers and under the bunker. The weigh larry accomplishes the following desirable results: It transfers the coal from overhead storage to stokers; weighs and records the total amount of coal drawn from the overhead bunker; weighs and records the total amount of coal delivered to each stoker; and transfers coal from any part of overhead storage to any stoker, thus avoiding dead or unusable overhead storage over boilers which are not in operation.

Weigh larries vary in capacity from 1000 to 20,000 lb. or more, depending upon the size of plant, the length of travel, and the number of boilers served.

When the boilers are fired with pulverized fuel, automatic coal scales may be introduced between the coal bunker and each boiler, thus obtaining an accurate record of the amount of coal burned by each boiler.

Foreign-Substance-Removal Equipment. Coal, as received, will contain blocks of wood, timbers, coupling knuckles, links and pins, mining-machine cutter bits, and other refuse. Unless these are removed, they are likely to damage subsequent handling equipment seriously; therefore means are provided to get them out. Frequently an attendant is supposed to watch for injurious material as the coal flows from the car, and remove it. Unfortunately, man is not a dependable tool for many purposes, and is therefore unsatisfactory.

Hammer and ring mills have effective arrangements for catching and removing tramp iron or other materials that will not pass through their cages. The Bradford breaker prevents the larger pieces from passing through its perforations and reaching the bunkers. Apron feeder conveyors may be provided with magnets at their discharge end to remove tramp iron of all kinds and prevent its reaching and injuring the crusher.

When coal is to be pulverized, it is especially important to remove all iron before it can reach the fine pulverizers. This is done by installing a magnetic pulley on a belt conveyor over which the coal passes, which will effectively remove the iron.

Ashes Handling. Where a small amount of ash is to be handled, the wheelbarrow and shovel still hold first place. When the ashes must be elevated and discharged at street level into wagons or into a small overhead bin, the ash lift and centrifugal discharge bucket elevator serve the purpose and require minimum investment. Frequently portable belt conveyors or elevators are advantageously used to load piles of ashes into wagons or trucks.

For conveying and elevating the ash and discharging it into an overhead bin, the steam jet is well adapted where the ash must travel a tortuous path and where there is little space for other types of equipment. This system requires considerable steam if the quantity of ashes hoisted is large; also the abrasive quality of ashes tends to wear out the turns and pipes, unless they are specially reinforced.

If the ashes can be handled in the same equipment that is used for handling the coal, the overlapping pivoted bucket carrier makes an efficient and satisfactory installation.

The skip hoist is the best ash-handling tool, when the quantity is large enough to warrant the necessary investment, and when separate ash-handling equipment is required or advisable. Frequently the ashes are drawn from pits or hoppers into industrial cars which are pushed along a track and dumped into the skip bucket for hoisting and dumping. As the skip bucket is suited for handling large clinkers, small ash, or soot, it is commonly used for them as well as for the coal. The equipment is the same as for coal except that the automatic loader is seldom used.

Large boilers produce large quantities of ash, hence are often provided with big cast-iron ash hoppers and gates lined with tile; also with clinker chambers, clinker grinders, sluiceways, nozzles, and pumps; or they may have railroad tracks located under the ash hoppers, so that the ashes may be emptied directly into railroad cars. Storage bins of concrete, of cast-iron sections, or of steel lined with tile, brick, or concrete, are employed for storage of ashes until a sufficient quantity has accumulated to be drawn into the railroad cars or trucks.

Locomotive Coaling Stations

Elevating and conveying machinery is extensively used in the locomotive coaling stations of the country.

At a large, all-steel, six-track coaling station on the New York Central, for example, one will see coal being delivered to the overhead storage pocket by means of a balanced-bucket skip hoist.

As in power plants, the pivoted bucket carrier also is a popularly used type on locomotive coaling station work, being employed for handling both the coal and the ashes.

At another station, with two unloading tracks and four coaling tracks under two 500-ton concrete pockets of circular shape, there are two track dump hoppers with apron conveyors feeding the coal to a gravity-discharge elevator-conveyor, which delivers it to either of the two storage pockets.

The selection of the type of conveyor or elevator to be used depends upon the capacity desired, local conditions, and individual preferences.

Retail Coal Yards

The retail coal yard may employ overhead pockets and deliver the coal to these pockets either by means of a gravity-discharge bucket elevator, a pivoted bucket carrier, or a trolley-bucket conveyor system.

The gravity-discharge V-bucket elevator has been used a great deal, and discharges the coal to the various bins direct when it follows a rectangular path with the upper run operating the length of the building. The discharge is through gates in the bottom of the trough along which the buckets push the coal.

The discharge from a scraper flight distributing conveyor is similar, when a flight conveyor is used in combination with a

gravity-discharge bucket elevator delivering to it at the one end of the pocket lantern.

To avoid degradation, some form of lowering chute is used to "ease" anthracite coal to the bottom of pocket or top of pile.

There is a growing tendency to build silo-type concrete pockets and to install the trolley-bucket system of handling the coal.

The latest form of trolley-bucket system is fully automatic, serving to unload coal (or coke) from hopper-bottom railroad cars direct to any point along the top of storage piles of any height, at maximum speed, without transfer, and with minimum degradation, since the trolley bucket automatically lowers itself to the pile—this contact of bucket with pile effecting the discharge of the bucket's contents. There is but a short drop from the track dump hopper loader into the trolley bucket. The discharge to the pile (usually inside of a pocket) is a gentle spreading or flowing of the material over the pile. The material handled is at rest with respect to the bucket while the latter is being trolleyed up and on to its predetermined discharge point.

The system permits the use of high bins or silos, thus saving ground space and eliminating mechanical handling for loading trucks. The delivery chutes are so located in the bins that coal can be drawn off direct to trucks or to a bagging platform which is level with the truck body. The attendant can devote most of his time to seeing that coal keeps flowing from the railroad car into the track hopper.

Many coal yards, especially the smaller ones, unload the coal on a trestle siding through hopper bottoms of cars to ground bins, and do the reloading to delivery trucks by means of portable loaders, which are either of the belt conveyor, flight conveyor, or bucket loader type, depending upon the kind and size of coal handled and other conditions.

For cleaning anthracite coal (or coke) before delivering to truck, the bucket loader is often equipped with a screen of either the shaking or vibrating type.

The flight conveyor loader is widely used for reloading bituminous coal, especially coal with large lumps, as the flights keep the lumps from rolling back.

Making and Handling Coke

At the steel mill, coal must be converted into coke before it can be used to provide the heat for melting the mixture of iron ore and limestone.

The coke must be tough, range in size between 2-in. and 3-in. cubes, and be so constituted chemically as not to add to the undesirable impurities in the iron. To produce such coke, the coking coal should be carefully selected and prepared. Generally, three or four kinds of coal are mixed to provide the proper chemical ingredients.

In getting this coal from the track dump hopper to the crusher and to the mixing bin, it is handled by the usual forms of conveyors, such as belt conveyors, bucket elevators, pivoted bucket carriers, or skip hoists, depending upon the plant layout.

A motor-propelled larry car handles the prepared coal from a bin to the coke ovens, charging them through openings in their tops.

The coal requires up to 24 hours for coking, depending on the quality of coke required and the nature of the by-products to be derived. A coke-pusher car pushes the coke from the desired oven into a quench car running on tracks on the other side of the row of ovens. This car takes the coke under a quench tower where the coke is water-drenched, and then discharges it to the coke wharf for cooling.

The wharf is a long, flat surface sloping downward about 25 deg. from the horizontal, and the coke slides to the lower ledge, from which it is discharged through manually operated finger gates on to a belt conveyor, which carries the coke to the crushing and screening plant. Here the coke is prepared for blast furnace or foundry use in the quantities needed, and the remainder is sent to outside storage or to the domestic-coke screening plant. Coke that has been in storage is unsuited for blast-furnace use.

In the preparation plant one may see the liberal use of belt conveyors for handling the coke from one operation to another, coke crushers and screens of the shaker, multiple-disk, revolving grizzly, and vibrating types—the latter particularly being used in sizing and cleaning the coke for domestic use, just before delivery to trucks.

At the coal-gas plant the coke is a by-product. At one plant in mind, for instance, the accumulation of coke amounts to about 2000 tons daily. To dispose of such large quantities profitably requires the use of efficient mechanical-handling equipment and the preparation of the coke in such a way that it will meet the competition of anthracite coal for domestic use, as well as the growing demand on the part of householders for a cleaner coke. The oversize coke is sold as foundry coke.

Coke breaks up very easily, and for this reason should be handled as gently as possible so as to avoid an accumulation of "fines" or breeze. The belt conveyor is an ideal coke-conveying unit. The construction of transfer points should be watched so that chutes are made amply wide for the coke to flow over them in a thin stream, and no steeper than necessary. Pocket chutes which fill with coke have proved very satisfactory by eliminating chute wear and causing the coke to roll rather than to slide.

At the coal-gas plant one is likely to see the hot coke conveyed from under the vertical retort-type ovens by a de Brouwer drag-chain conveyor, consisting of two strands of short-pitch special sliding chain with flat crossbars at intervals of about 2 ft., and operating in a structural-steel trough which is lined with hard white iron, in view of the abrasive nature of coke. This conveyor is light in weight and operates slowly, and the joint wear is comparatively small due to the fact that there practically is no joint movement under stress except when passing around the head sprocket wheel.

This conveyor, which also acts as a quenching or cooling conveyor, takes the coke to storage or to the screening plant. Pivoted bucket carriers also have been employed for handling the hot coke, or a quenching car may dump the coke into a pit from which a monorail grab-bucket machine will reclaim and handle the coke to the storage pile or to a receiving hopper of the crushing and screening plant.

At the water-gas plant one is likely to see an automatic skip hoist alongside of the railroad track, serving to receive coke from the track dump hopper through an automatic loader and to deliver it into an overhead storage bunker, from the bottom of which the coke is delivered to the retort-charging buggies over a vibrating screen. This screen removes the breeze, the cleaner coke resulting in greater efficiency of the retort fire.

Many of the gas plants are now using a crawler-type bucket loader equipped with vibrating screen for reclaiming coke from pile direct to delivery truck. A self-feeder serves to feed the coke to within reach of the buckets. The vibrating screen cleans the coke thoroughly. There is also a smaller capacity bucket loader, hand-moved over ground, which cleans the coke very well over a shaker screen.

In the oil fields one may find petroleum coke pulled out of chambers on to a portable apron conveyor discharging to a portable belt conveyor for delivery to side-dump cars running to the screening plant.

Ore-Handling Equipment

Iron Ore. The steel companies are ever searching for ways and means to lower ore-mining costs, improve the quality of the

ore for blast-furnace use, and reduce the cost of handling the ore from the mine to the furnace.

Iron ore is mined underground and hoisted to the surface in skips or from an open pit by means of large-capacity stripping shovels delivering into cars. Restricted area and a deep pit may necessitate "milling" the ore to haulage level and raising it through a shaft which is sunk adjacent to the pit when the pit-car track grades have reached the limits of economical haulage with standard locomotives.

The cars used in underground mines are of 3 to 5 tons' capacity. They are dumped directly into skips or else discharged to underground loading pockets with measuring pockets between them and the skips. The skips range from a holding capacity of $2^1/_2$ tons to 8 tons, skips with a capacity of 4 and 5 tons being mostly used. In the open-pit mining the haulage cars may be the air-dump type, with a capacity of 20, 24, and 30 cu. yd.

When lean ore is mined it must be "benefited," thereby making the ore more suitable for use, besides effecting a saving in freight charges through not having to pay freight on the weight of the impurities and moisture which are removed by the treating processes used. There are five processes commonly employed, these being roasting, sintering, washing, washing and jigging, and magnetic separation. The nature of the ore and of its base determines the process that should be used, and all five methods involve mechanical handling of the ore.

At the primary screening and crushing plant where trainloads of run-of-pit ore are dumped, metallic apron feeders are employed to feed the oversize ore uniformly from the bar grizzly to the primary crusher. The crushed ore is then delivered by rubber belt conveyors to secondary crushers or is delivered to railroad cars for shipment to ship-loading docks.

The apron feeders must necessarily be of very rugged design and construction to withstand the punishment to which normal service subjects them; in fact, it was ore-feeding service that brought forth, 8 or 9 years ago, the distinctive type of heavy-duty ore feeder now used.

The sprockets, chains, rollers, and overlapping pans are usually made of cast manganese steel. The chains have no small rollers (therefore there are none to be lubricated), and are placed underneath the pans, out of the dirt, at locations which break up the span of the pans. The broad wearing surfaces of the chain links form substantial tracks for the large-diameter manganese steel rollers supporting the material-carrying run. These rollers are closely spaced and are mounted on heavy through-shafts turning in rugged, accessibly located bearings.

On short feeders the lower or empty return run pans and chains are unsupported between the head and foot shafts. Medium or long center feeders are provided with manganese steel rollers, suitably spaced, to carry the return run.

Troughing-type three-pulley anti-friction belt conveyors are used, practically without exception, for handling crushed iron ore in today's modern crushing, washing, or screening plant.

Copper Ore. Copper ore is mined underground or by open-pit method, and the system of getting the ore to the surface is similar to that at iron-ore mines.

The heavy-duty manganese steel apron feeder, already described under "Iron Ore," is employed for feeding the run-of-pit ore from dump hopper to crusher direct or to a conveyor.

At one property in mind, the feeder is 8 ft. wide and employs 18-in. pitch conveyor chains. This feeder has been operating over three years at a handling capacity of approximately 8000 tons per day. It requires no attention and receives none, except greasing once a day and cleaning the floor underneath of a small quantity of "fines" which stick to the pans due to rather heavy sprinkling of the ore before it is dumped.

Trains from the pit dump six 40-ton cars into a bin, from which the feeder, which is 72 ft. long, conveys the ore to a 56-in. gyratory crusher. Besides the "fines," the feed contains a large percentage of coarse material, with pieces 5 or 6 ft. long and 3 ft. by 3 ft. or more in cross-section.

The feeder speed is $9^1/_2$ ft. per min., and the handling capacity is 900 tons per hour. There is no leakage through the top run nor spill between the skirt boards and the conveyor's side flanges. The control is by push-button, the operator (located at the crusher) shutting down the feeder just before the bin is emptied. There is no gate at the bin throat, and there is never any jamming.

Belt conveyors form the ideal and popular conveying medium for handling the crushed ore.

Nickel Ore. This ore is mined very extensively in the Province of Ontario, by the underground method—the Frood mine, for example, being designed to hoist the nickel-copper ore in two 10-ton balanced skips at the rate of 6000 tons a day.

This mine has levels of 1200, 1600, 2000, 2200, 2400, 2600, and 2800 ft. Primary crushing is done below the 2800-ft. level, the jaw crusher located at this point being fed from an ore pass from this level and the levels above. The crushed ore is discharged into an ore pocket, and then into measuring hoppers just before delivery to skips.

Treatment of ore in the Frood rock house involves crushing, coarse screening by trommel screens, fine screening on vibrating screens, hand picking of waste on belt conveyors, and magnetic separation, entailing the use of a large number of anti-friction belt conveyors.

At the Levack mine, designed to hoist 3000 tons a day, there are one heavy-duty-type manganese-steel apron feeder and one rolled-steel pan conveyor in use in the rock house and 18 belt conveyors. The apron feeders also serve as picking conveyors. A feature worth mentioning is the extensive use of magnetic head pulleys on the belt conveyors for separating the ore from waste rock, the product of this mine containing a larger percentage of nickel than copper.

The crushing mill, concentrator, and smelter at Copper Cliff, Ontario, is designed to crush, concentrate, and smelt approximately 8000 tons of nickel ore per day. Inasmuch as the ore is handled entirely by conveyors from the time it leaves the receiving bins until it reaches the roasting furnaces in the smelter, a great many of them are necessary. Consequently they form a very important link in the process. In the smelter conveying system are 47 belt conveyors, using a total of 24,000 ft. of rubber-covered conveyor belt. All cold material is handled on belt conveyors, ranging in width from 24 in. to a maximum of 48 in.

In addition there are several scraper flight conveyors, chain drag conveyors for handling hot calcine, and a number of encased 14-in. spiral ribbon conveyors, as well as drag conveyors, for handling all dust.

Gold. The handling of materials at underground gold mines, of which there are a number in operation in the "north country" of Canada, is very similar to the procedure for extracting nickel-copper ore, but not quite so extensive.

The ore is received from the mine by skips and discharged into ore bins in the head frame. From these bins the ore may be fed by pan conveyor, chain conveyor, rotary grizzly, etc., either direct to a jaw crusher or to a belt conveyor and then to the crusher. The crushed material is then usually passed over a vibrating screen and the oversize is fed to a cone crusher for further reduction. The screens and cone crusher are usually in a closed circuit, and the ore is handled almost entirely on rubber-covered belt conveyors. Inclined belts are used in the mines of Ontario almost to the exclusion of bucket elevators.

The ore, after being crushed to about $^3/_8$ in., is conveyed by belt conveyor to the fine-ore bins in the mill. From these bins

the ore may be fed by roll feeders, pan conveyors, or short-center belt conveyors to a belt conveyor for distribution to the fine-grinding department, which may comprise ball, tube, or rod mills. At this point the ore is made into a free-flowing solution, and circulated through classifiers, thickeners, agitators, precipitating equipment, filters, etc. The "tailings" from the filters are usually discharged to a flat belt conveyor.

As different ores require different methods of handling, there also will be deviations from the general flow sheet just outlined.

Earth Excavation

The removal of Denny Hill, 110 ft. high, containing 4,500,000 cu. yd. of dirt, was a big undertaking, and it is significant that this little mountain, which tended to retard the commercial expansion of the City of Seattle, was conveyed a distance of about 3000 ft. to the sea entirely on belt conveyors within 24 months after the contract was let, the first 6 months of this period having been consumed entirely in the assembling of the equipment and placing it in operation.

Belt conveyors were decided upon as the most logical, since such equipment was light in weight and could be readily supported on a wooden structure above the street-car trolley lines. The belt conveyor also fitted admirably into the scheme, as it operates so noiselessly, and by its use it was possible to keep the streets clean and to permit traffic to proceed normally and without interference. All belt idlers were of the anti-friction type, thus keeping power costs and attention to lubrication down to the absolute minimum.

The dirt was dug by six 2-yd. electric shovels and delivered to portable field belt conveyors through steel feeding hoppers fitted with apron conveyor feeders. Whenever required, the material was crushed or mashed by the shovel dipper through grizzly bars set 10 in. apart over the hopper. There were 12 field conveyors 250 ft. between centers, delivering to a central receiving hopper serving the belt conveyor, 960 ft. between centers, which carried the dirt up over the street. This conveyor delivered to a conveyor, 1560 ft. between centers, and it, in turn, to a belt conveyor, 440 ft. between centers, running along the face of one of the docks at the waterfront, where the dirt was delivered by chute to self-dumping scows.

The scows were constructed with the top and bottom alike, and with internal water chambers divided into two parts. After the scow was loaded, it was towed out into the bay and water was let into the one side of the empty chamber in the scow hull, and as the scow listed, due to the water entering this chamber, the dirt began to roll, and this shifting of the load resulted in the scow turning completely over during the operation of dumping. Then what was the bottom of the scow became the top, ready to receive another load of dirt and to be dumped in the same manner, each time turning over in the dumping operation.

All belts used were 36 in. wide. Those over the street operated at a speed of 600 ft. per min. The portable conveyors ran at a belt speed of 400 ft. per min. The average handling capacity of the main belt line was 600 cu. yd. per hour, bank measurement, and the equipment worked three shifts per day, $7^3/_4$ hours per shift. Many of the conveyor belts lasted through the entire job, and the maintenance was not great, taking into consideration the conditions under which the conveyors had to operate and the service rendered.

As the dirt built up rapidly on the steel chute bottoms, the transfers between conveyors over the street were made by having the conveyors discharge direct to the belt of the conveyor ahead, with nothing more than chute sides at these points.

The contract price for removing Denny Hill was 25 cents per cubic yard. The digging was sublet at 9 cents a yard delivered to field belt conveyors. this figure being included in the total price of 25 cents per yard.

Portable belt conveyors also have been employed in the process of removing dirt from excavations for large buildings.

Conveying of Other Materials

Only a few of the many other materials handled in bulk will be covered under this section, and this will be done briefly.

Salt. This is handled by bucket elevators, skip hoists, belt conveyors, flight conveyors, and screw conveyors. The belt conveyor is widely used, and to avoid incrustation and corrosion of the conveyor idlers, these idlers have been granitized, with good results. Screw conveyors handling wet salt to driers have been made of Monel metal to prevent discoloration and contamination of the salt.

Sawdust. This is usually conveyed by wide-link chains which push the material along the trough in which the conveyor operates.

Hogged Fuel. The waste wood of the saw mills and paper mills is conveyed by wide-link chain conveyors as used for sawdust, by double-strand flight conveyors using wooden flights intermittently mounted on chains, and on belt conveyors.

Pulpwood Chips. Pulpwood chips for making paper have been handled by flight conveyors, screw conveyors, bucket elevators, and belt conveyors. The belt conveyor is the ideal type, as it carries the chips, thus preventing their breakage. Small, dirty chips produce a short-fiber paper pulp, which is no longer desirable in the manufacture of high-grade finished paper.

Fullers' Earth. This material, used in large quantities in filtering oil at refineries, is handled by bucket elevators, pivoted bucket carriers, suspended roller flight conveyors, and belt conveyors. At one of the most modern of these refineries the earth is delivered to filters and to storage bins by means of anti-friction belt conveyors equipped with traveling trippers.

Mixed Concrete. This is now often handled over a system of portable belt conveyors in the construction of large concrete buildings and in the pouring of foundation piers. For the construction of Diablo Dam, recently completed, a unique arrangement of swinging belt conveyors, suspended from 400-ft.-high steel concreting towers, was worked out to reach all parts of the job.

Crushed Ice. Ice for refrigeration lends itself to handling in screw conveyors, and this, for example, is how it is handled from the crusher to the packers in the extensive lettuce-packing industry of California.

Sludge, Sand, and Grit. These are removed from sewage settling tanks by a special form of flight conveyor.

Coffee. Coffee berries are handled by bucket elevators and belt conveyors in the modern coffee-roasting plant.

Corn. In the corn-canning plant conveyors handle green unhusked corn, clean corn on the cob, corn husks, and cobs in bulk. The flight conveyor usually is employed for handling the green corn, husks, and cobs, and the belt and apron types for the clean corn on the cob.

Rotary Mud. This is now salvaged over vibrating screens. Thus the oil-drilling industry is able to remove the cuttings very effectively and place the mud so necessary in drilling, in good reusable shape, free from foreign materials. The screen also performs the important function of degassing the mud.

Conclusion

Thus, from these concrete examples, there may be learned the amazing extent to which mechanical conveying equipment enters into the expediting of deliveries, the enlarging of plant handling capacities, and the reduction of industry's production costs.

MH-53-9

The Industrial-Type Internal-Combustion-Engine Locomotive

By S. B. SCHENCK,[1] EAST PITTSBURGH, PA.

The paper seeks to show that the internal-combustion type of locomotive can be used to advantage and at a much lower operating cost than the steam locomotive for industrial-plant use. The electric drive, in combination with gasoline or Diesel engines, places the internal-combustion type on a par with the steam locomotive so far as mobility is concerned, and ahead of the latter type with respect to availability for service, economy of operation, safety, visibility, convenience, and general performance. The electric drive is declared to be better than the conventional clutch and gear transmission between engine and axle as being better to operate, having more tractive power on grades, and in being much easier on the engine. There is available a wide range of internal-combustion type of locomotives using electric drives.

IN GENERAL, industrial rail transportation presents a marked exception to the prevailing progressive changes in different elements, methods, and machinery of industry. Many industrial plants that install up-to-date machinery or that use new methods of production still continue to use the steam locomotive for their rail transportation.

Probably this situation exists because of the fact that the steam locomotive has served industry long and faithfully as a motive-power unit, and it is still accepted as entirely suitable by many operators. On the other hand, when the almost exclusive use of the internal-combustion engine is considered for such essential industrial elements as construction machinery, airways, marine shipping, or highway transportation, the question arises whether the internal-combustion engine could be adapted satisfactorily to rail transportation. This question is emphasized when the cost of operating steam locomotives is reviewed critically—and incidentally such cost analyses often disclose real surprises to progressive plant managements, particularly when the steam locomotives are of ancient vintage.

The internal-combustion engine can be utilized on locomotives to good advantage from economy and operating standpoints, although much depends on the method employed to transmit the power of the engine to the rail, or in other words, on the type of locomotive. Recent developments in locomotive power transmissions have produced the electric drive, which, in combination with gasoline or Diesel engines, places the internal-combustion-engine type of locomotive on a par with the steam locomotive with respect to mobility and ahead of the steam locomotive with respect to such operating factors as availability for service, economy of operation, safety, visibility, convenience, and general performance. The electric drive has many advantages over the conventional clutch and gear transmission between engine and locomotive axle, in that it is easier to operate, gives better pulling power and superior overall performance on grades, is much easier on the engine, and produces a locomotive of greater general reliability and availability. It is rapidly supplanting the mechanical drive on locomotives weighing between 12 and 25 tons, and is still more widely used on locomotives weighing 30 tons and upward.

Gasoline-electric locomotives for industrial service are now available over a weight range from 12 to 90 tons, utilizing engine powers from 120 to 600 hp. Diesel-electrics range between 30 and 110 tons at present, although this weight range will doubtless be widened in the near future. Varied designs of locomotives have been produced, and for most industrial work the following locomotive characteristics are well established:

1 Reliable power plants
2 Pulpit, or center-type, cab with double control stations
3 Maximum visibility
4 One-man operation
5 Adequate locomotive auxiliaries
6 Swivel-type trucks
7 Engine power ordinarily about 6 to 8 hp. per ton of locomotive weight.

These features are embodied in the locomotives illustrated, except for the type of truck. All of the features are found on locomotives using dual power plants, center-type cab, and swivel trucks, as shown by Figs. 1, 2, 3, 7, and 9. Fig. 8 illustrates a single power-plant locomotive with swivel trucks and a pulpit type of cab. Other combinations of these features are shown by Fig. 6, where the dual power plant is adapted to the rigid wheelbase, two-axle type, or by Figs. 4 and 5, that typify construction ordinarily used on the smaller locomotives, weighing about 25 tons or under, where a single engine, four wheels, and end type of cab give very satisfactory results.

Equal power on locomotives up to about 500 to 600 hp. can be obtained by the use of either single or dual power plants. The single power-plant type, illustrated by Fig. 8, is preferred by many operators on account of there being only one engine and generator to control, inspect, and maintain. Obviously, a single large engine has fewer wearing parts than two smaller engines. The large engine usually operates at slower speed than an engine of half size, and it therefore can embody greater general ruggedness, stamina, and design factors which tend toward longer life, great reliability, and satisfactory maintenance.

On the other hand, the use of dual power plant provides a flexibility in locomotive operation and safeguarding of service unobtainable by a single power plant. Because locomotives weighing in a range from 30 to 110 tons have been equipped with dual power plants, a brief review of the operating features of this type should be interesting.

From the standpoint of first cost, at present dual power plants totaling about 500 hp. or lower usually are less expensive than single power plants of equal capacity, on account of the smaller

---

[1] General Engineering Department, Westinghouse Elec. & Mfg. Co. Mr. Schenck has had four years' experience in this department in the application and equipment of self-propelled cars and locomotives.

Presented at the "Three-M" (Management, Materials, Maintenance) Congress held in Cleveland, Ohio, April 13 to 17, 1931, under the auspices of the A.S.M.E. and the S.I.E.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

engines being in standard production by their manufacturers. This is particularly noticeable where gasoline engines are concerned. There are fewer available sizes of locomotive-type oil engines, so that this situation does not prevail to the same extent as with gasoline engines, and in some cases the single power plant may have lower first cost. Two engines also afford greater safeguard to the service, since it is unlikely that both engines would

be out of service at the same time, and experience has shown that minor repairs can be made to one engine while the locomotive continues in service, working from the other engine. Under such circumstances service interruptions are minimized, for with one engine working, the locomotive can operate at half load and full speed or at full load and half speed.

The dual power plants may also assist in securing minimum fuel consumption, for in light service, such as occurs in much of the usual switching duty, one engine can be shut down at the will of the operator and the service easily be covered by the remaining power plant. With gasoline engines this can show a saving in fuel of 10 per cent or more as compared to working two engines in the same service, and it can show a greater saving if one large engine of equal power were used. The saving is considerably smaller for Diesel engines, due to inherent differences between the light-load fuel-consumption rates of the gasoline and Diesel engines. For either type in suitable service, the operation of a single engine of the dual power plant secures more nearly full load for a larger proportion of the time, hence at better fuel-consumption rate that results in reduced fuel consumption for the locomotive.

It is interesting to note that in much switching service large

(Built by G. D. Whitcomb Co., Westinghouse equipped.)

power in the engine is not required continuously, nor can it always be used advantageously. As an example, switching the cars from floats and classifying the cars in a yard showed the following daily average division of engine operating time and cars handled by a dual power plant, 330-hp., 50-ton gasoline-electric locomotive:

Time, locomotive in service, min	429
Time locomotive standing, total min	275
Time locomotive moving, total min	154
Distribution of locomotive moving time:	
Two engines and four motors, 30 min., cars moved	252

One engine and four motors, 96 min., cars moved	575
One engine and two motors, 28 min., cars moved	82
Cars moved, total	909
Total number of movements	283
Average length of run with trains, ft	278
Estimated ton miles, including light locomotive	2907
Estimated locomotive miles, total	15.2
Gasoline consumption, gal	60

In similar service, but with two engines working continuously, the fuel consumption averaged 72 gal. per 8-hour day. In the service referred to, the single 175-hp. engine and four-motor combination had no difficulty in maintaining the schedule of the yard operation and could kick cars as fast as the ground crew could handle them conveniently. The yard is comparatively level, and the trains were relatively short, being limited to the load on the float or in most cases to the maximum number of cars the locomotive could handle from the float at one trip up the 3

(Built by Heisler Locomotive Works, Westinghouse equipped.)

per cent grade and 18-deg. curve. The 50-ton gasoline-electric locomotive was handling larger trains from the float than the 65-ton steam locomotives were reported to handle.

A gasoline- or Diesel-electric locomotive with the pulpit, or the center type of cab, and with double control stations, allows operation with one man, thus reducing the usual switching-crew expense between 20 and 25 per cent per locomotive hour. Double control stations permit the operator to step from side to side of the cab and operate the locomotive from either side, enabling him always to operate from the side that has maximum visibility along the train or from where the ground-crew signals are most easily seen. When box cars are handled in large numbers, between buildings, an elevated operator's station in the center cab gives exceptional vision toward the crew on the tops of the cars. For example, the brakeman can be seen easily on the top of the fourth or fifth box car from the operator's station of a locomotive recently placed in yard switching. These features all aid materially in speeding up the switching service, thus indirectly reducing the expense in addition to saving the wages of the second man in the cab. In comparison with a steam locomotive, the visibility in the gasoline- or Diesel-electric is generally much better, and the fireman is never needed, although sometimes local operating rules require the second man in the locomotive cab.

For locomotives built as shown by Fig. 3, with 165-hp. to 225-hp. engines, visibility is much increased, not only by the raised platform in the center cab, but by the very low height of radiators and engine hoods. With this locomotive a man on the ground standing half a car length ahead of the locomotive can be seen by the seated operator, looking diagonally across the hood and radiator. A steam locomotive could hardly be built to give such maximum visibility.

When engine power and locomotive size require large engines,

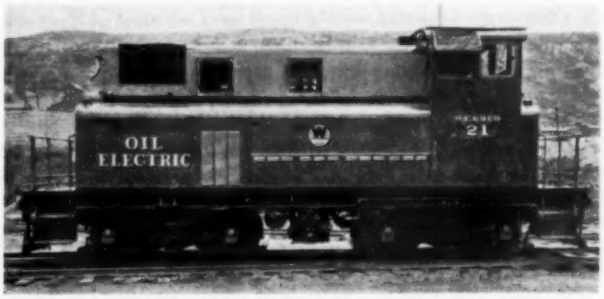

FIG. 8 70-TON, BALDWIN-WESTINGHOUSE 400-HP. DIESEL-ELECTRIC LOCOMOTIVE, FOR GENERAL SWITCHING AND HAULAGE

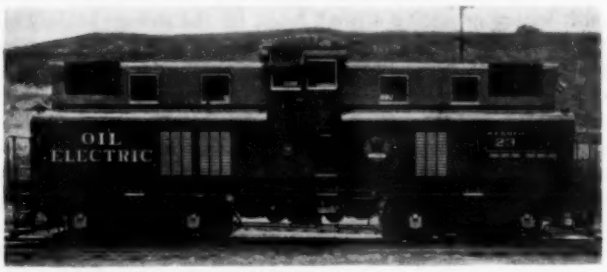

FIG. 9 110-TON, BALDWIN-WESTINGHOUSE 800-HP. DIESEL-ELECTRIC LOCOMOTIVE, FOR HEAVY-DUTY SWITCHING AND HAULAGE

FIG. 10 39-TON, 310-HP. LOCOMOTIVE-TYPE LARRY CAR
(Built by Differential Steel Car Co., Westinghouse equipped.)

it is evident that the same type of construction cannot be used as with smaller engines. The 800-hp. Diesel-electric locomotive shown by Fig. 9 has center cab with elevated operator's stations which give excellent visibility for this size of locomotive. Obviously the enclosure will be much larger than for the 400-hp. engines and different from that for the 180-hp. engines for the locomotive shown by Fig. 3, so that the operator does not have the same near vision across the hood and radiator as on the smaller locomotive, but he still gets better visibility than on a corresponding size of steam locomotive.

Where a large single engine is used, visibility in one direction is difficult to obtain on account of the bulk of the engine being in front of the cab. The locomotive shown by Fig. 8 is a good example of maximum visibility, convenience in operation, and compact assembly where the pulpit-type end-mounted cab is

used. Fig. 5 shows similar general features on the small single power-plant locomotive, where the size of engine permits good visibility to be obtained with conventional cab arrangement.

Often an industrial plant has use for both large and small locomotives. Where a certain size of power plant can be used on the small locomotives, and two of them used on larger locomotives, there is a gain in the standardization from the standpoint of the smaller variety, fewer number, and less expensive repair parts to stock, less total locomotive time lost waiting for special non-stock repair parts, and easier maintenance, as there is greater interchangeability of assembled parts. The size of the engine will not change the importance of these factors.

Where the industrial-plant service requires a large locomotive for a few operations and several small ones for most of the work, the small locomotives can be arranged for operating two in multiple, and thus give the same performance as a single locomotive of double the power. This is the equivalent of double-heading steam locomotives, except that only one man is required for the multiple-unit locomotive and the locomotives will operate in synchronism. Or again, multiple-unit operation may be desirable to distribute the required locomotive weight over numerous axles and at the same time obtain very short wheelbases for minimizing track upkeep or for operating large power on light-weight rails and around very sharp curves.

One-man operation is a feature of all the gasoline- or Diesel-electric locomotives. It takes no more effort for the operator to run a 110-ton locomotive than it does to run one weighing one-tenth as much. Starting the engine is a matter of operating a push button or setting a small lever, for the storage battery on the locomotive cranks the engine until it starts firing. The absence of smoke and steam enables the operator to observe crew and roadside signals with ease. He is comfortably housed and seated, and there is no boiler coal to handle, no steam pressure to keep up, and no ashes to dump, so that he can give full attention to his job of keeping the locomotive moving. There are no gears and clutches to handle, as on a mechanical-drive type of internal-combustion locomotive; hence the operator's duty is much lighter on the gas- or Diesel-electric, and he does not become so tired as the day's work progresses. This assists in improving the quantity and quality of work done by these types of locomotives. Experience has shown a reluctance on the part of the usual steam engineer to begin running a gas- or Diesel-electric, but after a few days' operation on either of these types, most engineers do not want to go back to operating a steam- or a mechanical-drive locomotive.

The average industrial railroad or yard involves sharper curves than on a steam railroad, and very often the condition of the track is only fair. Hence, the industrial type of locomotive should have a short and flexible wheelbase to give good tracking characteristics and to reduce rail wear on curves. Fig. 9 shows the usual swivel-truck arrangement that has proved exceptionally well suited for the average industrial track. Trucks of similar general design on lighter weight locomotives have given very satisfactory service on temporary tracks such as are laid in open-pit mines. In one mine the steam locomotives were derailed almost daily, but there have been very few derailments for the two years of operation of gas-electric locomotives. This mine also found the gas-electric could usually rerail itself, something that could seldom be done with the steam locomotive. In another large industrial plant the use of oil-electrics with swivel trucks, as typified by Fig. 9, is reported to have reduced track maintenance by about 20 per cent. These factors indicate some of the indirect savings made by the internal-combustion-engine type of locomotive.

Two general methods are used to operate locomotive auxiliaries, such as radiator cooling fans, air compressor, and main-motor blowers. The electric drive produces the best general result, although the mechanical drive has given satisfactory performance in switching services. The electric drive is necessary when radiator or blower fans are to be operated intermittently or when the fans cannot be driven direct from the engine or when the air compressor is to be operated at full speed with the engine either idling or running at operating speed. These conditions occur more often on the larger locomotives, and the locomotives shown by Figs. 8 and 9 are so equipped.

Electric auxiliary drive involves separate motors and their control, so that the comparative simplicity of the mechanical drive makes a strong appeal to many operators, although it has certain inherent operating and installation handicaps. It has given satisfactory service on industrial and switching locomotives of the type shown by Figs. 3 or 5, where the radiator fan is belt driven and the air compressor is belt or chain driven.

Fig. 7 shows a distinctive type of internal-combustion-engine locomotive that is exceptionally well suited for heavy-duty, slow-speed service. It utilizes power plants similar to those on the locomotive illustrated by Fig. 3, but the motors are mounted on the under side of the locomotive frame and are geared to a longitudinal drive shaft that transmits the power through universal joints and bevel gears to one axle on each truck. Siderods connect this axle to the other on the same truck. The axles are all connected mechanically through the siderods and drive shaft, with the result that the locomotive develops exceptionally high tractive effort before the wheels slip. On recent test, with sand on fair rail, the drawbar pulled developed repeatedly was over 40 per cent of the weight on the locomotive drivers. This type of locomotive provides a means for securing large power on narrow gages, as a change in track gage usually affects only the trucks and locomotive body width, so that within limits the same power plant and motors can be used for different gages.

An entirely different gas-electric locomotive is the burden-bearing type, illustrated in general by Fig. 10. This is in reality a dump car equipped with two 155-hp. gasoline engines and electric drives. It is designed to be more of a haulage unit than a general switching locomotive, but when loaded it is well adapted to handle trailers, and when empty to do the small amount of switching required around quarries, storage yards, etc. Doing double duty in this way, investment in equipment is reduced and the range of locomotive operation is widened.

Another type of industrial locomotive uses internal-combustion engines, either gasoline or Diesel, in combination with a storage battery. The battery acts as a reservoir capable of supplying power much in excess of that from the engine alone, thus materially improving the locomotive performance for short-time peak tractive-effort demands. Since the battery is charged from the engine-generator set mainly when the locomotive is not working or when the engine is idling, it is evident that this type of locomotive is best suited for services where there is much engine-idling time or where the locomotive is not kept in continuous duty. It is advantageous when the service requires locomotive operations inside of buildings where engine fumes are undesirable. Careful analysis of the service is always necessary to insure the proper size of battery and satisfactory balance between battery and engine power. If the battery is too small or if worked too hard, comparatively short battery life and consequent abnormal battery replacement expense may be expected. The analysis may also disclose service which is "lop-sided," so to speak, where the battery would be quickly discharged and there would remain insufficient time or available engine power to recharge it, so that the locomotive would have to be taken out of service for battery attention, thus reducing locomotive availability. The combination locomotive is heavier for equal continuous power than a straight gasoline or oil-electric, because

the battery is heavier than an engine of equal continuous output. Extra weight is very useful sometimes, but cannot always be considered advantageous. These factors indicate that the combination type of locomotive is adapted better for comparatively light intermittent duty or for special applications, rather than for general, all-round switching and transfer work.

The engine power which has been applied on industrial gasoline- or Diesel-electric locomotives varies much, depending on service, investment, available engine sizes, kind of fuel, and other factors. At present, satisfactory performance is obtained with gasoline-electric locomotives having an engine power range from 5 to 10 hp. per ton of locomotive weight, with an average of between 7 and 8 hp. per ton. Diesel-electrics range from 5 to about 7 hp. per ton, with an average of about 6 hp. per ton. There are many indications that the horsepower per ton will increase as suitable sizes of engines become available at satisfactory prices. A much wider range of suitable gasoline engines is available as compared to Diesel engines, and most engine builders are in standard production for gasoline engines of around 250 hp. or under, while comparatively few engine builders have Diesels in large production. The result is approximate price variations as follows:

	Dollars
Under 150 hp. gasoline, per horsepower	8 to 10
165 to 225 hp. gasoline, per horsepower	10 to 12
250 hp. gasoline, per horsepower	15 to 20
300 hp. gasoline, per horsepower	22 to 25
180 to 240 hp. Diesel, per horsepower	25 to 35
300 to 400 hp. Diesel, per horsepower	40 to 50

With both gasoline and Diesel engines available in comparable sizes, but at different prices, it naturally follows that the Diesel electric locomotive will cost more than the corresponding size of gasoline-electric. Either type has higher first cost than a corresponding steam locomotive. However, the better pulling power, ability to do more work, and smoother accelerating characteristics of the gasoline- or oil-electric locomotive enable it to start a heavier load than a steam locomotive of the same weight so that either type can be 25 to 30 per cent lighter in weight than a steam locomotive of corresponding tractive effort. If the first cost of an up-to-date steam locomotive is taken at 100 per cent, the approximate first-cost ratios of the other types are as follows:

65-ton steam	100
50-ton gasoline-electric	145 to 160
50-ton Diesel-electric, two engines	195 to 210
50-ton Diesel-electric, single engine	200 to 215

It appears that the internal-combustion-engine type of locomotive must show great savings over a steam locomotive to overcome the handicap in first cost. Both gasoline- and Diesel-electrics do this without question. One company operating a 35-ton gasoline-electric in 24-hour-a-day service in place of a 50-ton steam locomotive reports $8.60 per day saved, including fixed charges.

Another company reports that their 45-ton gasoline-electrics show, among other savings, the elimination of about $9 a day as the cost for keeping up steam during off-turns for the steam locomotives.

A 70-ton Diesel-electric in railroad switching service has given a saving of at least $40 per 24-hour day over steam switching. In heavy-duty mill switching, certain 60-ton 300-hp. Diesel-electrics operate at a cost of $2.93 per locomotive hour, including fixed charges, as compared to $5.10 per hour for steam locomotives. In the smaller sizes a 12-ton gasoline-electric has been operating at between one-half and two-thirds of the cost of the replaced steam locomotive. At another plant one 15-ton gasoline-electric has replaced two steam locomotives. These examples are typical, although costs and savings will vary over wide ranges, depending on the service. Accounting methods also play an important part in fixing the costs and savings.

In the final analysis, the economies of the respective types of gasoline-electric, Diesel-electric, mechanical-drive, or combination battery-Diesel will usually determine the type best suited for a given application. For example, a gasoline-electric in the same service as a corresponding Diesel-electric will use roughly twice as many gallons of fuel, and the gasoline may cost three times as much per gallon as the fuel oil. The gasoline-electric locomotive will therefore have higher fuel expense than the Diesel-electric, but against this must be set the lower fixed charge of the gas-electric and its other operating expenses which tend to be lower, such as maintenance. Since the service fixes the fuel consumption, and therefore sets the fuel expense, the total operating cost of the gas-electric will exceed the Diesel-electric when the service requires gasoline at the rate of 6 or 7 gal., or more, per locomotive hour.

It may be seen therefore that there is available a wide range of internal-combustion-engine type of locomotives using electric drives. These locomotives have been proved in industrial service, with satisfactory results. The use of this up-to-date motive power has so many advantages over the steam engine and shows such attractive savings that it well merits the attention of every user of industrial locomotives.

Types of Materials Used in Materials-Handling Equipment

By HERVEY J. SKINNER,[1] BOSTON, MASS.

Materials-handling equipment means to most people a conveyor for carrying solids, but the author defines it also as a pump for handling liquids or a steel cylinder for transporting gases. The material used in the construction of such equipment must meet a wide variety of conditions. The author discusses wood, concrete, glass, rubber, copper, lead, nickel, aluminum, and iron and steel. The fundamental research initiated within the last ten years by the large steel companies furnishes a foundation which few other industries possess for the production of many new alloys.

MATERIALS-handling equipment in its broadest sense includes any apparatus in which material, whether solid, liquid, or gaseous, is contained or by which it is moved from one location to another. In the minds of many people, materials-handling equipment means some sort of a container or conveyor for solids, although a pump for handling liquids or a steel cylinder for transporting highly compressed gases is just as truly a piece of materials-handling equipment.

The material used in the construction of such equipment must meet a wide variety of conditions. In practically all cases tensile strength and resistance to abrasion or wear are essential. In addition there are many instances where ability to resist heat and corrosion and other special characteristics are necessary.

In the construction of materials-handling equipment the basic materials available are comparatively few, although there are many ramifications of these materials. The basic construction materials which may be mentioned are wood, concrete, metals, glass, rubber, and ceramic materials. During the past 10 or 15 years there has been a remarkable increase in the kinds of material from which equipment is constructed. Many of these may be termed freak constructions and have proved impractical, but others have won a well-deserved place in equipment manufacture. Rubber-lined tanks and glass piping are examples of equipment that only a few years ago would have been regarded as visionary.

Wood

Wood finds many uses in any plant. Its use for tanks is well established and familiar to plant engineers. Wooden piping, however, is not so well known. Wood has certain advantages over iron and steel. Its first cost is low and its maintenance almost nothing. It is a non-conductor of heat, and is not subject to corrosion. Steel tanks require paint both inside and out at more or less frequent intervals. While wooden tanks are often painted on the outside for sake of appearance, it is generally considered better not to paint them, since it does not help to preserve them. Wood absorbs a certain amount of water, and with the outside of the tank sealed with a coating of paint, the evaporation of this absorbed water, which may cause deterioration, is retarded since the wood cannot breathe. Being a non-conductor, the contents of a wooden tank will remain cool for a longer period in summer, and in winter are better protected from the frost. Although wood tanks in exposed locations may require a heating system, the heating unit need be only about one-third the size required for a steel tank of the same size.

Wood pipe is made in two types, one consisting of a barrel of California redwood staves bound together by individual steel bands or spirally wound wire, and the other a bored pipe made by boring through the center of a piece of straight-grained clear redwood. The former type is built in sizes ranging from 2 in. to 15 ft. in diameter and will withstand static-pressure heads up to 350 ft. Wood pipe has good flow qualities, since it has no lap joints or connection irregularities. It has proved its value in many cases where conditions require pipe which will resist acid and other corrosive influences, and in the disposal of certain types of gases which are destructive to ordinary flue materials.

Concrete

The use of concrete should be mentioned, although its limitations are well known. It has advantages for certain types of apparatus where strength is desired, but it is bulky as compared with steel. It is affected by acids and is not wholly resistant to alkalis or even water. Alkalis have a slow deteriorating action, the concrete losing its strength and gradually disintegrating. Water exerts a slight solvent action on the lime of the cement, precipitating iron from the water which is deposited on the surface of the concrete. It is believed that this coating of iron helps preserve the concrete from further deterioration.

When it is advisable to use concrete for acid or alkaline conditions, the best treatment is to apply a protective coating of tar or asphalt, but these are not always permanent and usually cannot be reapplied. Various materials have been tried in the concrete mix for preventing corrosion, but their use has not been successful, and while sometimes a harder surface more resistant to abrasion is obtained, they do not increase appreciably the resistance of the concrete to corrosive agencies.

Lean concrete deteriorates more rapidly than concrete rich in cement on account of its greater porosity and permeability. In the construction of cement-lined pipe a very rich mortar is used which is practically watertight. For this reason solvent action is reduced to a minimum, and cement-lined pipe has been in use for many years with marked success. The amount of lime dissolved by the water is slight and will cause no appreciable trouble where there is a reasonable flow. Instances are on record,

---

[1] President, Skinner & Sherman, Inc. Mr. Skinner's firm of consulting chemical engineers is engaged in research and development problems for various industries. He is technical adviser to the Associated Industries of Massachusetts, a member of the American Institute of Chemical Engineers, the American Water Works Association, and other organizations.

Presented at the "Three-M" (Management, Materials, Maintenance) Congress held in Cleveland, Ohio, April 13 to 17, 1931, under the auspices of the A.S.M.E. and the S.I.E.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

however, where water has stood in cement-lined pipes and has become sufficiently hard to be objectionable for many purposes.

Another form in which concrete pipe is becoming industrially important in the handling of liquids, particularly water and sewage, is centrifugally cast reinforced-concrete pipe. This method of production gives the concrete a smooth, even appearance which reduces friction to a minimum.

Glass

Glass is a most striking example of the development of a familiar material whose application has been extended to new industrial uses. The manufacture of mechanically strong glass, chiefly of the borosilicate type, is responsible for this extension in the use of glass. "Pyrex" glass made by the Corning Glass Works is a glass of this type. It has a very low expansion coefficient, which renders it resistant to sudden changes of temperature. It also has high mechanical strength so that it is capable of withstanding sudden shocks due to rough handling. Its high surface hardness, which is only three points below that of the diamond, and its exceptionally smooth surface cause it to resist certain kinds of abrasion better than steel.

"Pyrex" glass tubing and piping are used extensively in many industries and are available in both flanged and bell-and-spigot joints. Flanged pipe can be obtained up to 3 in. in diameter and socket pipe up to 12 in. in diameter. The smooth surface minimizes friction loss, and the resistance of the glass to chemical attack prevents contamination of product. The transparency of glass is a valuable feature as it allows full visual evidence and control of flow or movement inside the piping, and also enables one to observe the surface cleanliness.

Considerable research has been carried on by the Corning Glass Works with a view to improving the earlier methods of making joints with glass piping. The first installations were made with bell-and-spigot joints, using cements, or with straight pipe runs, using rubber-hose connections. The limitations of these types of joint led to the flanged type with a thin gasket and split metal flanges for clamping together the glass flanges.

This method has proved very satisfactory where a pipe line is installed permanently and where it is important that the liquid handled has a minimum contact with anything other than glass. The food industries have welcomed this addition to the types of piping available for their purposes, and one of the foremost beverage plants in the country has replaced all of its pipe lines with the "Pyrex" glass-flange type.

More recently a new type of joint has been developed by mechanically shaping the ends of plain tubing so that the bore remains constant but the external diameters increase. In other words, the ends of the pipes are cones, with the bore of the tube extending through the cone and the base of the cone forming the end face of the tubes. These are clamped together with a specially designed metal clamp which is easy to assemble.

Glass tubing finds wide application in heat-exchanging operations, particularly where corrosive substances have to be handled, one factory alone using 18 miles of "Pyrex" piping. Although the actual heat transmission is greater through metals than through glass, it has been found that the permanently smooth surface of glass counterbalances the greater heat transfer of metal, and that after a few months of use the heat-transfer values of glass and metal not only approach each other, but that there is an advantage in favor of glass. It has been demonstrated that metal tubes lose some of the initial efficiency because of internal roughening, due to corrosion, and also because the external surface in contact with the cooling liquid becomes roughened and coated.

As a result of these investigations, glass-tube heat exchangers are becoming quite a well-known piece of equipment, not only in the chemical industries, but in the public-utility field, as an equipment well suited to the handling of ammonia liquors resulting from the operation of gas plants.

Another interesting application of glass is as a lining for tanks and similar equipment. "Glascote," made by the Glascote Company, has positive adherence to steel and is consequently durable and resistant to physical shocks. Its coefficient of expansion is the same as that of steel, so that it stands up under quick changes of temperature, and its composition makes it resistant to chemical action. Completely glass-lined mixing tanks, reaction vessels, and other equipment, with glass-coated agitators and coils, are available and used in many industries where cleanliness and the prevention of corrosion are essential considerations.

The Pfaudler Company also builds acid-resisting glass-lined steel equipment for various purposes, including glass-lined pipe and fittings. Freight cars equipped with glass-lined tanks are commonly used for the transportation of milk and other products.

Rubber

Rubber is another material whose field of usefulness has been greatly extended by comparatively recent inventions. Rubber is chemically inert and is resistant to the action of most corrosive solutions. Hard-rubber piping and fittings have been in use for a long time. More recently its use has been extended to larger pieces of apparatus and to the lining of metal equipment. The "Ace" process of the American Hard Rubber Company interposes a relatively thin layer of soft rubber between the metal surface and the hard-rubber lining, and bonds the latter securely to the metal.

The "Vulcalock" process of the B. F. Goodrich Rubber Company is another advance in the use of rubber in materials-handling equipment. By this process it is possible to unite rubber to metal, wood, concrete, and other materials. The bond is so strong that the rubber will often tear before it can be separated from the metal surface to which it is applied. The Vulcalock process can be used with the most elastic grades of soft rubber as well as with flexible hard rubber. More than one hundred steel tank cars lined with rubber by this process are in use for the transportation of acids and other corrosive liquids.

Rubber-lined tanks, piping, valves, and other fittings are in general use. Rubber-covered fans in which the entire wheel shaft and interior of the housing are covered with rubber find special application in ventilating systems where corrosive gases and fumes have to be handled.

"Armorite," another Goodrich product, is a rubber compound developed for high resistance to abrasion. In certain types of abrasive service it has been found to outwear ten times its thickness of hard steel. It is particularly valuable in lining chutes, hoppers, and spouts that are subject to abrasive wear. Rubber-coated screen wire for the screening of sand and gravel and other abrasive material finds useful application. These rubber linings can be applied to concrete tanks, aluminum, stainless steel, and certain compositions of brass. Its life is almost indefinite so long as the tank is intact. It can be used at temperatures up to 150 deg. fahr., but will deteriorate when exposed to oils, particularly mineral oils.

Metals

The metals most commonly used in materials-handling equipment are iron, copper, nickel, aluminum, lead, tin, and zinc and their various alloys. With the advance in our knowledge of the science of applied metallurgy, many other elements have been added to these basic metals to obtain desirable properties. As such additive metals may be mentioned chromium, nickel,

manganese, tungsten, vanadium, molybdenum, bismuth, and cadmium.

Copper

Copper is one of the oldest metals and its uses are well known. Its advantages are due to a combination of characteristics. The metal is easy to fabricate and can be made in almost any form required. It has a considerable degree of resistance to a limited variety of corrosive reactions. As the metal itself, it is used mainly in sheets for lining or covering equipment made of wood or other materials, and in the form of special apparatus.

The alloys of copper with other metals are numerous and find many important applications. The various brasses and bronzes, which are alloys of copper, zinc, lead, and tin are used extensively for piping, valves, and other fittings under conditions which are too corrosive for iron or steel. "Admiralty Metal," an alloy of copper, zinc, and tin, was developed especially for resistance to sea-water corrosion and is used generally for condenser tubes in which the cooling medium is salt water.

Among other bronzes developed especially to withstand corrosion may be mentioned "Aterite," a nickel-brass, "Meco Metal," a copper-nickel-zinc alloy, and "Ampco," an aluminum-bronze.

Lead

Lead in the form of pure metal finds many uses, although they are for the most part confined to the lining of tanks, pumps, piping, etc. It is used extensively where sulphuric acid enters into any chemical process. Its purity is of great importance, and unless it is highly pure its resistivity is of a low order. It lacks the characteristic of physical strength, which is sometimes offset by the addition of other alloying metals like antimony, with a corresponding reduction in its resistive properties.

Lead-lined iron pipe has found many uses for conveying liquids which are corrosive to iron. "Crawlproof sheet lead," made by the National Lead Company, is one of the newest developments in sheet lead, and is a chemical lead sheet reinforced inside with antimonal-lead supporting bars to prevent buckling and wrinkling.

Nickel

In certain specialized equipment, nickel has been found advantageous. It is both rustproof and highly resistant to corrosion, and its hard, non-porous surface is easy to clean and to keep clean. It finds considerable application in the food industry and in the manufacture of pharmaceuticals. Nickel tubing is used extensively in these industries as well as others for heating and cooling purposes.

Of the alloys of nickel, Monel metal is perhaps the most important. This is an alloy of nickel and copper with high nickel content. It has unusual strength and toughness which, together with its non-corrosiveness, makes it an ideal metal of construction in the food and dairy industries. Laundries have found it of value because of its rustproof qualities, and dyehouses are using Monel-metal equipment on account of its being unaffected by the dye liquors. It is used in the manufacture of machine parts such as gears and pinions, and because of its elasticity and toughness it is well adapted to the weaving process of making wire cloth.

Nickel is used extensively for plating purposes. It is easily deposited on iron, takes a light polish, and keeps it well, although it requires repolishing from time to time. A thin skin of chromium deposited on top of the nickel gives a light nickel-colored surface of extreme hardness, so hard in fact that it cannot be polished. Chromium is not so extremely hard in itself, but the combination which it forms with hydrogen during the plating process gives the hardest metal coating of which we know. The chromium layer need be only 0.000017 in. in thickness to give a coating that resists both rust and corrosion. The chromium-plating industry has grown enormously, and chromium-plating plants have been established in every important center of the country.

Aluminum

Aluminum is in a class by itself on account of its lightness. It is very sensitive to the action of alkalis, but is resistant to the action of many acids. Its resistance to corrosion is dependent on its purity, very slight amounts of certain impurities having a marked influence on its properties. It is available as sheet metal, castings, forgings, structural shapes, bars, rods, and tubing.

The heat treatment of aluminum alloys has multiplied its use and has given it the ductility and strength of mild steel.

The use of aluminum alloys has already opened up a wide field. "Duralumin," an alloy with copper, manganese, and magnesium, has found many valuable applications where lightness and strength are desired. It gave the Germans the material for the construction of airplanes during the latter part of the war, and it is now used for the framework of dirigible airships.

This alloy suffers from intercrystalline corrosion, and the attempts to overcome this defect met defeat until a coating of pure aluminum was sprayed on the surface by the Schoop process described below. Accelerated tests over a period of a few years indicate the efficiency of this coating to protect against intercrystalline corrosion. As a result of these experiments with coating, it is possible to cast a duplex ingot containing "Duralumin" in the interior and pure aluminum on the outside. This duplex ingot, known as "Alclad," can be rolled and worked into desired shapes.

The addition of a small proportion of magnesium to aluminum gives an alloy, "Magnalium," that is almost as light as aluminum and almost as strong as steel. An alloy of aluminum and calcium is lighter and harder than aluminum and more resistant to corrosion.

In connection with aluminum, mention should be made of the "calorizing" process patented by the General Electric Company whereby aluminum is driven into the surface of another metal, usually mild steel, to form an aluminum alloy. This alloy is immune to oxidation up to a temperature of 1650 deg. fahr., and completely resists corrosive reactions. Calorized steel pots provide durable containers for salt and lead baths, and the alloy has been very effective in the petroleum industry in protecting tubes in oil-cracking stills.

Metal Coating

Non-ferrous metals for coating other metals are made use of extensively in equipment for the handling of material. These may be applied by immersion in molten metal, known as hot dipping, by electroplating or by metal spraying. Tin is usually applied by the hot-dipping process. A sheet of iron dipped in melted tin comes out coated with a thin layer of the latter metal and furnishes the material so universally used as tin cans. If the tin is scratched, the iron beneath rusts more rapidly than if the tin were not there, on account of the electrolytic action which is set up, and iron being the negative element of the couple suffers at the expense of the tin.

With zinc, the opposite is the case, since it is negative toward iron, and when the two are in contact and exposed to corrosion, the zinc oxides first and the iron remains intact until the zinc has entirely dissolved. Ordinary galvanized iron is usually made by hot dipping in zinc, although the latter may also be applied electrolytically. "Sherardizing" consists in tumbling the articles to be coated in a drum with zinc dust which

is heated to 800 deg. fahr. The zinc at this temperature combines with the iron and forms a series of alloys, ranging from pure zinc on the top to pure iron at the bottom of the coating. This gives an efficient coating, since even if cracks appear, the iron is more or less protected so long as zinc remains. Electro deposits of zinc are apt to be more porous.

A more recent development of coating metals is the "Schoop" process, by which a wire of zinc or other metal is fed into an oxy-hydrogen air blast of such heat and power that the molten metal is projected with the speed of bullets, and any object which is subjected to this metallic spray may be coated with a deposit as thick as desired. A distinct advantage of this metal-spraying process is that it can be applied to the finished article even after the latter is in place, since the spraying apparatus is easily portable. A long list of metals can be successfully sprayed.

Iron and Steel

Iron and steel, of course, find the greatest use in the construction of equipment for the handling of material. Pig iron, the base of all iron and steel products, is the product obtained in the blast furnace from the crude iron ores. The essential properties of iron and steel depend upon the amount of certain other elements present, such as carbon, phosphorus, silicon, manganese, and sulphur. Cast iron contains roughly 93 per cent iron, and the other elements mentioned make up the remainder. It is essentially an alloy of iron, carbon, and silicon. It has relatively little strength, and cannot be used where strength or ductility is an essential property.

The treatment of cast iron to produce iron and steel products in useful form consists essentially in varying the properties of the elements other than iron and also in obtaining these elements in proper combinations. Malleable iron, for example, is remelted cast iron subjected to a heat treatment so that the carbon is uniformly distributed throughout the metal in the form of rosettes. This gives to the iron good machinability, fair strength, and fair ductility. Wrought iron is the name given to commercial iron made by refining the pig iron at a temperature so low that it is obtained in a pasty condition which permits the slag formed during the operation to be uniformly distributed throughout the mass. The process of making steel consists of several operations carried out in such a manner that the product is free from slag and contains the necessary modifying elements in proportions to produce the characteristics desired.

In recent years many new steel products have been developed which will withstand heat and corrosion to a marked degree. Corrosion is, as is well known, a serious factor, and an immense amount of research work has been carried on looking to the development of products which will resist it. Anything like an accurate estimate of the loss resulting from the corrosion of metals in common use is obviously out of the question. It has been estimated that the annual replacement of iron and steel products alone due to corrosion may reach as high as 2 per cent of the total tonnage in use. Assuming that there are 500,000,000 tons of iron and steel products in the United States, the loss would amount to 10,000,000 tons, or something over 30 per cent of our annual production of iron and steel products.

Chemically pure iron is not a commercial product. In fact, comparatively few people have ever seen the pure metal, which is soft, ductile, and white like silver. Commercially pure iron, however, containing less than approximately 0.16 per cent of impurities, is available. It is useful for structural work and other purposes where atmospheric conditions are severe. "Armco Iron," made by the American Rolling Mill Company, is an example of commercially pure iron.

High-silicon cast iron is resistant to the corrosive action of most acids and is extensively used for large pieces of apparatus. "Duriron," made by the Duriron Company, and "Tantiron," made by the Bethlehem Foundry and Machine Company, are examples of these ferro-silicon alloys. They contain 14 to 15 per cent of silicon, and the balance is iron with small amounts of carbon, manganese, sulphur, and phosphorus. In order to obtain non-corrosive properties it has been necessary to sacrifice toughness, but the composition is balanced so as to produce a metal with the best acid-resisting qualities, combined with a moderate amount of transverse strength and resistance to shock. These alloys are silvery white, close-grained iron, very hard and rather brittle. They are available only in castings, being too hard to machine with ordinary cutting tools, but may be finished by grinding into shape with some of the newer abrasives. They can be remelted by the oxyacetylene flame, although careful preheating and after-cooling of the welded parts are essential. They are rustproof and will withstand the action of most of the common acids except muriatic. Standard equipment in the shape of pipes and fittings, pans, chutes, kettles, pumps, valves, and cocks are available, and it is also possible to produce large castings for large-scale production.

Stainless steel and rustless iron are meeting a variety of uses. The element which is responsible for the stainless properties is chromium, when present in percentages between 12 and 15 per cent. The stainless steels usually contain 0.3 to 0.4 per cent of carbon and, in order to obtain the property of stainleasness, special heat treatment is required. Heating to a bright red heat, followed by rapid quenching, produces an alloy of iron and chromium which retains in solution the carbides of these two metals, thereby preventing an otherwise corrosive action. When special resistance to deterioration is required, the content of chromium may be increased to 20 or even 30 per cent.

Stainless steel found its first wide application in cutlery, where the advantages of cleanliness immediately established the steel in that field. More recently it has come into use where other corrosive conditions must be met, such as for exhaust valves in gas engines, piston rods for steam engines, and pumps for acid mine waters. Steels with the lower carbon contents have the best stainless properties, although they are not so hard as those with a high carbon content. These steels when suitably chosen for the particular purpose in view are practically immune to rusting and are very resistant to mild-acid corrosion. Stainless steel is available in bar stock in a wide variety of sizes and sections. Forged stainless pipes may also be secured in sizes beyond the limits of the ordinary piercing mills.

Stainless alloys low in carbon, which are not hardened, are often termed "rustless iron." They find wide application in sheets and in drawn and stamped articles. The sheets are annealed to be as soft as possible, as high ductility is more important than mechanical strength. Tank cars made of rustless iron are being used in the shipment of nitric acid.

Closely allied to the chromium steels but quite distinct are the chrome-nickel steels and alloys. The earliest use of chrome-nickel steels was for armor plate, and for many years these were the only alloy steels which were widely used. Later they came into general use for automotive steels, and are now used for all kinds of construction. The typical chrome-nickel steel will run from 0.60 to 1.50 per cent of chromium and 1.25 to 3.50 per cent of nickel, with 0.3 to 0.5 per cent of carbon.

When chromium and nickel are used in larger percentages, very tough stainless steels are obtained which possess high resistance against corrosion and remarkable ductility. Typical of these alloys are those containing 18 per cent of chromium and 8 per cent of nickel, made under the Krupp Nirosta patents.

Several manufacturers are licensed to make these Nirosta KA alloys. "Rezistal," made by the Crucible Steel Company, "Standardalloy," made by the Standard Alloy Company, Inc.,

and "Enduro," made by the Republic Steel Company, are typical examples. "Allegheny Metal," made by the Allegheny Steel Company, is another alloy of substantially the same composition These alloys are ductile and malleable, and are twice as strong as mild steel. They may be drawn, stamped, machined, cast, or welded. The corrosion-resisting properties are superior to any other ferrous alloy available in commercial quantities. Another unique feature is their ability to take a polish to a mirror-like surface which because of its rustproof properties is permanent, as distinguished from a plated surface which will wear or peel off. Although these alloys are expensive, the first cost sinks into insignificance when compared to the expense of replacement made necessary by rust and corrosion.

The application of these alloys has been most diversified, and in some cases the question has been raised as to whether their utilization by industry has not followed too closely on the heels of the metallurgist without sufficient tests as to durability over a period of time. This is particularly true where parts made from these alloys are used under high-pressure conditions.

The chemical industry has been quick to appreciate the advantages of these alloys, and they are found in nitric acid plants, in ammonia plants, and in many other cases where they are used for piping, condensers, heat exchangers, and other purposes. In the petroleum-oil industry they are used extensively in cracking stills and other parts subject to corrosion at elevated temperatures. The non-tarnishing properties make them ideal for the food and dairy industries and for kitchen equipment in hotels, restaurants, and hospitals. Laundries find them particularly valuable as they are not affected by bleach or other chemicals which are sometimes used.

More recently the possibility of these alloys for architectural and ornamental purposes has been recognized. In this connection it is of interest to note that the top of the Chrysler Building in New York is fabricated from these chrome-nickel alloys. In the new Empire State Building, "Allegheny Metal" is used, not only for ornamental purposes and for the dirigible mooring mast, but for mullions and window trim.

This brief survey of some of the many types of materials available for materials-handling equipment and the advances which have been made in comparatively recent years may indicate the immense range of possibilities which lie ahead.

It is only within the past decade or so that the large steel companies have undertaken fundamental research, or research looking toward the development of new products on a large scale. Heretofore the research of the steel companies has been confined more or less to improving methods of analysis, and the very accurate and rapid methods which have been developed whereby it is possible to determine carbon, manganese, silicon, phosphorus, sulphur, and other elements to a hundredth or a thousandth of a per cent are a tribute to the steel industry. They give the steel companies a foundation for further research which probably no other industry possesses, since the effect of even traces of these other elements is most marked, and unless methods are available for their determination, many false steps are easily possible in any research program. Such a foundation will surely be productive of many new steel alloys.

Great developments may be expected from the science of metallurgy. Of the more than fifty metals known, not half of them are in common use. The number of possible combinations of metals in alloys is infinite, and it is impossible to predict what properties may be obtained with new combinations and with some of the newer and rarer elements. Tantalum, for example, the metal used in incandescent lamps before the tungsten filament was developed, is now being produced by the Fansteel Products Company and is just coming into use for the lining of equipment. It is as hard as cold-rolled steel, yet ductile and workable, and inert to practically all corrosion.

Columbium, the sister-metal to tantalum, is awaiting development. It is a beautiful white metal with properties similar to tantalum, except that its density is only one-half as great. Beryllium is another metal with interesting possibilities. It is lighter, much harder, and four times as elastic as aluminum.

There can be little doubt that the future holds in store much greater advances than have been witnessed in the past few years, and it behooves every plant engineer, as well as others in charge of materials-handling equipment, to follow the progress of developments so that he can apply them as soon as they have been demonstrated to be practical.

Suspended Cables With Large Sags

By ROBERT C. STRACHAN,[1] NEW YORK, N. Y.

The curve assumed by a cable having its own weight and the applied load uniformly distributed over its length differs but little from a parabola if the deflection or sag is small; but as the actual curve is a catenary, modified more or less by the elastic deformation of the cable, the difference between the two curves becomes too great to be disregarded when, in the case of suspended structures other than suspension bridges, the sag exceeds a certain limit. The catenary being an exponential curve, its solution presents unavoidable difficulties. As a means of overcoming these in great measure, the author has compiled a table of hyperbolic radians tabulated as angular functions, whose use he shows by means of several worked-out examples.

IN THE design of cables for suspended structures other than bridges, the conditions encountered make it sometimes necessary to allow the cable to deflect or sag a greater distance below the supports than that which is suitable in suspension bridges.

The curve assumed by a cable having its own weight and the applied load uniformly distributed over its length differs but little from a parabola if the deflection is small; but as the actual curve is a catenary, modified more or less by the elastic deformation of the cable, the difference between the parabola and the actual curve becomes too great to be disregarded when the sag exceeds a certain limit.

The catenary is an exponential curve, and its solution therefore presents unavoidable difficulties. As a means of overcoming these difficulties in great measure, Table 1 (see Addenda) has been compiled. By its use, as there explained and illustrated, the angle A, in degrees, corresponding to a hyperbolic ratio u may be found without difficulty, and hyperbolic functions of u are trigonometric functions of A.

The equation of the catenary referred to an origin situated outside the curve on the axis of symmetry, at a distance a from the vertex, is

$$y = a \cosh\left(\frac{x}{a}\right) \quad \ldots\ldots [1]$$

The distance a is the parameter. The ratio x/a is a measure denoting hyperbolic radians or "hyps," designated by the symbol u, and the angle of slope of the curve at any point is the Gudermannian angle corresponding to u for that point. If the supports are on a level and L is the span, x becomes $\frac{1}{2} L$ at either support, and therefore for those points

$$u = \frac{L}{2a} \quad \ldots\ldots [2][2]$$

and A, the angle made by the terminal tangent with the x-axis, is

$$A = \text{gd } u \quad \ldots\ldots [3]$$

With u known, A may be taken from the table, or vice versa.

The horizontal component H of the tension at any point of the curve is equal to wa, where w is the unit weight. Hence, denoting the direct tension at the support by T,

$$H = \frac{Lw}{2u} \quad \ldots\ldots [4]$$

$$T = H \sec A \quad \ldots\ldots [5]$$

If a limiting value of H is fixed, u for any span may be calculated by Equation [4], thus determining all the remaining elements of the curve. Otherwise, u and A must usually be obtained by successive approximation and interpolation. An illustration of this process follows.

Let the sag v be 0.2 L; then

$$\frac{\text{exsec } A}{2u} = \frac{v}{L} \quad \ldots\ldots [6]$$

Trial angles are assumed and the exsecant and u taken from tables. The guide for finding a trial angle is that tan A is a little more than $4v/L$. When two angles sufficiently close together have been found to bracket v/L, the desired functions may be obtained by interpolating between them, with results as below:

	exsec	u	exsec/2u	
39°–58′	0.30477	0.76215	0.19994	
			0.20000	= v/L
39°–59′	0.30509	0.76253	0.20005	

From which:

$$A = 39°\text{–}58.55'$$
$$\sec A = 1.30494$$
$$u = 0.76236 \text{ hyps}$$

For the assumed case, therefore, L and w being known, Equations [4] and [5] give

$$H = \frac{Lw}{2 \times 0.76236} \qquad T = 1.30494H$$

and for C, the length of the curve,

$$C = L \frac{\tan A}{u} \quad \ldots\ldots [7]$$

or

$$C = \frac{L \times 0.83838}{0.76236}$$

If C and L are known, a close approximation is obtained by the following formula in which q represents C/L:

$$u = \sqrt{(120q - 20)^{1/2} - 10} \quad \ldots\ldots [8]$$

After finding A corresponding to u, the remaining elements may be calculated by Equations [4], [5], and [6].

[1] Consulting Engineer. Mem. Am.Soc.C.E. From 1900 to 1927 Mr. Strachan was identified with the design and construction of New York City bridges, buildings, and tunnel and subway structures, first as engineer of design in the various departments having control of bridges, tunnels, and transportation and later as assistant chief engineer of the Department of Public Markets. His work comprised both original constructions and alterations on steel and reinforced concrete buildings as well as cantilever, movable and suspension bridges, and tunnel design. In 1927–1928 he was engineer of terminals for the Port of New York Authority.

[2] See Addenda for this and other formulas cited.

From Equation [7], $q = \tan A/u$, and the above approximate u may be corrected by bracketing as illustrated, using tan A instead of exsec A. The results found with Equation [8], however, are sufficiently close for many purposes, with sags as large as $0.25L$.

If the curve C and sag v are known, approximations are unnecessary, as the parameter may be found directly by the formula

$$a = \frac{\frac{1}{4}C^2 - v^2}{2v} \quad \ldots\ldots\ldots\ldots\ldots\ldots [9]$$

and A is found by

$$\tan A = \frac{\frac{1}{2}C}{a} \text{ or exsec } A = \frac{v}{a}$$

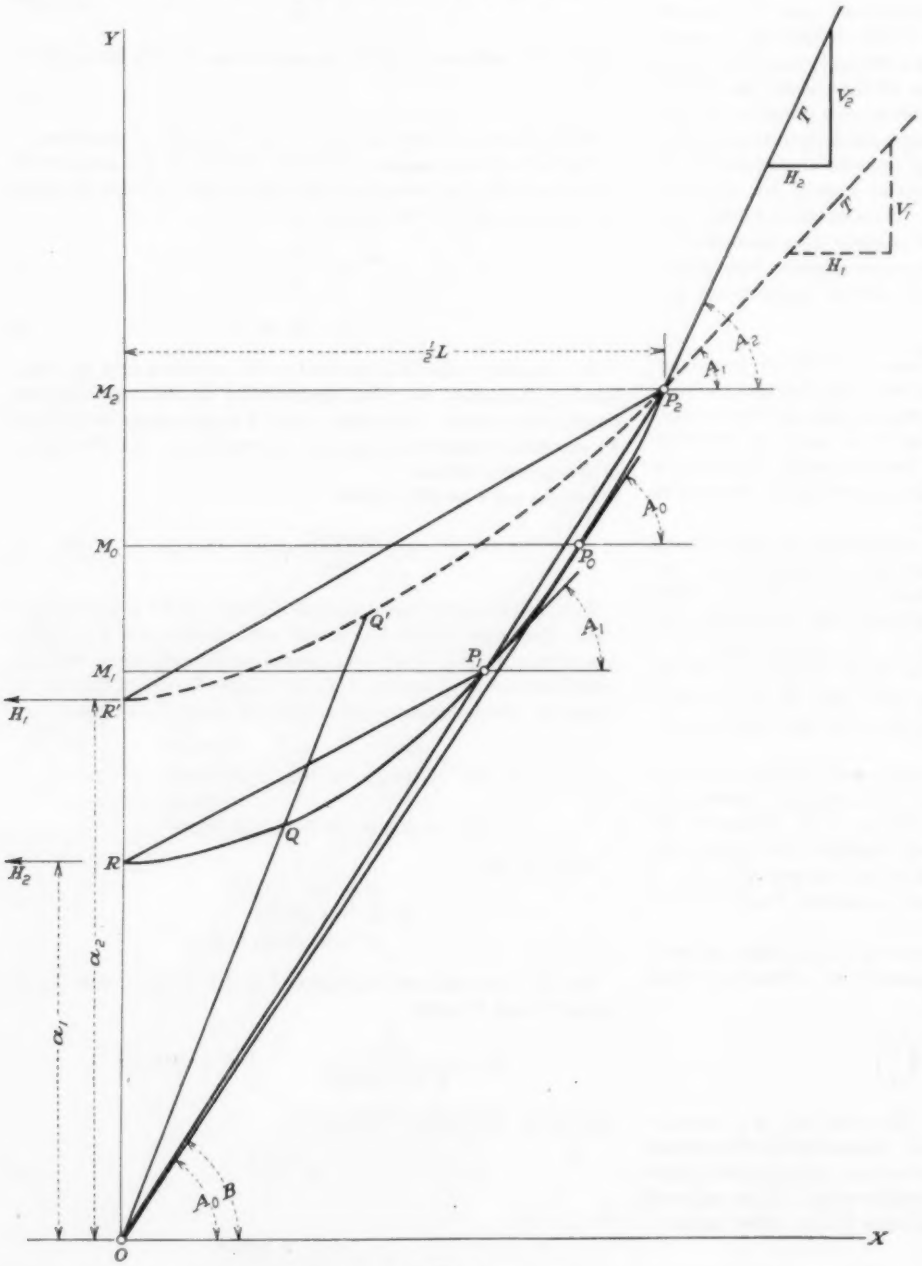

FIG. 1

OP_0 is tangent to catenary; OP_2 is secant.
$u_1 = M_1P_1/a_1 = L/2a_1$; $u_2 = L/2a_1$
$u_0 = M_0P_0/a_1 = 1.19968$ hyps
$A_1 = \text{gd } u_1$; $A_2 = \text{gd } u_2$; $A_0 = \text{gd } u_0 = 56° 27' 57''$.
cosec $A_0 = 1.19968$
$\cosh u_1/u_1 = \cosh u_2/u_2 = \tan B$
w = unit weight of cable and load
$H_1 = wa_2 = Lw/2u_1$; $H_2 = wa_1 = Lw/2u_2$
$V_1 = w \times \overline{P_2Q'R'} = Lw \tan A_1/2u_1$
$V_2 = w \times \overline{P_2P_1QR} = Lw \tan A_2/2u_2$
$T = w \times \overline{OM_2} = \frac{1}{2}Lw \tan B = \sqrt{H_1^2 + V_1^2} = \sqrt{H_2^2 + V_2^2}$
T is minimum when $B = A_0$; $T_{min} = 0.75444\,Lw$

After finding u corresponding to A, all other elements are then given by Equations [2], [4], and [5].

As T is necessarily greater than H in every case, it is often preferable to fix a limit for T rather than for H. Referring to [4] and [5], sec A = cosh u, therefore

$$T = \tfrac{1}{2}Lw\frac{\cosh u}{u} \quad \ldots [10]$$

and for a given span and tension the ratio cosh u/u is determined.

In Fig. 1 it is seen that a line drawn from the origin O at an angle A_0 with the x-axis is tangent to the curve at P_0, and any other line from O at an angle B greater than A_1 and less than 90 deg. cuts the curve at two points, P_1 and P_2. From the similar triangles it is evident that the condition

$$\frac{\cosh u}{u} = \tan B$$

is fulfilled at both P_1 and P_2, and

$$\frac{\cosh u_1}{u_1} = \frac{\cosh u_2}{u_2} = \tan B. \quad [11]$$

Drawing P_2R' parallel to P_1R and constructing the curve $P_2Q'R'$ so that for any point thereof

$$\frac{OQ}{OQ'} = \frac{OP_1}{OP_2}$$

we have two arcs with respective sags M_2R' and M_2R, the same span L, and the same tension T; for these two curves,

$$H_1 = \frac{Lw}{2u_1}; \quad H_2 = \frac{Lw}{2u_2};$$

$$T = \tfrac{1}{2}Lw \tan B \ldots\ldots [12]$$

The lengths of the curves are

$$C_1 = \frac{L \tan A_1}{u_1}; \quad C_2 = \frac{L \tan A_2}{u_2}$$

$$\ldots\ldots [13]$$

Both u_1 and u_2 may be found when tan B is known. As noted on Fig. 1, for the point of tangency,

$$u_0 = 1.19968 \text{ hyps}$$
$$u_1 < u_0 \text{ and } u_2 > u_0$$

Trial angles may be used to bracket the value of tan B, which is equal to both sec A_1/u_1 and sec A_2/u_2.

Another way is to take a limited number of terms of the series resulting from the expansion of Equation [11], replacing u_1 and u_2 by x. If powers higher than the sixth are neglected we shall have the following, after arranging the terms in the form of the general equation:

$$x^6 + 30x^4 + 360x^2 - 720x \tan B + 720 = 0 \ldots . \quad [14]$$

This equation has two positive roots, one of which is u_1 and the other u_2, and by well-known methods both may be evaluated to any desired number of decimal places.

Horner's method is especially adaptable. The requisite number of terms in [14] will depend upon the desired degree of precision for the final results. If the roots are carried to one or two places only, these approximations may be used as guides in bracketing.

With suitable modifications all the methods outlined will apply to spans in which the supports are at different elevations.

The Addenda following comprise statements of the relations of elements and the derivation of formulas.

Addenda

THE fundamental relations between the ratio u expressed in hyberbolic radians (hyps) and its corresponding angle A in degrees, are, as shown with Table 1,

$$\sin A = \tanh u \qquad \cos A = \operatorname{sech} u$$
$$\tan A = \sinh u \qquad \cot A = \operatorname{cosech} u$$
$$\sec A = \cosh u \qquad \operatorname{cosec} A = \coth u$$

The angle A is known as the Gudermannian angle in recognition of the mathematician Gudermann who first demonstrated its properties; and the symbol "gd," analogous to "sin," "cos," "sinh," "cosh," etc., is used to express this fact; thus:

$$A = \text{gd } u$$

and following the analogy of inverse functions,

$$u = \text{gd}^{-1} A$$

In a catenary with supports on a level, let

L = span
C = length of curve
v = deflection or sag
A = angle made by terminal tangent with horizontal
a = parameter of the curve.

TABLE 1 HYPERBOLIC RADIANS TABULATED AS ANGULAR FUNCTIONS[1]

Explanation of Table. If A, an angle in degrees, is the Gudermannian angle corresponding to a ratio u, expressed in hyperbolic radians (hyps), their relation, indicated thus,

$$A = \text{gd } u, \text{ or } u = \text{gd}^{-1} A$$

is such that

$$\sin A = \tanh u \qquad \cos A = \operatorname{sech} u$$
$$\tan A = \sinh u \qquad \cot A = \operatorname{cosech} u$$
$$\sec A = \cosh u \qquad \operatorname{cosec} A = \coth u$$

The table gives u in hyps for angles at 10-min. intervals, and intermediate values are to be derived by interpolation in the usual way. The angle A for any value of u having been found, all the hyperbolic functions of u may be taken out of trigonometric tables.

EXAMPLE 1. Given, $u = 0.84532$ hyps. Required, tanh u.
From table the next lower $u = 0.84482 = \text{gd}^{-1}\, 43° 30'$ (Diff. = 40.2 per min.)

$50 \div 40.2 = 1\frac{1}{4}'$

$\text{gd } u = 43° 31\frac{1}{4}' = A$

$\tanh u = \sin 43° 31\frac{1}{4}' = 0.68862$ Q. E. F.

EXAMPLE 2. Given, coth $u = 1.07405$. Required, u.
$\operatorname{cosec} A = 1.07405 \quad A = 68° 36'$
From table, $\text{gd}^{-1}\, 68° 30' = 1.66149$ (Diff. = 79.6 per min.)
79.6×6 min. $= 478$

$\text{gd}^{-1}\, 68° 36' = 1.66627 = u$ Q. E. F.

EXAMPLE 3. Given, chord of parabola $L = 200$ ft. Sag $v = 60$ ft. Required, exact length of arc $= C$.
Inclination of terminal tangent $= A$.

$\therefore \tan A = 4v/L = 1.2. \quad \therefore A = 50° 11.7'$
From table, $\text{gd}^{-1}\, 50° 10' = 1.01521$ (Diff. = 45.5 per min.)
45.5×1.7 min. $= 77$

$1.01598 = \text{gd}^{-1} A$

$0.84665 = \text{gd}^{-1} A/1.2$
$1.56205 = \sec A$

$2.40870 =$ coefficient of $L/2$.

$$C = \frac{L}{2}\left(\frac{\text{gd}^{-1} A}{\tan A} + \sec A\right)$$
$$= \frac{200}{2} \times 2.40870 = 240.87 \text{ ft.} \quad \text{Q. E. F.}$$

(1) Referring to Fig. 2,

If $x = \frac{1}{2} L$, $\frac{x}{a} = \frac{L}{2a}$

$$\frac{L}{2a} = u = \text{gd}^{-1} A$$

$$\frac{C}{2a} = \sinh u = \tan A$$

$$\therefore \frac{C}{L} = \frac{\sinh u}{u} = \frac{\tan A}{u}$$

$$\frac{v}{a} = \cosh u - 1 = \text{exsec } A$$

$$\therefore \frac{v}{L} = \frac{v}{2au} = \frac{\text{exsec } A}{2u}$$

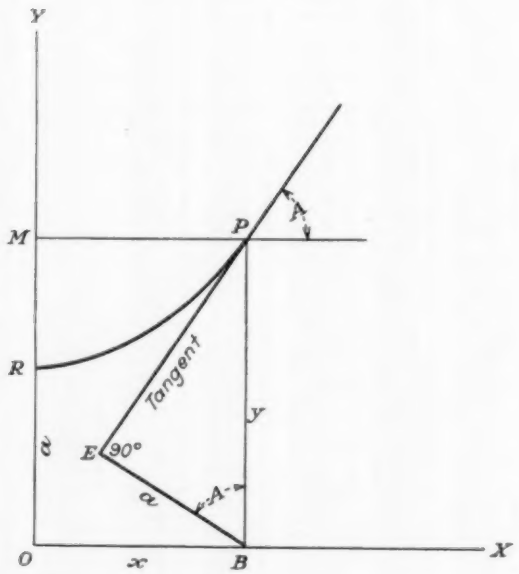

FIG. 2

Arc $\overline{RP}$ is a catenary with origin O.
$x/a = u$; $A = \text{gd } u$; $u = \log_e \tan (\frac{1}{2}A + 45°)$
$y/a = \cosh u$; $\overline{RP}/a = \sinh u$; $\overline{RM}/a = \cosh u - 1$
$EP = \text{arc } \overline{RP}$; $EB = a$
$a^2 = y^2 - \overline{EP}^2 = (a + \overline{RM})^2 - \overline{RP}^2$
$\therefore a = (\overline{RP}^2 - \overline{RM}^2)/2\overline{RM}$

(2) Equation [8] is derived as follows:

Let $q = \frac{C}{L} = \frac{\sinh u}{u}$

$$qu = \sinh u = u + \frac{u^3}{6} + \frac{u^5}{120} + \text{etc.}$$

$$q = 1 + \frac{u^2}{6} + \frac{u^4}{120} + \text{etc.}$$

Neglecting powers above the fourth,

$$u^4 + 20u^2 + 120 = 120q$$

hence

$$u = \sqrt{(120q - 20)^{1/2} - 10}$$

(3) Equation [14] is derived as follows:

$$\tan B = \frac{\cosh u}{u}$$

$$\therefore u \tan B = \cosh u = 1 + \frac{u^2}{2} + \frac{u^4}{24} + \frac{u^6}{720} + \text{etc.}$$

Neglecting powers above the sixth and reducing,

$$u^6 + 30u^4 + 360u^2 - 720u \tan B + 720 = 0$$

which becomes Equation [14] by writing x instead of u.

(4) *Point of Tangency in Fig. 1.* If from any point P on the curve a tangent and an ordinate be drawn to intersect the

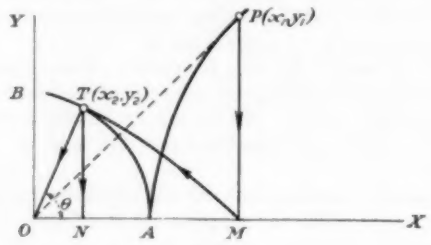

FIG. 3

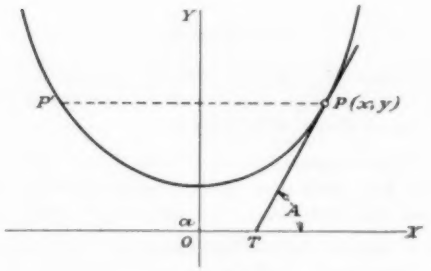

FIG. 4

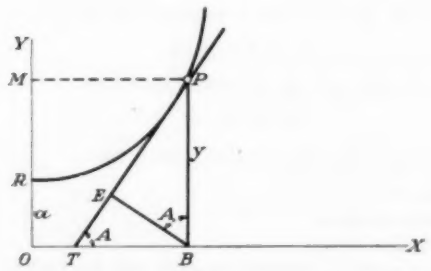

FIG. 5

x-axis, the distance between the intersections is coth u when the parameter is taken as the unit. For the point P_0 the tangent passes through the origin, hence in this case

$$u = \coth u = \text{cosec } A$$

By successive approximation and bracketing, this condition is found to be fulfilled when

$$u = 1.19968 \text{ hyps}$$

$$A = 56° 27' 57''$$

(5) *Length of Parabolic Arc as Stated in Explanation of Table 1.* A well-known formula is

$$\frac{C}{L} = \frac{\sqrt{1 + 16k^2}}{2} + \frac{\log_e \left(4k + \sqrt{1 + 16k^2}\right)}{8k}$$

Where $k = \frac{v}{L}$ $\therefore 4k = \tan A$

If $u = \text{gd}^{-1}A$, $\tan A = \sinh u$, and $\sqrt{1 + 16k^2} = \sec A = \cosh u$

$$\therefore \log_e (4k + \sqrt{1 + 16k^2}) = \log_e (\sinh u + \cosh u) = u$$

Hence $$C = \frac{L}{2}\left(\frac{\text{gd}^{-1}A}{\tan A} + \sec A\right)$$

Discussion

R. B. DALE.[3] The author presents an interesting and valuable mathematical analysis of the catenary curve. It is doubtful whether the true catenary may be found in practical engineering structures; in any event its occurrence is very infrequent. The author recognizes this fact in his statement, somewhat casually made, that ". . . the actual curve is a catenary, modified more or less by the elastic deformation of the cable. . . ." This fact deserves to be emphasized more fully.

The mathematical analysis of the catenary curve given in this paper properly belongs to the mechanics of rigid bodies. For application to practical structures, the effect of the elasticity of the material of the cable should not be neglected. The actual cable will stretch or deflect a very considerable amount, particularly with large sags, if the structure is loaded to the economic value of the material. The theoretical catenary curve for which this analysis is made then no longer exists in the actual structure. Two methods are ordinarily used to determine the elastic effect. The first and more approximate method is called the "elastic theory," and the second and more exact, the "deflection theory." These methods have been worked out quite fully in the case of suspension bridges. Discrepancies in the application of these two theories to practical structures are of a nature to indicate that deflections cannot safely be ignored.

Dr. Arvid H. Baker in his thesis entitled "Suspension-Bridge Analysis by the Exact Method Simplified by Knowledge of Its Relations to the Approximate Method,"[4] appropriately states as follows: "In work of this nature involving several days of labor to properly establish even a minor relationship, one is prone to draw conclusions from meager data and fail to state the restrictions to which the conclusions are subject, thus very often leading astray those who might accept the conclusions as the truth." Dr. Baker further points out that the discrepancies between the "elastic theory" and the "deflection theory" as applied to suspension bridges are very considerable, and he offers correction factors by which the labor of determining stresses is greatly reduced and simplified.

It would seem desirable for the author to continue his praiseworthy efforts by adding to his contribution an analysis of the catenary as modified by the more exact "deflection theory" as applied to a specific structure.

In this discussion the writer is joined by his associate, Mr. J. E. Thompson, who offers several interesting notes with reference to the mathematical theory of the paper.

J. E. THOMPSON.[5] The Gudermannian angle, function, and notation occur in connection with the hyperbola instead of the catenary, but as the hyperbolic cosine (cosh) is defined in connection with the hyperbola and the graph of the cosh is a catenary, there is a relation between the Gudermannian angle and the catenary. This relation is briefly outlined here, and a few notes are added on the equations of the paper.

Referring to Fig. 3, the arc ATB is a quadrant of the circle $x^2 + y^2 = a^2$, of the radius $OA = a$. The curve AP is part of the rectangular hyperbola $x^2 - y^2 = a^2$, of hyperbolic "radius" $OA = a$.

Through any point $P(x_1, y_1)$ on the hyperbola erect the ordinate $PM = y$, from M draw the tangent MT to the circle T, draw the radius $OT = a$, making the angle $MOT = \theta$, and erect $TN = y_2$.

If h is the area of the hyperbolic sector $OAPO$, then the ratio $2h/a^2$ is called the "hyperbolic angle" U. That is,

$$\frac{2h}{a^2} = U \qquad [15]$$

The circular angle θ is said to "correspond" to the hyperbolic angle U and is defined as the "Gudermannian angle" of U (from the mathematician Gudermann, who first made extensive use of its properties). This relation is written

$$\theta = \text{gd}\, U \qquad [16]$$

From the figure,

$$\overline{MT}^2 = \overline{MN}^2 + \overline{NT}^2 = (x_1 - x_2)^2 + y_2^2$$

and

$$\overline{OM}^2 = \overline{OT}^2 + \overline{MT}^2, \text{ or } x_1^2 = a^2 + \overline{MT}^2$$
$$\therefore x_1^2 = a^2 + (x_1 - x_2)^2 + y^2$$
$$= a^2 + x_1^2 - 2x_1x_2 + x_2^2 + y_2^2$$

But from the circle,

$$x_2^2 + y_2^2 = a^2$$

$$\therefore x_1^2 = a^2 + x_1^2 - 2x_1x_2 + a^2$$

whence

$$x_1x_2 = a^2$$

and

$$\frac{x_1}{a} = \frac{a}{x_2} \qquad [17]$$

This relation is also obtained directly from the right triangle OTM and its altitude TN.

In the right triangle TON, $\frac{TO}{ON} = \frac{a}{x_2} = \sec\theta$. Hence by [17],

$$\frac{x_1}{a} = \sec\theta \qquad [18]$$

which is also obtained directly from the triangle OTM.

Now in the circle ATB, by definition

$$\frac{y_2}{a} = \sin\theta, \qquad \frac{x_2}{a} = \cos\theta$$

are the circular sine and cosine of the circular angle θ.

Analogously the definitions of the hyperbolic sine and cosine of the "hyperbolic angle" U of Equations [15] are, in terms of the coordinates and hyperbolic "radius" a,

$$\left.\begin{aligned}\frac{y_1}{a} &= \sinh U\\ \frac{x_1}{a} &= \cosh U\end{aligned}\right\} \qquad [19]$$

Comparing [18] and [19], it is seen that

$$\sec\theta = \cosh U \qquad [20]$$

when the circular angle θ is the Gudermannian of the hyperbolic

[3] Head, Department of Mechanical Drawing and Machine Design, Pratt Institute, Brooklyn, N. Y. Mem. A.S.M.E.

[4] Engineering and Science Series, No. 24, Rensselaer Polytechnic Institute.

[5] Instructor, Department of Mathematics, Pratt Institute, Brooklyn, N. Y.

angle U, the corresponding circle and hyperbola being related as shown in the figure.

The expression [20] is the third of the first set of six relations given in the Addenda to the paper, A and u being there used instead of θ and U.

From the ordinary trigonometric relations among the circular functions and the analogous relations among the hyperbolic functions, using Equation [20] as the fundamental relation, the other relations of the set are readily obtained.

Note particularly the first of these six relations, namely,

$$\tan A = \sinh u \quad [21]$$

Use will be made of this relation later.

Consider now the graph of the equation

$$y = a \cosh \left(\frac{x}{a}\right) \quad [22]$$

(Note that x, y, and a here are not the x, y, and a of the hyperbola discussed above.)

This curve is shown in Fig. 4 and is called the catenary. It is the shape taken by a chain or a perfectly flexible but inelastic heavy cord hung between two supports whose distance apart is less than the length of the cord, which is thus allowed to sag but does not stretch.

The variables x, y of Equation [22] are the coordinates of any point P on the curve and a is called the parameter of the curve. Geometrically, it is the y-intercept of the graph.

At the point P, draw the tangent PT to the catenary, making the angle $XOP = A$. The slope of the curve at P is then

$$m = \tan A \quad [23]$$

In order to find the slope of the curve analytically, differentiate its Equation [22], a being constant. This gives

$$m = \frac{dy}{dx} = \sinh \left(\frac{x}{a}\right) \quad [24]$$

If now we call x/a the "hyperbolic angle" u, so as to be able to use tables of hyperbolic functions in plotting, then Equations [22] and [24] can be written

$$y = a \cosh u \quad [25]$$
$$m = \sinh u \quad [26]$$

Comparing [26] and [23], $\tan A = \sinh u$, which is the same as [21].

This result brings out the relation of the Gudermannian to the catenary, and by virtue of this result and the definition relations [16] and [17], we can write

$$A = \text{gd } u \quad [27]$$

where

$$u = \left(\frac{x}{a}\right) \quad [28]$$

Equation [27] is Equation [3] of the paper.

If $P(x, y)$ and P' in the figure are the points of support of the catenary, then $P'P$ is the span L of the catenary suspension. But $P'P = 2x$. Therefore $2x = L$, or $x = L/2$ and

$$\frac{x}{a} = \frac{L}{2a}$$

or, by [28],

$$u = \frac{L}{2a} \quad [29]$$

This is Equation [2] of the paper.

If in Fig. 4 of the catenary, the ordinate $PB = y$ be erected and BE be drawn perpendicular to the tangent PT, the result is as shown in Fig. 5.

Here the angle BPT is the complement of the angle PTB, and also of the angle PBE. Hence the angle $PBE = A$, as shown in Fig. 5.

In the right triangle PBE, $y/EB = \sec A$. Hence, by Equation [20] (or the third of the set of six relations in the paper, $\sec A = \cosh u$),

$$\frac{y}{EB} = \cosh u$$

Also, by Equation [25], $y/a = \cosh u$

$$\therefore \overline{EB} = a$$

as shown in Fig. 5. This figure corresponds to Fig. 2 of the paper.

By the usual formula for the length of a curve, it is found from Equation [25] that the catenary arc

$$\overline{RP} = a \sinh u \quad [30]$$

Also $\overline{RM} = \overline{OM} - \overline{OR} = y - a = a \cosh u - a$.

$$\therefore \overline{RM} = a(\cosh u - 1) \quad [31]$$

In the right triangle PBE, $\overline{EP}/a = \tan A$. Hence by [27],

$$\frac{\overline{EP}}{a} = \sinh u$$

whence

$$\overline{EP} = a \sinh u$$

Comparing this with [30]

$$\overline{EP} = \text{arc } RP \quad [32]$$

Relations [30], [31], and [32] are those used by the author in the analysis of his Fig. 2. His analysis of Fig. 1 in his paper is self-explanatory.

The remaining formulas and equations and the table of the paper are analytical results derived from the results given in these notes, by the ordinary theory of hyperbolic functions.

Author's Closure

In the discussion by Professors Dale and Thompson the suggestion is made that the effects of elastic deformation should be emphasized more fully. The author recognizes the importance of these effects, and the necessity of making the most careful calculation of their amounts in the case of actual structures exceeding moderate dimensions. However, the article was prepared more especially to show that it is possible to simplify the laborious procedure almost always entailed when we discard the assumptions commonly made for the deeply sagging curves often necessary in transmission-line cables and similar constructions.

Any one who has gone through the operations necessary to the solution of a problem involving hyperbolic functions applied to a structure of specific dimensions realizes why approximations so often take the place of theoretically exact methods in such work.

The author hopes that his Table 1, coordinating hyperbolic with trigonometric functions, may be of practical value when applied to either short or long spans in which the sag-span ratio is great. Its field of usefulness is not affected by the factor of elastic deformation, the importance of which depends upon actual dimensions and other construction details.

MSP-53-1

Case-Hardening With Ammonia Gas

By V. O. HOMERBERG[1] and J. P. WALSTED,[2] CAMBRIDGE, MASS.

It has been the dream of metallurgists for many years to produce a steel of good toughness with maximum surface hardness and wear resistance. To produce these properties with a minimum of distortion has been the subject of much research work of a high order. In the past the most successful method of obtaining these properties has been by subjecting low-carbon steel to the action of a carburizing material at high temperatures. Under these conditions the steel takes up carbon in its surface layer, changing that portion of the material into a high-carbon steel capable of hardening, while the core remains low in carbon with the usual toughness and shock-resisting properties. By a suitable double heat-treatment the core can be brought to maximum physical properties while the case can be made hard and wear-resistant. This process of case-hardening by means of carbon is somewhat cumbersome. The necessary heat-treatment after carburizing is a frequent cause of distortion of the hardened parts.

A new process of case-hardening has been developed which has all the advantages of the older method. Besides being free from the troublesome warpage it surpasses the older method in the hardness of the case produced. The classic research of Doctor Fry at the Krupp Works, Essen, Germany, is responsible for the introduction of this valuable metallurgical development. Researches of a very high order in France and in this country have brought the process to its present high state of development. A great deal of credit is due Dr. Norton and Mr. De Fries of the Ludlum Steel Company for the excellent work which they did immediately after the introduction of this process into this country several years ago. This new process, known as "nitriding," now a commercial success, is described by the authors in this paper.

THE PROCESS of case-hardening by means of ammonia, "nitriding," is remarkable for its simplicity. The parts to be hardened are placed in a heated furnace, subjected to the action of ammonia gas for a definite time, and then removed. The articles, as they come from the furnace, are hard and require no further treatment. This is a distinct advantage over the older case-hardening methods.

J. P. Walsted

V. O. Homerberg

The ammonia used in the process is the commercial anhydrous material commonly used in refrigeration. A simple modification of fittings makes it possible to use the commercial product with convenience. The ammonia on passing over the steel breaks down to some extent into nitrogen and hydrogen; the nitrogen in the nascent condition readily entering the steel. The gases passing out of the furnace consist of hydrogen, unabsorbed nitrogen, and undissociated ammonia. The exit ammonia may be conducted to the outdoors or readily dissolved in water and drained into the sewer. As these gases are the only waste products the problem of waste disposal is very simple.

The temperature of nitriding is low compared to other heat-treating processes. This allows the parts to be heat-treated before nitriding without danger of subsequent destruction of desirable physical properties. Since the nitriding leaves a clean surface free from scale a convenient feature of the process is the fact that heat-treating precedes the ammonia hardening. Parts coming from the nitriding furnace are ready for service without further expenditure of work. Moreover, the low temperature removes all danger of warpage during case-hardening, provided that all strains have been previously removed.

The hardness obtained by nitriding is remarkable. The resistance to wear, made possible by this treatment, if intelligently applied will undoubtedly result in great economic saving. The resistance to corrosion shown by nitrided steels has been known for some time. The success of the nitriding, while it does not solve the problem of corrosion, does eliminate this important factor in many instances.

The investigation conducted by Dr. Fry began with a consideration of the combining power of various alloying elements toward nitrogen and the stability of the resulting nitrides. He found that aluminum ranked first, both as to the amount of nitrogen with which it combined as well as the stability of the aluminum nitride formed. This compound showed no loss in nitrogen even when heated at 1832 deg. fahr. Other elements which form nitrides with high nitrogen contents include molybdenum, manganese, chromium, vanadium, titanium, and tungsten.

Plain carbon steels, various alloy steels, including those containing aluminum, and aluminum together with various other elements such as chromium and molybdenum, were subjected to the action of ammonia gas under definite conditions and the resulting surface hardness was determined in each instance. The outcome of this investigation by Dr. Fry was the manufacture of a series of alloy steels containing varying amounts of carbon, together with approximately 1 to 1.25 per cent aluminum, 1.5 per cent chromium, and 0.2 per cent molybdenum. Alloy steels having this particular combination of alloying elements were chosen because they showed the maximum surface hardness when exposed to ammonia gas under definite conditions. Furthermore, this hardness was retained at elevated temperatures and the specimens showed a marked resistance to atmospheric,

water, and salt-water corrosion. These steels are marketed under the name of "Nitralloy," the different ranges of carbon content being designated as grades "G," "H," etc.

Table 1 gives the analyses and Figs. 1 and 2 show the physical properties of two of the Nitralloy steels after proper heat-treatment and before nitriding.

The presence of molybdenum tends to toughen both the core and the case resulting from the ammonia treatment. Particular attention is called to the high impact values which indicate that these steels have high shock-resisting properties.

TABLE 1 ANALYSES OF NITRALLOY "G" AND "H"

Nitralloy	G	H
Carbon	0.36	0.23
Manganese	0.51	0.51
Silicon	0.27	0.20
Aluminum	1.23	1.20
Chromium	1.49	1.58
Molybdenum	0.18	0.20
Sulphur	0.010	0.011
Phosphorus	0.013	0.011

the steel to form nitrides. These nitrides are very likely in a fine state of dispersion in the case, and impart the extreme hardness to the surface of the steel, a hardness which gradually

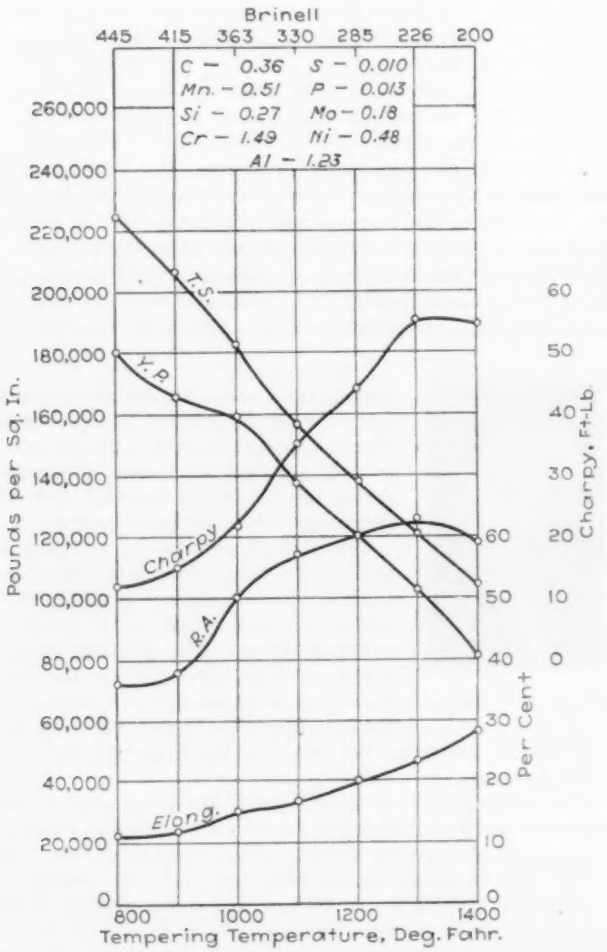

FIG. 1 PHYSICAL PROPERTIES OF NITRALLOY "G" AFTER HEAT-TREATMENT AND BEFORE NITRIDING

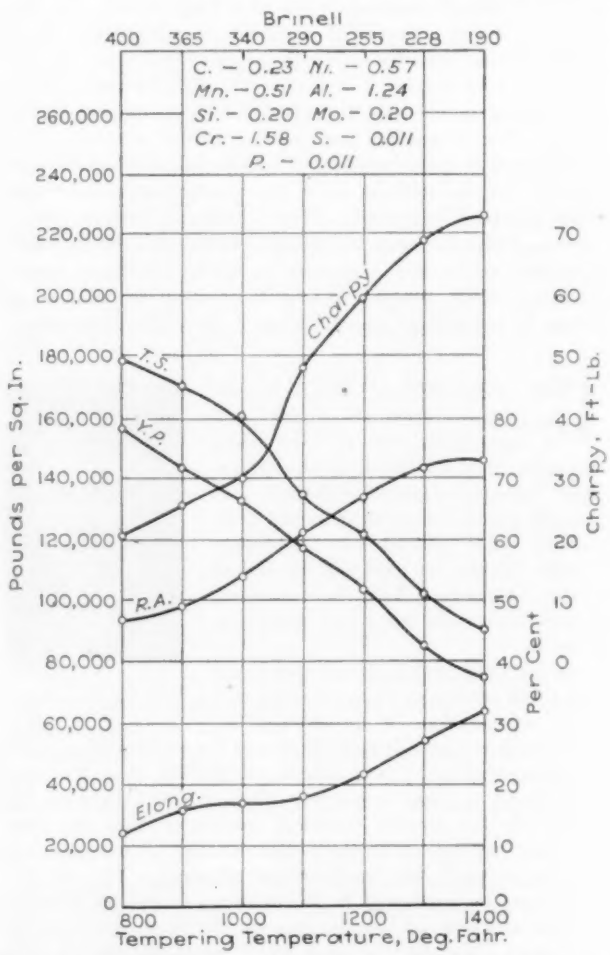

FIG. 2 PHYSICAL PROPERTIES OF NITRALLOY "H" AFTER HEAT-TREATMENT AND BEFORE NITRIDING

The equipment required for the case-hardening of articles with ammonia consists of a suitable furnace provided with automatic temperature control, an air-tight container, which should be made of a material not susceptible to ammonia hardening, for holding the articles to be nitrided, a tank of ammonia provided with a suitable needle valve for controlling the flow of the gas and, finally, a special pipette for determining the extent of the ammonia dissociation.

Special furnaces for nitriding are now being made by a number of furnace manufacturers. Some of these furnaces are provided with a fan in each instance for insuring active gas circulation. The ammonia gas decomposes to a certain extent into nitrogen and hydrogen. The nitrogen, which is very active at the moment of decomposition of the ammonia gas, undoubtedly combines to a certain extent with the iron and with the alloying elements in decreases inwardly until it corresponds to that of the core.

The time of exposure of the articles to the action of the ammonia gas at the nitriding temperature varies from 2 to 90 hr., depending on the service to which they are to be subjected. No heat-treatment is given to the parts after nitriding, the articles being cooled in the box, generally to room temperature. The nitriding temperature generally varies from 900 to 1000 deg. fahr., 975 deg. fahr. being commonly used.

The necessity for the complete removal of strains set up in forging, machining, and in hardening in order to prevent warping or distortion during nitriding has been emphasized. Straightening of parts after nitriding may be required if this precaution is not observed. This is especially likely to occur in thin flat sections or in parts having a large diameter at one end and a long section with a smaller diameter at the other end, such as in cer-

tain types of spindles, fine pump plungers, etc. It has been found quite possible to straighten such parts even when done cold. Since the hardness of the case is not affected at 1000 deg. fahr., it is obvious that the straightening operation can be well applied to the hot material.

Great emphasis should be given to the necessity for the complete removal of the decarburized layer before nitriding. If this precaution is not observed, the nitrided case will lend itself to chipping and flaking. The photomicrograph, Fig. 3, shows the appearance of the case resulting from the nitriding of a decarburized specimen. The black areas represent voids. Sufficient material must be left for final machining or grinding before nitriding to insure the complete removal of all traces of decarburization resulting from the forging and the heat-treating operations.

A typical procedure to follow in the case of an article machined from an annealed bar is to rough-machine, heat-treat, finish-machine, and then nitride. The heat-treatment involves quenching in oil from the proper hardening temperature followed by tempering at a temperature which is at least as high as that used in nitriding in order to obtain proper physical properties for the core and to relieve machining and hardening strains. Sufficient time should be allowed for this operation in order to prevent warping or distortion on nitriding. The final machining or grinding must remove all traces of decarburization. Nitriding for the proper time to meet the conditions completes the operation, except for a possible finishing operation, such as lapping, on the nitrided article. The treatment of forgings should be considered with due precaution to eliminate decarburization before case-hardening with ammonia.

Photomicrographs, Figs. 4 and 5, show the microstructure of Nitralloy "G" nitrided at 975 and 1200 deg. fahr., respectively, for 48 hr. It will be noted that the depth of case as the result of nitriding at 1200 deg. fahr. is much greater than that obtained by nitriding at 975 deg. fahr. However, a marked decrease in the hardness accompanies this increase in case depth. The curve shown in Fig. 6 indicate the results obtained by making the hardness determinations on tapered specimens. In order to take advantage of the greater case depth obtained at the higher nitriding temperature, and of the greater hardness when nitrided at 975 deg. fahr., a double cycle of nitriding is frequently advocated in order to curtail the time of exposure by nitriding first at 1200 deg. fahr. for a suitable length of time, followed by nitriding at 975 deg. fahr. to obtain the desired surface hardness. Nitriding at 975 deg. fahr. followed by a short time exposure at 1200 deg. fahr. has been recommended also in order to produce a tougher case than when 975 deg. fahr. is used alone, although the surface hardness of the article treated in this manner will be equal to or only slightly less than that obtained at 975 deg. fahr.

TABLE 2 GROWTH OF CYLINDERS ON NITRIDING

Nitriding temperature, deg. fahr.	Increase in length, in.	Increase in diameter, in.
900	0.001	0.0003
950	0.002	0.0009
1000	0.003	0.0011

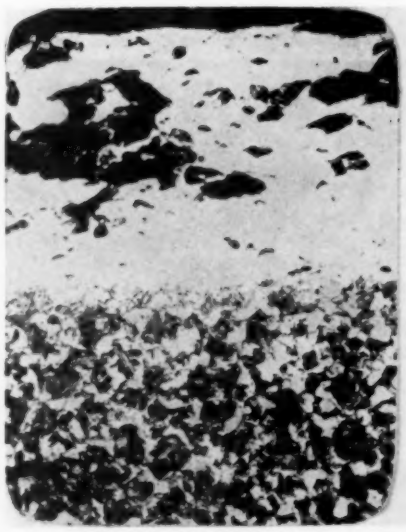

FIG. 3 NITRALLOY "G" DECARBURIZED THEN NITRIDED. NITAL ETCH, MAG. × 100

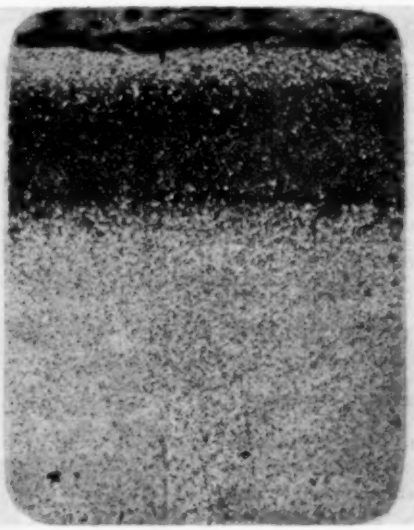

FIG. 4 NITRALLOY "G" NITRIDED FORTY-EIGHT HOURS AT 975 DEG. FAHR. NITAL ETCH, MAG. × 50

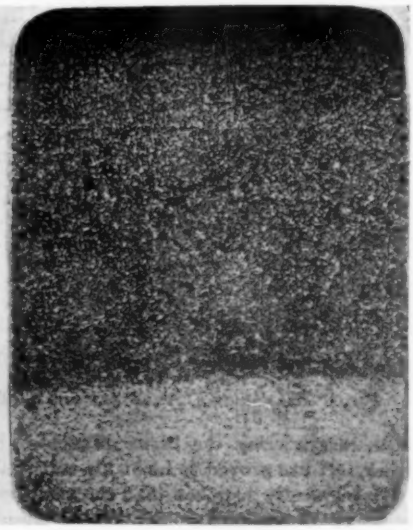

FIG. 5 NITRALLOY "G" NITRIDED FORTY-EIGHT HOURS AT 1200 DEG. FAHR. NITAL ETCH, MAG. × 50

A slight growth takes place during nitriding. Table 2 shows the increase in the length and in the diameter of cylinders of Nitralloy "G" previously oil-quenched from 1650 deg. fahr. and tempered at 1000 deg. fahr. for 4 hr., followed by nitriding at the indicated temperature for 48 hr. Prior to nitriding, these cylinders were ground accurately, after which they measured 5.8160 in. in length and 0.7100 in. in diameter.

This growth can be allowed for in the final machining or grinding before nitriding, or it can be removed afterward by lapping or by some other suitable means. Advantage of this growth can be taken in the case of parts where their usefulness will be destroyed as soon as a slight wear has taken place. The renitriding of such articles, especially at a higher temperature, will produce sufficient growth to make them useful again.

Since a certain amount of growth takes place on nitriding the presence of sharp corners should be avoided. In the case of a cylinder, the growth of the cylindrical surface, together with the growth of the circular section, will combine to push the edge outward. This edge will be very brittle and will chip quite readily. The presence of well-rounded corners and generous fillets should be given careful consideration.

The growth is dependent upon the amount of nitrogen introduced and, therefore, upon the case depth. It is independent of the size of the article. A step-down cylinder, nitrided at

975 deg. fahr. for 48 hr., showed the same growth in the smallest section, which was 1/2 in. in diameter, as in the largest, the diameter of which was 2 in.

The hardness of nitrided articles cannot be determined by the usual Brinell machine, Shore scleroscope, or the present Rockwell tester. Any chipping of the case will give an erroneous reading. The Vickers machine, Herbert Pendulum, Firth Hardometer, and the Shore Monotron are suitable for the purpose. The

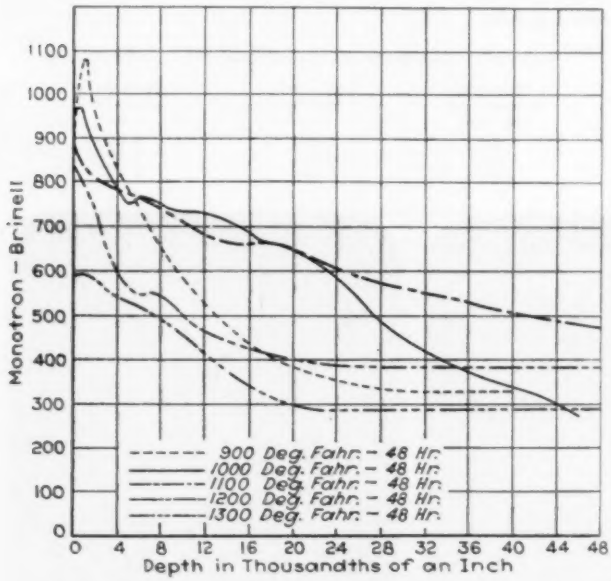

FIG. 6 HARDNESS DETERMINATIONS ON TAPERED SPECIMENS

authors are using the Shore Monotron in their investigative work. It has proved to be highly satisfactory for the purpose.

It frequently happens that threaded portions or other areas must be protected in order not to become surface hardened. Nickel plating gives satisfactory results; tin or solder may be used provided that certain precautions are taken. Only that amount of tin which can be retained by surface tension should be present in order to prevent particles of molten metal from dropping onto articles at a lower level in the nitriding box and thus produce protection at undesirable points. The authors are using a paint of tin oxide mixed with glycerin. The glycerin is an excellent vehicle and decomposes into volatile compounds during the nitriding process so that the tin oxide can be readily reduced to metallic tin by the active hydrogen which is produced as a result of the decomposition of the ammonia.

WEAR RESISTANCE OF NITRIDED SURFACES

The wear resistance of nitrided surfaces should prove to be of great interest to mechanical engineers. The authors are well aware of the fact that wear tests in order to be of maximum value should be conducted in a manner which will similate service conditions.

General conclusions cannot be made after the completion of a series of tests because there is no justification in stating that one metal is more resistant to wear than another except with the qualification that it is true when the tests are conducted under the same conditions. Guillet[3] studied the wearing properties of nitrided Nitralloy, especially with respect to the automotive industry. Some of the data presented by him are included in the following:

[3] Guillet, Lecture to Academy of Sciences in Paris, France.

WEAR OF CYLINDERS

On a car with cast-iron cylinders after 30,000 km. (18,630 miles) the wear was 0.016 in. On a car with nitrided cylinders it was 0.0008 in.

On an aviation motor after 100 hours running the wear of the cylinders of heat-treated steel was 0.0032 to 0.004 in. and the wear of nitrided cylinders was not measurable.

The oil consumption under the same conditions per hp-hr. was:

	New motor	After 100 hours
For a cylinder of heat-treated steel	4–5 grams (60–75 grains)	12–15 grams (180–225 grains)
For a cylinder of nitrided steel	4–5 grams (60–75 grains)	4–5 grams (60–75 grains)

V. T. Malcolm[4] reported on the excellence of nitrided Nitralloy

FIG. 7 APPARATUS USED FOR DETERMINING WEAR RESISTANCE

in its resistance to wear. His paper is of great value because of its practical aspects.

Since there is no universal wear-testing machine nor test methods, the question of wear resistance should be studied under actual service conditions whenever possible.

[4] V. T. Malcolm, Use of Nitrided Steel in High-Temperature High-Pressure Steam Service. Nitriding Symposium, Convention of American Society for Steel Treating, Cleveland, September, 1929.

Lieutenants Kiefer, Crist, and Kindell[1] conducted such tests since they were interested in specific applications of nitrided Nitralloy in which its wear resistance was of paramount importance.

The apparatus used by them, shown in Fig. 7, was made by adapting a drillpress for the purpose. A driver provided with a keyway was substituted for the drill. The upper shaft carries a special fixture for holding the upper specimen. Another special shaft supports the lower specimen and rotates in contact with ball bearings in order that the torque developed by the friction can be determined.

A grooved disk is bolted to the bottom of the shaft for determining the torque. A spring balance is attached to this disk by means of an ordinary door spring which serves to dampen the vibration.

The lower fixture is shown in greater detail in Fig. 8. The base is rigidly fixed to the drillpress table by means of four bolts. The lower shaft (4) is made free to rotate by means of the ball race (5) which is retained in the fixture by means of ring (6). The upper and the lower specimens are shown in contact at (3). The male part (2), which is in the center of the upper driving tool, keeps the upper and the lower shafts in line by rotating in the ball race (1). In this manner (1) and (2) take up all side thrusts and thus prevent wabbling and insure perfect alignment.

A wheel (7) is fitted to the end of the lower shaft and serves to provide the lever arm for measuring the torque. Screw (8) is used to fix a steel wire from the bottom of this shaft to a spring scale for obtaining the other factor (force) which is required for the torque determination.

Hollow cylinders, having an outside diameter of $2^1/_2$ in., an inside diameter of $1^3/_4$ in., and a height of $1^3/_8$ in., were used in the tests.

TABLE 3 NITRIDED NITRALLOY AGAINST NITRIDED NITRALLOY, NITRIDED AT 950 DEG. FAHR. FOR 90 HR.

Run	Specimen	Time hours	Final temp., deg. fahr.	Torque, in-lb.	Friction coef.	Loss in weight, gram	Loss in height, in.	R.p.m.	Total no. of revolutions
1	1	5	401	15	0.237	0.525	...	1150	345,000
	2					0.465			
2	1	5	420	20	0.316	0.606	...	1150	690,000
	2					0.510			
3	1	5	430	22	0.347	0.349	0.001	1150	1,035,000
	2					0.615	0.001		
4	1	5	400	14.4	0.227	0.592	0.001	1150	1,380,000
	2					0.250	0.001		

Upper specimen = No. 1. Lower specimen = No. 2.
Total no. of revolutions = 1,380,000. Pressure = 12 lb. per sq. in.
Total loss in weight of upper specimen = 2.07 g. = 32 grains.
Total loss in weight of lower specimen = 1.84 g. = 28.5 grains.
2 sq. in. of wearing surface on each specimen.
Specimens were finish machined, but not polished, before nitriding.
No scoring occurred.
No lubrication. No loss in hardness took place on surface.

TABLE 4 NITRIDED NITRALLOY AGAINST GRAY CAST IRON

Run	Specimen	Time hours	Final temp., deg. fahr.	Torque, in-lb.	Friction coef.	Loss in weight, gram	Loss in height, in.	R.p.m.	Total no. of revolutions
1	NG	5	420	17	0.268	0.346	0.002	1150	345,000
	CII					0.492	0.002		
2	NG	5	425	20	0.316	0.313	0.000	1150	690,000
	CI					0.818	0.0025		
3	NG	5	400	19	0.300	0.121	0.000	1150	1,035,000
	CI					0.605	0.0025		
4	NG	5	425	18	0.284	0.170	0.000	1150	1,380,000
	CI					0.119	0.004		

Brinell hardness of gray cast iron = 140. NG = Nitralloy G. CI = Gray cast iron.
Total loss in weight of nitrided Nitralloy = 0.95 g. = 14.6 grains.
Total loss in weight of gray cast iron = 2.03 g. = 31.3 grains.
Specimens were finish machined but not polished before nitriding. No scoring occurred.

[1] Lieutenants Kiefer, Crist, Kindell, Thesis, "The Wearing Properties of Nitrided Nitralloy Against Various Alloys," submitted in partial fulfilment of the requirement for the degree of Master of Science from the Massachusetts Institute of Technology, 1929.]

The coefficient of friction was determined by means of the following formula:

$$T = \frac{2}{3} FW \frac{R^3 - r^3}{R^2 - r^2}$$

where

W = weight in lb. acting vertically on the wearing surface
T = torque in inch pounds
F = coefficient of friction
R = outside radius of specimen in inches
r = inner radius of specimen in inches
P = pull in pounds due to torque.

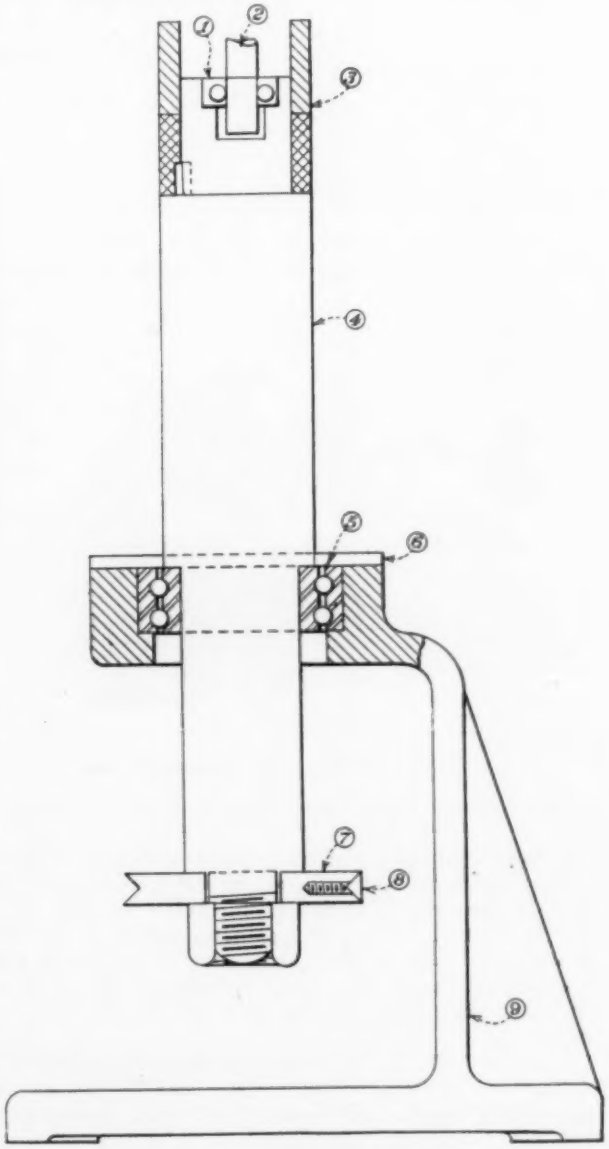

FIG. 8 FRICTION-TESTING FIXTURE

The tests were conducted without lubrication and without the application of external heat. Observations were made at 5-hr. intervals. These observations included the temperature developed by friction, torque, loss in weight and in height, and the condition of the wearing surfaces. The temperature was determined by means of a thermocouple which extended through the lower specimen holder to a point $^1/_{16}$ in. from the rubbing surface. Sections were examined microscopically after the com-

pletion of each test. Differences in the depths of the nitride case at the worn and at the unworn surfaces were noted.

TABLE 5 NITRIDED NITRALLOY AGAINST SPECIAL BRONZE

Run	Specimen	Time, hours	Final temp., deg. fahr.	Torque, in-lb.	Friction coef.	Loss in weight, gram	Loss in height, in.	R.p.m.	Total no. of revolutions
1	NG	5	200	16.6	0.262	0.279	0.0005	300	
	B-1					0.030	0.002		90,000
2	NG	5	205	14.0	0.221	0.306	0.0008	300	
	B-1					0.020	0.000		180,000
3	NG	5	320	12.0	0.190	0.078	0.0005	1150	
	B-1					0.130	0.001		525,000
4	NG	5	275	6.0	0.095	0.000	0.000	1150	
	B-1					0.132	0.001		870,000
5	NG	5	240	6.0	0.095	0.000		1150	
	B-1					0.116			1,215,000
6	NG	5	250	6.0	0.095	0.065		1150	
	B-1					0.110			1,560,000

Brinell hardness of B-1 was 86.
NG = Nitralloy G; B-1 = Special bronze (cast).
No scoring took place with this bronze and there was no pick-up by the Nitralloy. No lubrication was used.
Analysis of special bronze:

Copper	80.2	Tin	11.5
Nickel	5.5	Zinc	2.8
Lead	Trace		

Total loss in weight of nitrided Nitralloy = 0.73 g. = 11.2 grains.
Total loss in weight of special bronze = 0.54 g. = 8.3 grains.

Tables 3, 4, and 5 give the results of tests in which the nitrided Nitralloy was tested against itself, against gray cast iron, and

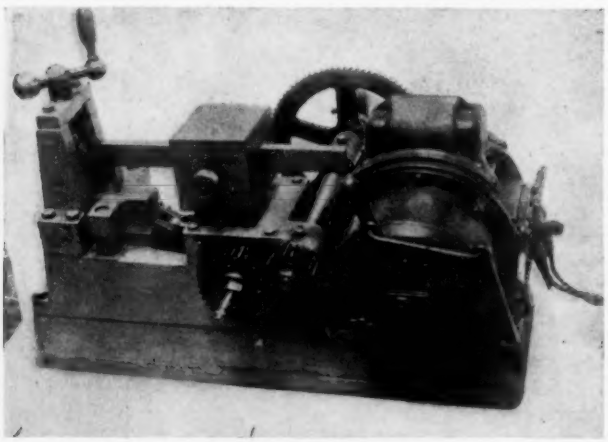

FIG. 9 WEAR-TEST MACHINE

against a special bronze the analysis of which is included in Table 5.

In the test in which nitrided Nitralloy was operated against the special bronze, fine particles from the former became embedded in the surface of the latter. In all cases the surfaces were entirely free from scoring; no appreciable decrease in the depth of the nitride case could be noted when the specimens were examined microscopically. Also, the surface hardness of the nitrided specimens was the same after the test as before it was started.

Lieutenants Blick and Buracker[6] not only confirmed the results obtained by Lieutenants Kiefer, Crist, and Kindell, but also tested the nitrided Nitralloy against itself at a temperature of 1000 deg. fahr. After 13.5 hr. with a total number of revolutions of 858,600, the loss in weight of each specimen was only 0.46 gram (7 grains) with a coefficient of friction of 0.28.

Captain H. V. Hopkins[7] conducted wear tests by means of the apparatus shown in Fig. 9. This apparatus is provided with a variable-speed motor and with a reciprocating mechanism whereby two specimens can be rubbed against each other under a desired load. Specimens 2 in. by 1 in. by $\frac{1}{2}$ in. were used in the tests. The stroke of the machine is 2 in., so that the specimens were rubbed together with a variation of contact area of 1 to 2 sq. in. The pressure, therefore, was twice as great at the end of the stroke as it was at mid-stroke.

The load was applied through a lever mechanism with a sliding weight. A handle operating a screw permitted vertical adjustment of the lever to compensate for the wear and for the varying thicknesses of specimens in order to maintain the lever in a horizontal position and to maintain a constant load. The load was varied from 13 to 150 lb.

All specimens were finished on a fine emery belt to approximately the average commercial surface for bearing purposes All grease and oil or grit were removed from the wearing surfaces before each test. The machine was stopped at frequent intervals to observe the condition of the surfaces. Approximately 60 combinations of materials were tested without lubrication in this machine at varying speeds and loads. Combinations of materials such as were used by Kiefer, Crist, and Kindell, and later by Blick and Buracker were run in this machine with results which checked closely with those obtained by them.

The results obtained in the wear tests in which the wear in one series was a consequence of rotary motion and in the other series of translatory motion indicate that the use of nitrided materials in engine or machine parts which are subject to severe wear conditions and difficult to lubricate offers promising possibilities

CONCLUSIONS

The physical properties of Nitralloy in the un-nitrided condition compare very favorably with those exhibited by the best of the structural alloy steels.

All parts should be heat-treated before nitriding in order to obtain desirable physical properties of the core and to insure proper grain refinement since the original grain size of the material is not reduced during the nitriding operation.

Nitriding at temperatures ranging from 900 to 1300 deg. fahr. inclusive shows that the depth of case increases, but the hardness decreases with the increase in temperature. It is possible to nitride at a relatively high temperature, 1200 deg. fahr. for example, to obtain considerable depth of case and then to nitride at a lower temperature, such as 950 deg. fahr., to obtain the desired surface hardness.

The presence of decarburization before nitriding produces a brittle case which is likely to spall or chip. This decarburized layer must be removed before the subjection of the parts to the action of the ammonia gas. Strains created by machining and by heat-treating of parts must be eliminated if warping or distortion in the finished articles is to be prevented.

Nickel plating and a coating of tin or solder will protect parts against nitriding. A coating of tin oxide in glycerin will also serve as a protective agent. A slight growth takes place during nitriding. Allowance can be made for this growth in the final machining or grinding operation, before nitriding, or by lapping, or by other suitable means after nitriding.

Nitrided articles offer marked resistance to atmospheric, water, and salt-water corrosion. Nitrided Nitralloy exhibits excellent wearing properties even when tested without lubrication against certain other alloys, notably against nitrided Nitralloy itself, and a special bronze containing nickel. In view of the many desirable properties possessed by nitrided articles, this subject should prove of increased interest to mechanical as well as to metallurgical engineers.

Nitriding Analyses—Their Physical Properties and Adaptability

By R. S. SERGESON[1] and M. M. CLARK,[1] MASSILLON, OHIO

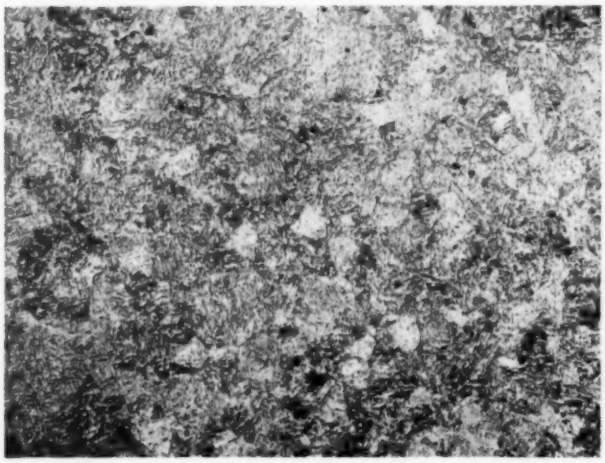

Fig. 1 Nitralloy Type G Water-Quenched From 1700 Degrees Fahrenheit—HNO_3 × 100—Normal Structure and Grain Refinement

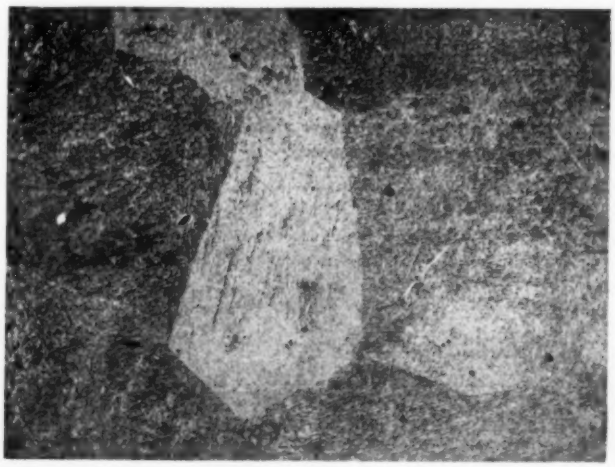

Fig. 4 Nitralloy Type G Water-Quenched From 2200 Degrees Fahrenheit—HNO_3 × 100—Highly Coarse Grained

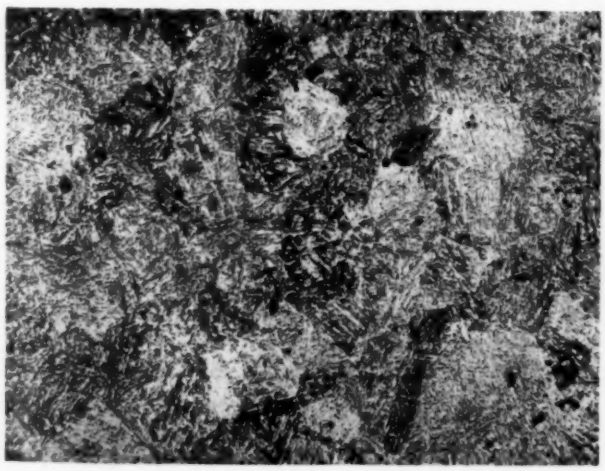

Fig. 2 Nitralloy Type G Water-Quenched From 1800 Degrees Fahrenheit—HNO_3 × 100—Slight Grain Growth

Fig. 3 Nitralloy Type G Water-Quenched From 2000 Degrees Fahrenheit—HNO_3 × 100—Coarse Grained

In this paper the authors give the range of analyses of the present chrome-aluminum-molybdenum nitriding steels. The physical properties of these analyses are given in detail both in regard to tensile and impact values. Some data on fatigue tests have been added. Mention is made as to the proper quenching temperatures and there is a suggestion as to the amount of stock to be removed for elimination of decarburized surface obtained previous to machining. Many applications which are operating highly successfully are given.

A LITTLE over two years ago all nitriding steels were in their early stages of development. They were made in the electric furnace in small lots and were high in price. If one wished to nitride he was forced to build his own equipment, and commercial nitriding was unknown. Today, however, nitriding analyses can be made in large tonnage in the open hearth, thus reducing the cost. Most of the furnace builders are marketing nitriding equipment, and many plants are taking

on commercial nitriding. The demand for the nitriding analyses is steadily gaining and it is quite important that a thorough understanding of their properties be obtained.

The following types are now available on the commercial market:

Type	C	Mn	Cr	Mo	Al
I	0.10/0.20	0.40/0.70	0.80/1.30	0.15/0.25	0.60/1.20
H	0.20/0.30	0.40/0.70	0.80/1.30	0.15/0.25	0.60/1.20
G	0.30/0.40	0.40/0.70	0.80/1.30	0.15/0.25	0.60/1.20
High C	0.55/0.65	0.40/0.70	0.80/1.30	0.15/0.25	0.60/1.20

These analyses are being forged with no difficulty at temperatures of 2175–2250 deg. fahr.

Before determining the physical properties of these analyses a preliminary investigation was conducted to determine the proper range of quenching temperature. This was accomplished

in each case by quenching a series of specimens from successive increasing and decreasing temperature intervals and studying their hardness and structure. This is termed a quenching cycle. Typical cycles are shown in Table 1 for type G (0.34 carbon) and type H (0.26 carbon). From results shown in this table and a study of the microstructures of quenched specimens, a quenching temperature range of 1700–1750 deg. fahr. has been recommended for obtaining the most uniform structure and hardness. Specimens were also quenched from temperatures of 1700, 1800, 2000, and 2200 deg. fahr. to note the effect of temperature on coarsening of grain. At 1800 deg. fahr. grain growth is evident and increases with temperature. Photomicrographs of this effect of temperature are shown in Figs. 1, 2, 3, and 4.

charts showing tensile, Izod and Charpy impact values were made using 1-in. round stock. These data in chart form are shown in Figs. 5 and 6, for types G and H respectively. However, as these analyses are being used in larger sections, data have been obtained to show the effect of size in heat-treatment. Specimens of types G and H were heat-treated in 4-, 3-, 2-, and 1-in. rounds and their tensile properties determined. Table 2 shows the values obtained, and Fig. 7 shows values in chart

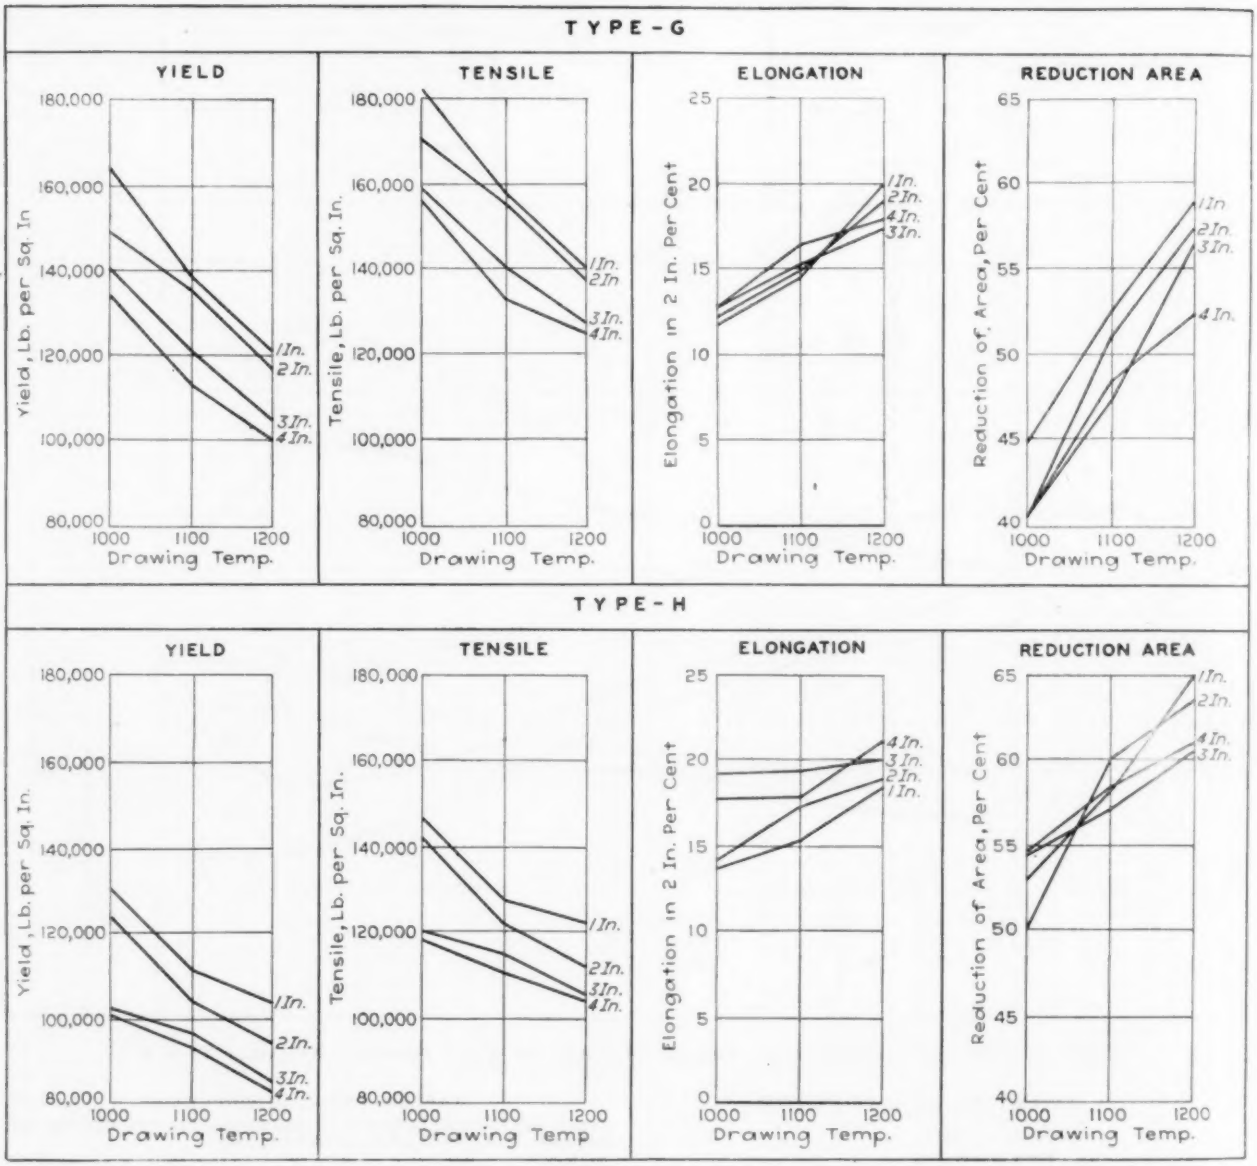

FIG. 7 YIELD POINT, TENSILE STRENGTH, ELONGATION, AND REDUCTION AREA FOR TYPES G AND H NITRALLOYS

form. These values were from tests taken longitudinally as near halfway center to edge as possible. They show clearly a marked decrease in yield point and tensile strength with increase in diameter, while the elongation and reduction of area are less affected.

TABLE 4 VALUES OBTAINED BY HEAT-TREATING

Tensile lengths were water-quenched from 1750 deg. fahr. and drawn from 1000 deg. fahr. to 1400 deg. fahr.

Analysis

C	Mn	S	P	Si	Cr	Al	Mo

FATIGUE PROPERTIES OF NITRALLOY G

While the authors do not have complete fatigue data, the following test it is believed will be of interest.

Nitralloy G stock 0.34 C, size $1^1/_2$ in. round, heat-treated, was used for tests. Tensile and fatigue (cantilever type) specimens were machined. The specimens were tested as heat-treated and as nitrided to give $^1/_{32}$-in. case. The results were as follows:

TENSILE TESTS

Treatment	Yield point, lb. per sq. in.	Ultimate strength	Per cent elong. in 2 in.	Per cent red. of area
As heat-treated.....	74,650	103,300	25.5	62.9
As heat-treated.....	74,550	102,000	25.0	63.4
As heat-treated and nitrided	83,200	105,700	10.0	12.2
As heat-treated and nitrided	83,500	108,700	10.5	12.5

FATIGUE TESTS

Treatment	Stress, lb. per sq. in.	Number of reversals	Remarks
Heat-treated	36,000	33,000,000	Did not break
Heat-treated	75,000	40,800	Bar broke
Heat-treated and nitrided	75,000	28,000,000	Did not break
Heat-treated and nitrided	85,000	1,411,000	Bar broke

It is quite evident that, at least in small sections, the nitrided case actually increases the fatigue limit of the steel.

Tensile and Impact Values of High-Carbon Nitralloy

A preliminary quenching cycle run on this type determined 1550 deg. fahr. as the proper quenching temperature with oil as a medium for quenching light sections and water for heavy sections (2-in. round or larger). One-inch round sections were heat-treated, being quenched both in water and in oil.

Table 3 gives data showing that little or no difference results due to the quenching medium when treated in the 1-in. round section.

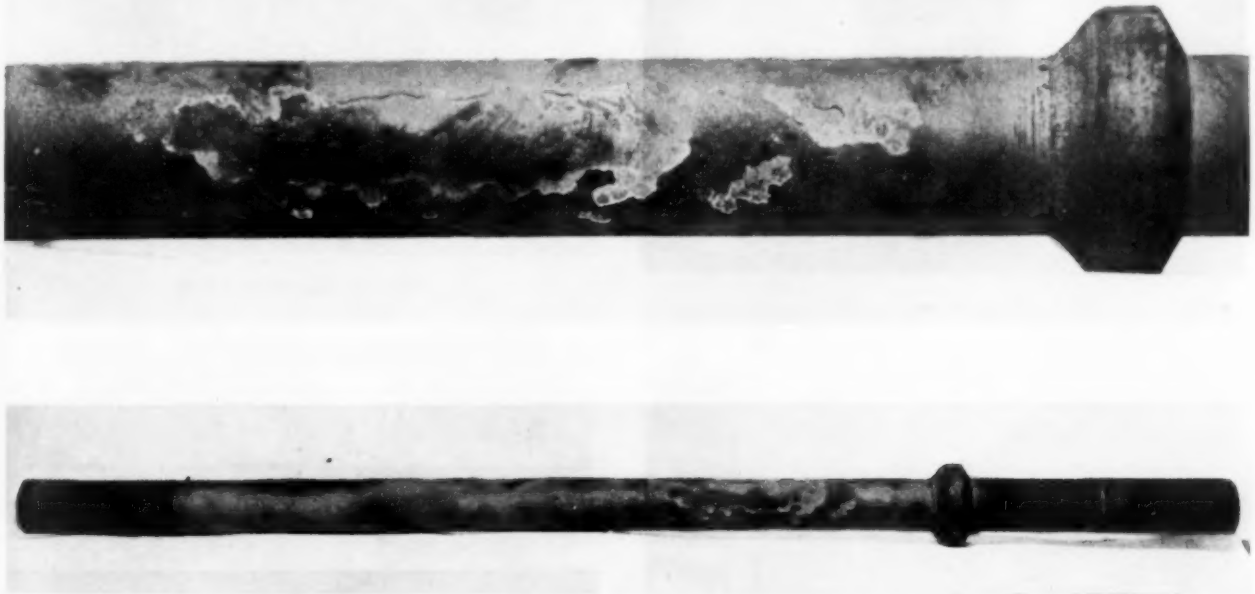

Fig. 9 Pumpshafts With Decarburized Surface—Nitriding Has Caused Spalling

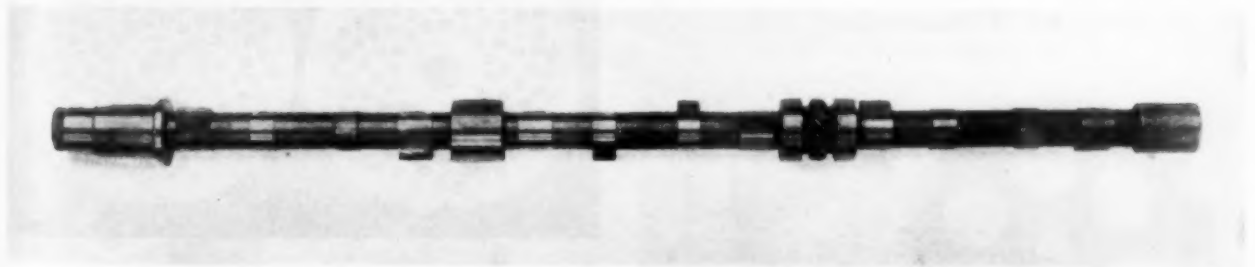

Fig. 10 Bus Motor Camshaft of Type G Nitralloy

Tensile Values and Impact Values of Type I

A preliminary quenching cycle on this type determined 1700–1750 deg. fahr. as the proper quenching temperature. Sections 1-in. round were heat-treated and water-quenched. Table 4 gives the values obtained by heat-treating. This product also lends itself to the making of flat products, e.g., sheet and strip, in which case water-quenching is difficult. Hence such products are normalized and drawn. Physical data on normalized and drawn stock are also included in Table 4. The normalized and drawn stock is applied to stamping and forming operations.

ADAPTABILITY

The experience of the authors as to the adaptability or selection of these nitriding analyses to the machine, automotive, and aviation fields dates back but little over two years. In that time there have been many successful applications, many more are still under test, and some few were failures. To give a clearer understanding, the various applications are listed and

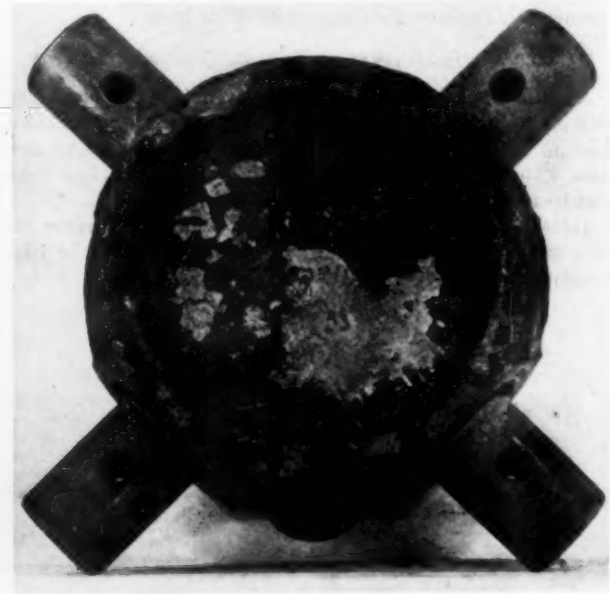

FIG. 15 UNIVERSAL CROSS

FIG. 16 BAR FOR CRANKSHAFT TURNING MACHINE

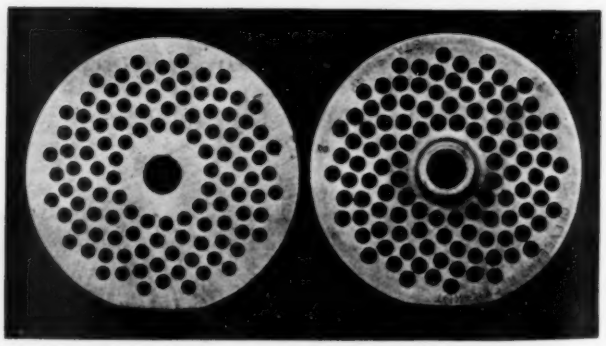

FIG. 17 MEAT-CUTTER DISKS

illustrations of many are shown. For best results, these analyses should be used in the heat-treated state, being fully machined before being subjected to the nitriding treatment. Although it has been previously stressed, it is again to be pointed out that, after heat-treating, the decarburized surface must be completely removed by machining. In general, a removal of $^{1}/_{16}$

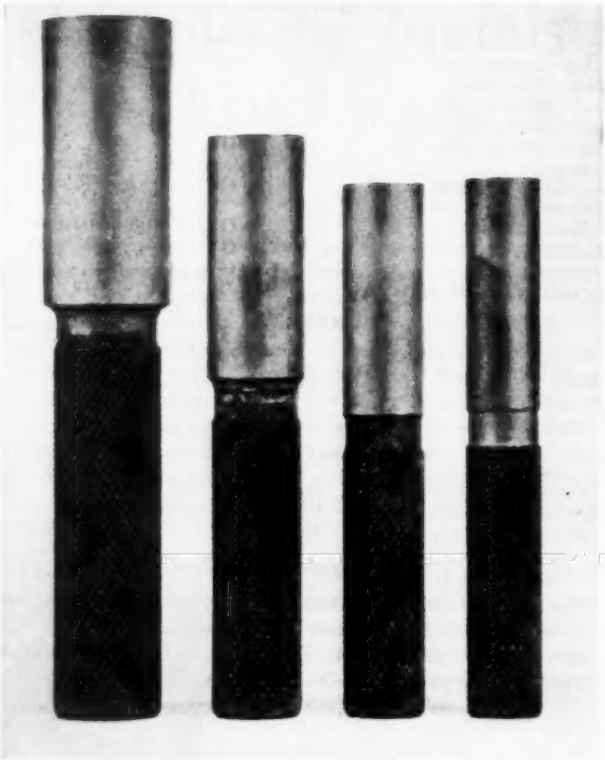

FIG. 18 PLUG GAGES

Replacing Metals by Synthetic Resins—Phenol-Resinoid Molding Technique

By LEON V. QUIGLEY,[1] NEW YORK, N. Y.

It is the purpose of this review to assist the engineer and mechanic whose experience has been chiefly with metals to get his bearings with regard to the synthetic resin plastics, which are becoming increasingly important in the metal trades. The paper deals particularly with that type of plastic or synthetic resin materials known as phenol resinoids. The review has involved a study of the literature of America, England, and the Continent covering the past five years, and relies also upon the technical archives of the American company which, during the past 20 years, since the inception of these materials, has been engaged in their manufacture.

WHEN a new class of material begins to rank with metal, stone, and wood as one of the four principal materials of construction, it becomes properly a subject for thoughtful consideration by engineers. Properties of the new material are to be evaluated, and not only in the absolute sense, but in relation to the properties of materials which they may replace. It is the purpose of this review to assist the engineer and mechanic whose experience has been chiefly with metals to get his bearings with regard to the synthetic resin plastics, which are becoming increasingly important in the metal trades. The paper deals particularly with that type of plastic or synthetic resin materials known as phenol resinoids. The review has involved a study of the literature of America, England, and the Continent covering the past five years, and relies also upon the technical archives of the American company which, during the past 20 years, since the inception of these materials, has been engaged in their manufacture.

The current issue of *The Industrial Bulletin*, published by Arthur D. Little, points out that the aggregate value of the products of the plastics industry is already more than one-tenth that of the products from both the lumber and wood-working industries of the United States. Yet the wood industry has been long established, while the plastics industry might be considered as still in the industrial nursery.

Considering the relation of phenol-resinoid materials to the metal industry, it should be remarked that they have, for specific purposes, replaced practically every known form of metal. For the heaviest duty in buildings and machines, it would appear that resinoids will not supplant metal. It is conservative to assume that for many less strenuous services they will replace metal entirely. The new material, technically described as phenol resinoid and popularly associated with the trade-mark name of the company founded by its inventor, should not be hastily rated as inferior or superior to metal, wood, or stone. In contrast to each one of these older substances it possesses inherent advantages and limitations. It is something distinct, and therefore can stand alone, not as a questionable substitute, but as an auxiliary new material having a technical personality of its own. Phenol-resinoid materials have attained their present widespread adoption because they are possessed of a remarkable assortment of properties and because they possess remarkable ease of adaptability. It is these two factors which chiefly govern the adoption and industrial position of any material.

The importance of manufacturing processes, based on plasticity of the raw materials, is that they make possible conversion directly to the desired final shape, with practically no loss of material, and at an expenditure of time and labor which is usually only a fraction of that which would be required if the part were shaped from rough stock by machining or cutting operations.

The most important group of industrial plastics, which, however, appears to be still in its infancy so far as varieties are concerned, is the class in which synthetic resins are used as a binder. The earliest of these and by all odds still the most important are the phenolic-resinoid materials. They possess extreme plasticity in the formative period. The finished product is resistant to practically all of the normal conditions tending to structural breakdown. It is characterized by a high degree of electrical and thermal insulation, and presents attractive surface, requiring practically no polishing as it comes from the mold. Structurally, the material possesses a degree of toughness and strength unusual in organic substance, and where this is not adequate, as in the case of fine machine threads, it is possible to mold metal threaded inserts into the finished piece.

The earliest plastics, such as cellulose nitrate, as well as the majority of the natural gums and resins, soften to such an extent under heat as to seriously limit their field of usefulness. One of the major factors which has brought about the rapid extension in the use of the phenolic-resin plastics is the extent to which they resist not only heat, but also other conditions, such as moisture, and mild acids and alkalies, which tend to break down the appearance and frequently the structure of many materials.

The history of man has been written in the "ages" of the materials from which his handiwork has been largely fashioned. If we may gage the future by even current progress, we appear to be rapidly entering the plastic era.

Replacement by Resinoid

In reference to the adoption of resinoid materials in new fields, "replacement" is a better word than "substitute." Substitution, according to Fred C. Bowman, writing in *Factory and Industrial Management*, is as old as the days of Tubal-Cain, who persuaded his neighbors to buy his iron tools to replace their stone hatchets, and adds that it probably took all of his 700 years to overcome their sales resistance.

Generally, the bad reputation of substitutes has been deserved. Much effort was spent it making a substitute look like the

Specific heat	0.30–0.40				
Effect of heat	Tends to harden and shrink slightly with improvement of electrical properties				
Dry	Withstands 250° F. Does not fuse		Withstands 475° F. for short periods Does not fuse	Withstands 250° F. Does not fuse	
Moist	Slight deterioration of electrical properties				
Effect of aging	No deterioration. Tends to improve in mechanical and electrical properties				

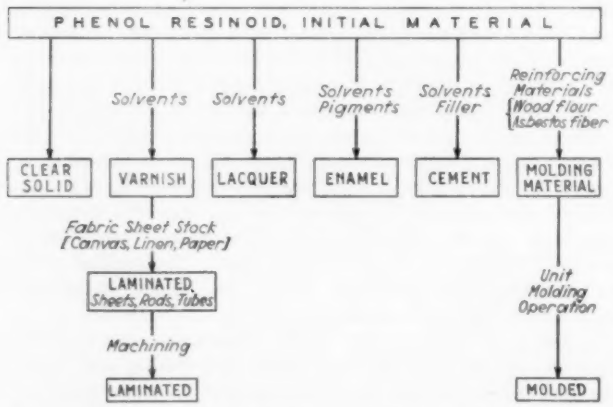

FIG. 1 CHART SHOWING RELATIONSHIP OF PRINCIPAL PRODUCTS FABRICATED FROM INITIAL PHENOL-RESINOID MATERIAL
(For structural purposes, the molded and laminated divisions are of chief importance.)

original and little thought given to making it behave right.

Within the last few years a new kind of substitution has come. Now a substitute must be better than the original. There is no attempt to deceive, and often none to produce resemblance. A mere saving of money is usually not enough to put over a substitute. It must have property merit.

Bakelite materials have many times been adopted for applications in which cast iron, steel, brass, tin, aluminum, lead, and a wide range of alloys were formerly employed. Usually this change of material of construction is based on decision by the designing engineer that the properties of the phenol-resinoid material justify its adoption as superior to the metal formerly employed. This does not mean, of course, that the metals are not highly satisfactory and preferable for many other applications. Block tin is still one of the world's metal utilities, but molded resinoid is fast replacing it for use as the caps for shaving-cream and tooth-paste tubes. This does not indicate that resinoid is a substitute for tin in the way most people would understand the meaning of the word.

The following, in order of importance, are the chief industrial fields using resinoid molding material:

1 Electrical manufacturing
2 Radio
3 Automotive
4 Mechanical
5 Gifts and novelties
6 Electrical, central station
7 Bottle and tube caps, packages
8 Building and hardware
9 Telephone
10 Textile
11 Chemical
12 Miscellaneous
13 Aviation

PROPERTIES

One important phase of mechanical engineering pertains to the adaptation of materials to new form, new properties, and new applications. It is the properties of a material which guarantee or jeopardize its engineering service. In the selection of a material of construction, engineering and economics must be simultaneously considered. Chief factors influencing selection are availability, cost, and properties.

The problem looks simple, but actually it is extremely complex. For instance, there are present properties and future properties. There are characteristics which will justify the application from the standpoint of safety and reasonable cost, but these may be far from the optimum characteristics available. Engineering ethics, and the honor of good craftsmanship, demand that we find for a given structure, machine, or commodity the material of construction which will be, during the life of the unit, the best.

There is only one good word for such a material or condition and that is optimum.

It is useful mechanical practice to seek to resolve, mentally, any object, structure, or machine into its component materials, then to ponder whether the best materials have been employed. Designing engineers apply this reasoning; all engineers will find it interesting and valuable. To recognize resinoid is not always easy. To recommend its adoption in many design problems requires knowing a wide range of properties and appreciating a specialized molding technique. The technical press has devoted some attention to this problem during the past five years. Knowledge of relative advantages and limitations will save metals from being unwisely replaced. With equal understanding, the resinoid materials should be conserved for optimum application.

Materials of Construction

In judging the suitability of a given material of construction, the engineer usually relies on current tables of properties, and adds to this actual service records of the material in typical range of application. In the case of metal, stone, or wood, the problem is easier. Resinoid materials, on the other hand, are made in the laboratory. There is seemingly no limit to the degree to which they can be improved by refinement and chemical alteration. Extensive research is being applied, and within the past two years new molding materials have been developed with shock resistance many times better than that of the best material previously made. There is therefore the problem of keeping one's information up to date. A second factor of difficulty is that it is next to impossible for any one man to know the complete record and service. New uses are being reported every day. The materials are used in literally every type of industry, and sometimes there are as many as a thousand applications in one small field. Because of the unusually large range of uses to which the materials have been found suited, a great many subdivisions of the materials have developed. It is possible to modify resinoid materials with respect to some 30 different properties. The result is that a single company may manufacture as many as 500 distinctive resinoid products. The properties of the resinoid product are also modified by the addition of such materials as wood flour, asbestos, graphite, linen, canvas, and paper. The chart, Fig. 1, will show the principal classifications of products in the resinoid industry.

Because of their relatively great importance in mechanical engineering, the laminated and molding materials will receive chief attention. (See properties chart, Table 1.) It will be the purpose in the remaining discussion to show that phenol-resinoid materials are properly to be ranked with metal, stone, and wood as a class of general-utility materials. They are in a sense a laboratory descendant of the former three. It is because they are somewhat akin to metal, stone, and wood that their combination of properties is so favorable and that their range of application is so broad. They are referred to as metal substitutes, synthetic lumber, and synthetic stone. Such designations are ill advised. They are true in a sense, but they lack conservatism. One should think of phenol resinoid as an individual material always ready to defer to metal, stone, and wood when these materials are better suited to the purpose at hand, and yet frequently able to solve in an optimum manner a question of design where each of the others has experienced difficulty.

Strength of Materials

At this point, there should be before one a rather definite idea of the ability of resinoid material to replace metal on a strength basis. George H. Dowty, in the June issue of *British Plastics and Molded Products Trader*, discusses the resinoid materials as applicable to over 100 airplane parts. He says, "Other things being equal, the material with the highest specific strength will be the most favorable for use in aircraft construction." His figure of merit, namely, the specific strength, indicates the relative load carried for a given weight of the material. It is obtained by dividing the tensile strength expressed in tons per square inch by the specific gravity. On this basis of comparison, he finds that the laminated resinoid materials are second only to steel, as in Table 2.

TABLE 2

Material	Tensile strength, tons per sq. in.	Specific gravity	Specific strength
Steel	60.0	7.85	7.6
Laminated resinoid material	10.0	1.35	7.4
Duralumin	18.0	2.75	6.5
Spruce	2.5	0.48	5.2
Resinoid material (molded)	2.5	1.35	1.85

On a weight basis, resinoid is six times lighter than steel and only half the weight of duralumin. It therefore follows that, weight for weight, the member fabricated in laminated material will be six times thicker than the corresponding steel member and double the thickness of the duralumin member. In airplane construction this design characteristic is considered an advantage, since the additional thickness gives greater rigidity and stability.

While in airplane design the property of tensile strength is considered especially important, designers in most industrial fields find it necessary to regard with equal care the property of shock resistance, or impact strength. The impact strength of laminated resinoid material, such as is used for gear stock, has a maximum value of 65 ft. lb. per sq. in. The average molded resinoid material was in its early years relatively low in impact strength. During the past few years new molding materials have been developed which yield products whose shock resistance is 10 to 20 times greater than the best previous grades, the maximum value now being 25 ft. lb. per sq. in. Any idea that resinoid molded materials are brittle or fragile is erroneous. It is possible to mold a resinoid part of fairly thin section which can be dropped 50 ft. to a concrete floor and suffer no fracture.

The tensile strength of molded resinoid materials is, at maximum, 8000, while that of the laminated form reaches 24,000. It will be seen on the basis of these figures that replacement of steel elements in the transportation field is impossible in installations which require tensile strength in the range of 60,000 to 120,000 lb. per sq. in. For the structure of bridges, rolling-stock carriages, and building frame, likewise for the construction of heavy machinery, steel in its various alloy forms, cast and wrought iron, also aluminum, hold the field well for metals. It is unfortunate that some writers waste time in predicting the immediate entry of synthetic resins as replacement in these heavy applications. The synthetic resins merit consideration in a very large field apart from heavy construction. It is quite true that they have replaced, and seemingly on a permanent basis, and with optimum effect, thousands of light machine elements and commodity parts. Up to the present time resinoid molded units have ranged in weight from a very small fraction of an ounce to 25 lb. The laminated resinoid can be produced in units weighing several hundred pounds. While these figures by no means indicate an upper limit, it will be seen that the resinoid replacement of steel is a factor for consideration by the machine shop and tool room rather than by the rolling mill. By the same token, it must be appreciated that resinoid properties and technique are of interest to men engaged in the production of die-cast metal parts and the machining of all types of metals.

As could be said for almost any material, phenol resinoid is seldom adopted because of any one property; rather for the sum total of its effect in reference to the requirements of a new design.

Typical Applications

A specific example of resinoid is in replacing cast iron. There is a recording machine known as the Egry register. It has two sides with area approximately 7 by 18 in. A depressed, decorative surface is desired; also, embossed reproduction of the firm name. The design must incorporate suitable provision for assembly, also several holes, bosses, flanges, etc., to accommodate transverse spindles and other parts of the operating mechanism. Based on production of the company in question, manufacture of these parts with resinoid made it possible to conserve 5000 sq. ft. of factory floor space which would have been required to accommodate the machinery essential to 23 grinding, drilling, and finishing operations which would be required with cast iron. Likewise, there was a saving of labor cost. In addition, the

weight of the finished machine was appreciably decreased, a factor of importance in the design of office and store machinery. Decrease in weight effected a saving in shipping cost, an economic factor which must also be considered.

Dental chair arms made of pressed steel required a subsequent enameling process. The chair arm was cold to the touch and the enamel too easily chipped. Molded from resinoid material and by means of a single unit molding operation, a strong, mahogany-finish part is produced with metal attachment inserts solidly embedded. The organic nature and low thermal conductivity of resinoid material make it warm to the touch.

Contrasting with the self-lubricating dashpot made from a molded mixture of resinoid and graphite is the grinding wheel application. In this field resinoid is used to bond the abrasive particles. The new abrasive wheel has come along with the demand for rapid accurate grinding. The Bakelite type of wheel is operated at 9000 surface ft. per min. as against 6000 for safe operation of vitreous wheels. Wheels may be produced of open structure especially suitable for snagging and cutting.

FIG. 2 TYPICAL EXAMPLES OF THE LAMINATED RESINOID PRODUCT
(Simple shapes can be molded, but detailed parts like the pinion are produced from disk blanks by hobbing machines or shapers. Process block, lower left, shows resinoid-impregnated canvas layers before and after press operation.)

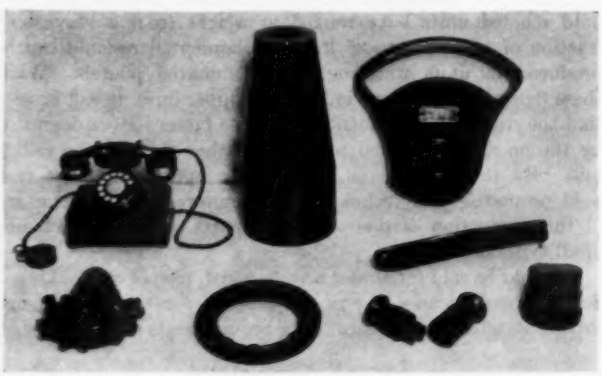

FIG. 3 TYPICAL EXAMPLES OF THE MOLDED RESINOID PRODUCT
(Insulator, center, weighs about 25 lb.)

They cut granite as rapidly as vitreous wheels cut marble, and wear away slower in the process.

There may be doubts as to the strength of molded articles, but the following should dispel them. The Philadelphia subway has adopted a car coupler made from a phenolic molding material. The main body of the coupler is of metal, and has two metal wings, each containing a molded part, which has embedded in it 14 metallic inserts. The inserts are used to make electrical connection, from coach to coach, of the various electrical circuits, and are so spaced that when the coaches are coupled the various electric circuits are completed. The couplings are of the jaw type. These molded parts have been found to stand up to the mechanical shocks of the train assembling yard.

In the textile industry, a cloth tentering machine is equipped with a large number of metal clamps, which are automatically opened and closed. These clamps are actuated by the sliding or rubbing action of the opener. Cast iron, and later, brass, was used for the opener, but both metals caused rapid wear of the clamps. This was regarded as serious because the clamps cost $4.75 each. During the past two years, resinoid laminated

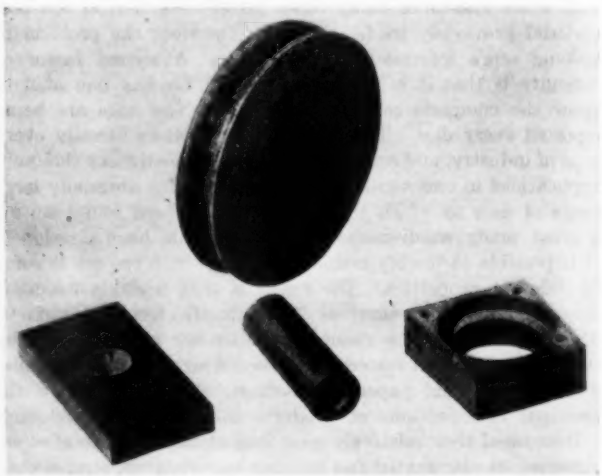

FIG. 4 AIRPLANE ACCESSORIES MADE FROM LAMINATED STOCK
(Guide pulley, control cable bushings, and engine mount shim.)

material has been used for the tenter clamp opener. There has been no discernible wear of the brass clamps. This is a nice illustration of resinoid, not only as a replacement, but as an ally of metal. A similar case is in automotive timing gear transmission, where a resinoid gear is meshed with two steel gears to promote the factor of silent operation. Recent improvement in canvas laminated gear blanks has increased the life of resinoid gears from 15,000 miles to almost that of the car.

Two of the most interesting replacements of brass have involved electric light fixtures of the ceiling type used in office buildings and switch plates for electrical switches and outlets. Both of these replacements are by the resinoid molding material. Resinoid laminated stock frequently replaces brass, a specific instance being the blades of electric fans. Replacement of brass for electric light fixtures eliminated the tarnish and the polish problem. Five years ago manufacturers were incredulous when the assertion was made that brass switch plates would be replaced. Now many millions of resinoid plates are made annually, and practically every new building is equipped with them. They are inert, non-corrosive, and require no polishing. Moreover, while a switch plate may not need to be an insulator, it is thoroughly sensible to make it of an insulating rather than of a conducting material.

Formerly the stem of an industrial thermometer was made of hard rubber reinforced by steel tubing. By molding the device completely of resinoid, six assembly operations are eliminated. The manufacturing cost is reduced 36 per cent. Steel inserts are molded integral with the resinoid in the molding operation. There were additional factors which influenced the choice of material, namely, heat and moisture resistance, electrical insulating ability, and mechanical strength.

For a special type of player harmonica an assembly of cold-rolled steel parts was replaced. In a resinoid only two parts

were required and 40 operations were eliminated. The part now resembles mahogany of high luster and embodies several lines of embossed lettering.

A paper napkin container and dispenser for restaurant use is essentially an end-open rectangular box with dimensions approx-

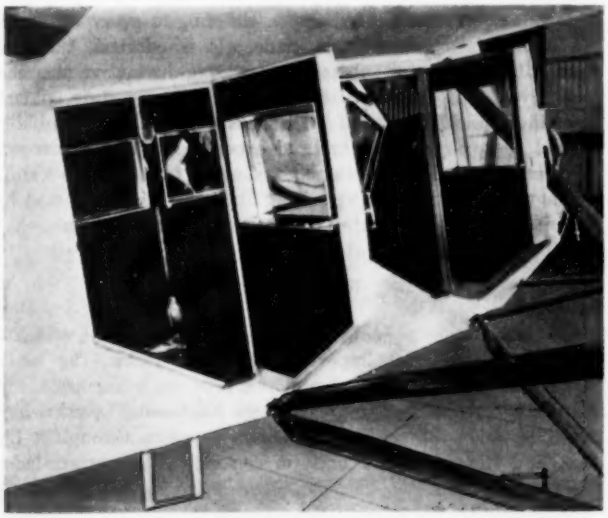

FIG. 5 RESINOID LAMINATED MATERIAL FOR AIRPLANE-CABIN WALL FINISH

imately 5 by 5 by 8 in. There are two large side apertures and a central partition. Resinoid materials in attractive colors have replaced metal because of their ability to yield such a device in a single operation (including the finish), also because there is no need of repeated daily polishing.

In the making of a radio speaker, resinoid, in molded and laminated form, respectively, replaced brass for bobbins and end plate. The metal finishing operations eliminated were, in the two cases, four and seven. In one instance the cost saving was 50 per cent; in the other, 60 per cent.

In a mechanical counting device there is a small ratchet wheel which operates at over 1600 r.p.m. In this service resinoid is reported to have been preferable to die-cast brass. After 30,000,000 revolutions it showed no perceptible wear.

The operating hand wheel of a letter-addressing machine, formerly of enameled steel, was replaced with resinoid rim molded integral with a two-spoke metal spider. The chief reason for the design change was to eliminate the chipping difficulty of the porcelain coating of the steel. A saving of 45 per cent was effected.

Not always is the competition with metal. On a burglar-alarm control box a $^3/_{\text{c}}$-in. slate panel was replaced by $^3/_{16}$-in. resinoid laminated stock. Each slate panel was drilled separately. Three resinoid laminated panels are drilled at once, eliminating 40 drilling operations. There is an appreciable saving in labor and tools. Additionally there is no breakage, and more uniform dielectric strength follows.

Surveying instruments are used in all climates—in the arctic regions at 60 deg. below zero, and in the tropics at 110 deg. and higher. Brass thumb nuts become very hot or cold, and fingers consequently freeze to the metal, or are scorched. Resinoid material, a non-conductor, overcame both difficulties. Operations eliminated on the different parts ranged from 9 to 32, and there was a saving of 40 per cent.

These instances of replacement with resulting design and property improvement, and with production economies of 40 and 50 per cent, are not unusual.

The remaining portion of this paper is intended to answer two questions which the mechanical engineer and mechanic are asking most frequently; namely, "Just what is this resinoid stuff, and what does one need to know about its technique or shop practice?"

WHAT IS RESINOID?

Phenol-resinoid material receives its name because chemicals known as phenols are used in its manufacture and because the

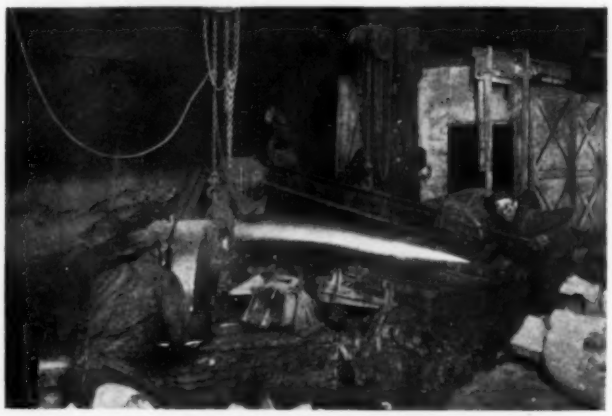

FIG. 6 HIGH-SPEED GRINDING EQUIPMENT
(Resinoid bonding wheels are being safely run at a speed of 9500 surface feet per minute.)

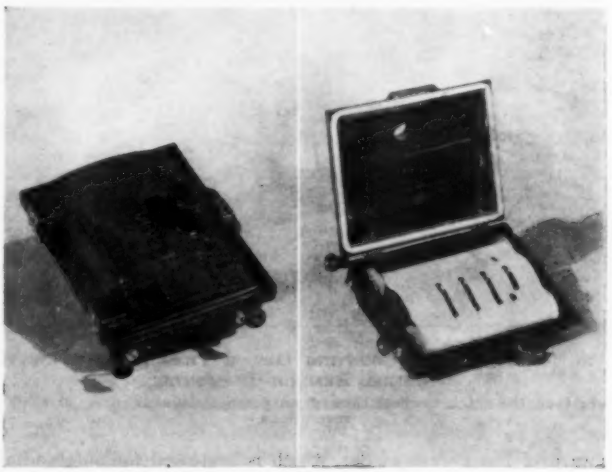

FIG. 7 EXAMPLE OF MECHANICAL ADVANTAGES WHICH RESINOID MATERIALS AFFORD
(The unit molding operation provides not only the channels, ridges, and apertures characteristic of the case interior, but yields also the grain leather exterior finish, and the embossed lettering.)

essential resulting products are somewhat like resins. It should be understood that a resinoid is not one of the natural resins like rosin, copal, or dammar. Resinoids are made in the laboratory by the building-up process of organic chemistry. This building-up process is the opposite of analysis. It is called synthesis. Synthetic chemistry is perhaps the highest form of chemical science because it is the most creative. Just as one develops an alloy steel which will have certain properties, so one can build in the laboratory a super-resin which will meet specifications better than any such material previously known.

Natural resins are useful for many purposes, notably in varnish making. The phenol-resinoid materials go beyond this to become materials of construction. Chemists in the latter part of

the Nineteenth Century knew that there was some possibility of making a synthetic resin from the reaction of aldehydes and phenols. Until the work of Dr. L. H. Baekeland, however, the world waited for an industrially successful super-resin which could serve as a material of construction. Announcement of the invention was made in 1909. When it was recognized by the

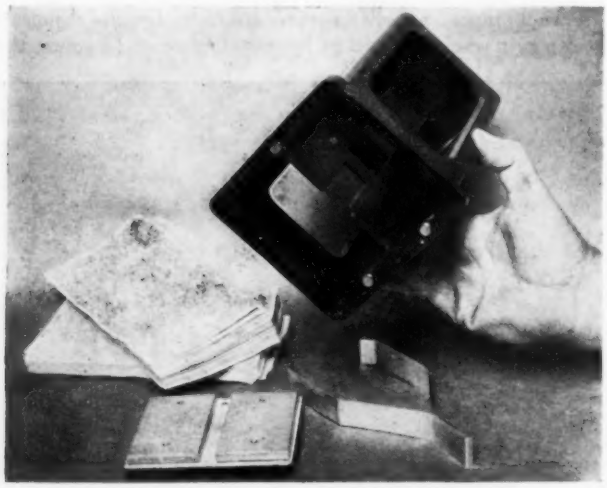

FIG. 8 MOLDED RESINOID NAPKIN DISPENSER
(This retains its luster with no necessity for polishing. The device is well designed from the standpoint of ease of manufacture.)

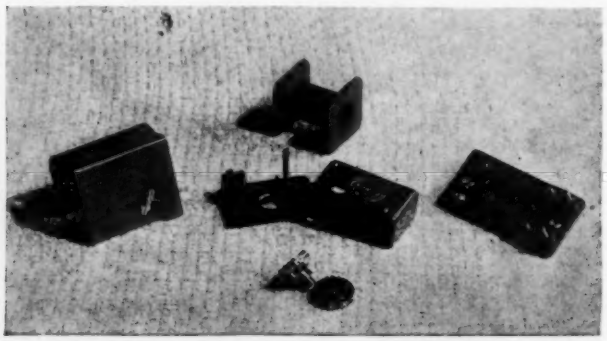

FIG. 9 MECHANICAL COUNTING DEVICE THAT INVOLVES SEVEN MOLDED RESINOID ELEMENTS
(Test on the ratchet wheel showed no perceptible wear after 30,000,000 revolutions.)

award of the Perkin medal, which is bestowed for outstanding industrial achievement, Dr. Charles F. Chandler, of Columbia University, epitomized the significance of the invention as follows: "Before Baekeland had published the results of his work, there existed not a single industry, nor a single application of any importance based on these condensation products. Since then, there have been started here and in Europe numerous factories where these processes are used for the most varied purposes, ranging from the manufacture of a billiard ball to that of a wireless telegraphic apparatus; the manufacture of a self-starter for automobiles to a wide range of uses, embracing such articles as switchboards for battleships, moldings for kodaks, armatures and commutators for dynamos and motors, telephone receivers, railroad signals, grinding wheels, etc."

In its physical appearance, Baekeland's product resembled the natural resins. Likewise in its initial state, it could be melted readily and dissolved. But, in a later state, it became quite different in properties. The agency of this change was heat; the process is described by the chemist as *polymerization*. When this change has been completed, the resinoid is radically different from natural resins. In careful appreciation of the physical resemblance and chemical dissimilarity, Baekeland adopted a distinctive term for his new material. This word is resinoid.

Under certain well-defined conditions two odoriferous, unpromising, liquid solutions of phenol and formaldehyde combined to form a solid resin-like substance, differing in every way from the liquids from which it is made. It is odorless, tasteless, inert—an entirely new substance possessing distinctive chemical and physical properties. In its raw or primary state, phenol resinoid is quickly softened by moderate heat and is soluble in alcohol or acetone. A very brief exposure to greater heat sets up a further chemical reaction and causes it to solidify to a state which will not permit of remelting and which is unaffected by solvents. Thus the material is thermo-plastic. More than this it is heat-reactive and heat-transformed.

THE LAMINATED TYPE

To manufacture phenol-resinoid laminated material, which is one of the two most important industrial forms, the initial resinoid is dissolved in solvents to provide a varnish. The varnish is then used to impregnate the laminating fabric, which is paper, linen, or canvas. The fabric passes through a dip tank and thus secures a uniform coating. The varnish-laden sheet passes from the dipping operation to drying apparatus. After being dried of solvent, the processed web is cut into sheets 100 in. sq., or of other dimension, as desired. A number of these sheets are then superimposed and placed in an hydraulic press operating with 350 deg. fahr. and 1500 lb. per sq. in. Under this action of heat and pressure a tough, dense, rigid slab is produced. If one of these slabs is examined it will show relationships and differences compared to wood, metal, and stone. Aside from its application for gears and pinions, this material is used for thousands of electrical and mechanical accessory purposes. Most recently it is being adopted for wall-paneling and in furniture manufacture. Tables and desks in modernistic design are composed of steel tubing and sheets of resinoid laminated material. Laminated pinions, adopted chiefly for the factor of silence or to resist atmospheres containing corrosive chemicals or abrasive particles, are used on motors rating from 1/4 to 100 hp. The drive is applied to practically all types of

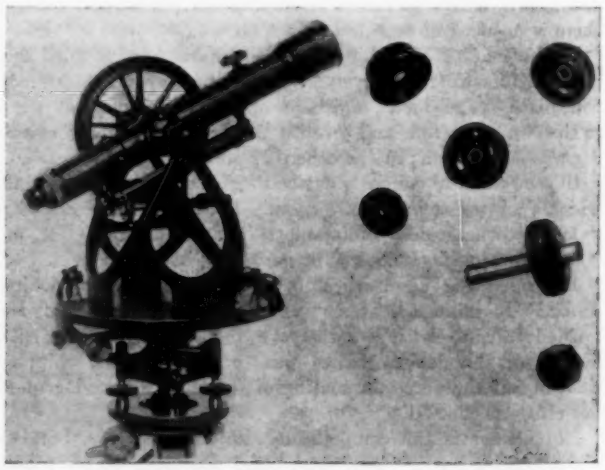

FIG. 10 EYEPIECE AND ADJUSTMENT WHEELS ON SURVEYOR'S TRANSIT MOLDED OF RESINOID MATERIAL
(Low thermal conductivity, in distinction to brass, is considered an advantage. Moreover, a unit molding process replaces 9 to 32 operations required with metal.)

shop equipment such as planers, milling machines, high-pressure pumps, broaching machines, etc.

By reason of its layer structure, the laminated material is generally stronger and tougher than the molded product. Moreover, the layer structure prevents its being molded to intricate shape. When applied to applications which are essentially flat, it requires very little processing. Otherwise it requires the usual machining operations which are applied to wood, metal, and stone. It will be understood, therefore, that this material replaces the older materials of construction on the basis of its chemical or physical properties, rather than from the standpoint of production economy.

The Molding Material

With the molding material the case is quite different. It offers all the properties of the laminated material with the exception that it is less strong mechanically. Its greatest advantage lies in the fact that it requires no machining, being converted by a single rapid molding operation into finished product form.

Molding materials are usually furnished in powdered form. This powder is supplied ready for molding in steel dies. It requires no mixing or modification by the consumer. Molding

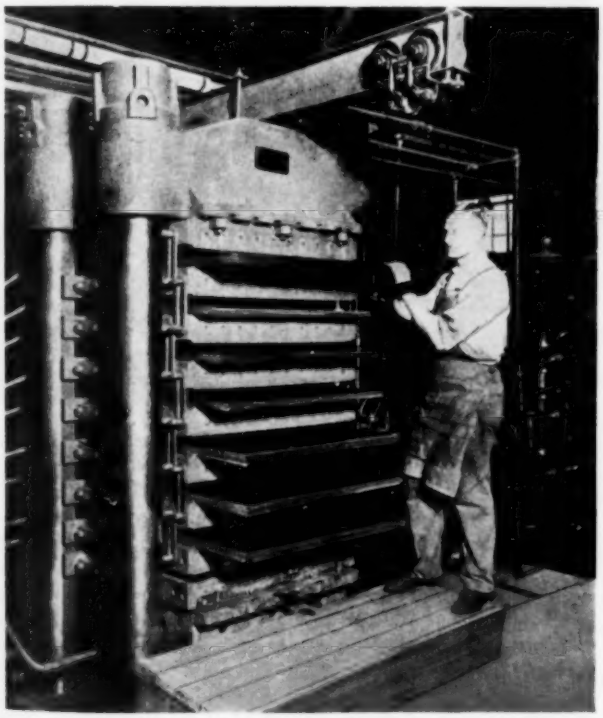

Fig. 11 Multi-Platen Press at 1500 Lb. per Sq. In. Bonds Resinoid-Impregnated Sheets of Canvas, Linen, or Paper Into Slabs of Bakelite Laminated

(The finished stock is adapted to thousands of uses, ranging from silent timing gears in the automobile to wainscoting in modern buildings.)

materials embody the resinoid material—in such state that it will be further converted during the molding operation—plus reinforcing material and color pigment. Reinforcing material is usually wood flour or asbestos fiber. It is not added particularly to cheapen the commodity, but rather to provide better molding qualities, greater toughness and strength, or additional heat resistance. For manufacture of dashpots, the addition of graphite imparts a marked degree of self-lubrication.

Die-Molding Production

As applied to metals, the term "die casting" is correctly defined as the art of casting molten metal into dies, these dies usually being constructed of special irons and steels. Hence in a broad sense this term embodies the processes of both "gravity" and "pressure" casting. The gravity method relies upon the force of gravity to carry the molten metal into the various cavities of the dies and therefore must be used in connection with metals of rather high fluidity. The pressure method employs the application of external pressure, either air or mechanical, or a combination of both.

From what has been said, it will be understood that resinoid molding is not a "die casting" operation in the usual sense of the term. There may be gravity effect after the start of the

Fig. 12 Bakelite Laminated Sheet Stock Used as Wall Finish

(The paneled enclosure of this filing department is an example. The ceiling light fixtures are an application of the molded product.)

molding operation, depending on the mold, but essentially the operation relies upon mechanical pressure. The charge is solid rather than liquid. Usually it is dry powder, though for purposes of convenience in loading, this powder may have been preformed into tablets or sheets. Mechanically, the molding process suggests the molding of hard rubber, but the process analogy is only partial.

Resinoid molding material might be defined as a general utility, partially converted, intermediate, raw material adapted to final conversion in dies operated with heat and pressure. It is not extruded, nor cast, nor is it "die cast" in the same sense that these terms apply in the molding of metal.

By the resinoid hot-molding operation, mechanically, the material is not merely set up in a new form, but its nature is changed chemically. In other words, as the molding operation progresses, the charge not only becomes different in form, but it is converted to a new material. The importance of this point cannot receive too much emphasis. Upon the understanding of it, depends success in resinoid molding technique and satisfactory product performance.

Hardened steel dies are used in molding resinoid materials. The die cavities are produced by hobbing or by the usual machining operations. Molding presses are usually hydraulic. Normal operating pressure is 1 ton per square inch. Temperature is normally 350 deg. fahr. These figures are not arbitrary; special material may require higher pressure or lower temperature. Steam is the popular heating medium, but gas and electrically heated platens are also common. The molding time for different resinoid materials covers an appreciable range. There are

hundreds of molding materials, hence a wide range of flow rates, color, and properties in general. Principally, however, molding time depends on weight and structure of product. Dies may be "hand," or mounted on the press, "semi-automatic." They may have one cavity or many. Dies are further classified as positive, semi-positive, and overflow.

The overflow mold is made so that the upper and lower portions rest one on the other as they are brought together under pressure. In the positive mold, the top plunger telescopes within the lower portion of the mold. In the overflow mold, the molding powder, or a preformed biscuit of it, may be used, provision being made for the excess material, or flash, to be squeezed out as the die members contact. In the positive mold, having no provision for overflow, the mold charge must be still more accurately apportioned.

The powder materials compress, in the molding process, to about 40 per cent of their original volume. In other words, to produce a flat tablet $^1/_2$ in. thick, the charge depth will be $1^1/_2$ in. The molding material suffers no appreciable loss in weight during the molding process. With well-designed molds and proper technique, molding accuracy within 0.002 in. is obtainable. For most purposes, tolerance of 0.005 in. is found adequate.

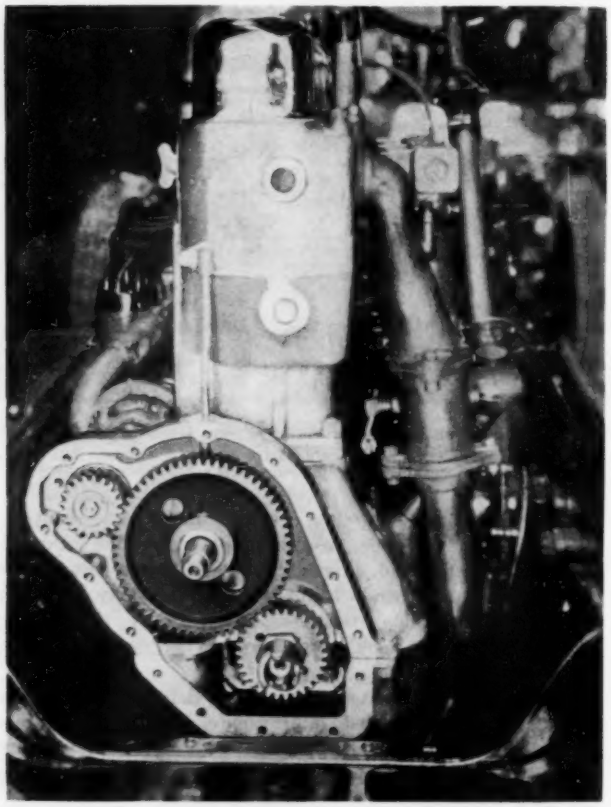

FIG. 13 THE MAJORITY OF AMERICAN AUTOMOBILES CONTAIN AT LEAST ONE LAMINATED RESINOID GEAR
(Most frequently it is in the timing mechanism and is installed intermediate with two metal gears.)

Knurling, embossed effects, bosses, grooves, holes, and screw threads are nicely obtainable in the molding process. Where special thread strength or bearing reinforcement is desired, metal bushings are incorporated. The embedding portion of the metal bushing is given a knurled grooved surface to promote adhesion.

SHOP PRACTICE SUGGESTIONS

A notebook record of service engineering experiences during the past five years contains many interesting incidents. Typical entries are the following:

(1) The premature hardening of a portion of a mold charge to the point where it is no longer plastic under heat, is usually called pre-curing. Pre-curing results in molded parts of poor strength and finish. It is caused by allowing the charge to stand in the mold for several minutes before being placed in the press. It is a simple matter to avoid pre-curing. The molder should put the mold in the press as quickly as possible before loading. He should also close the average mold within 15 to 30 sec. from the time it is placed between the platens of the press.

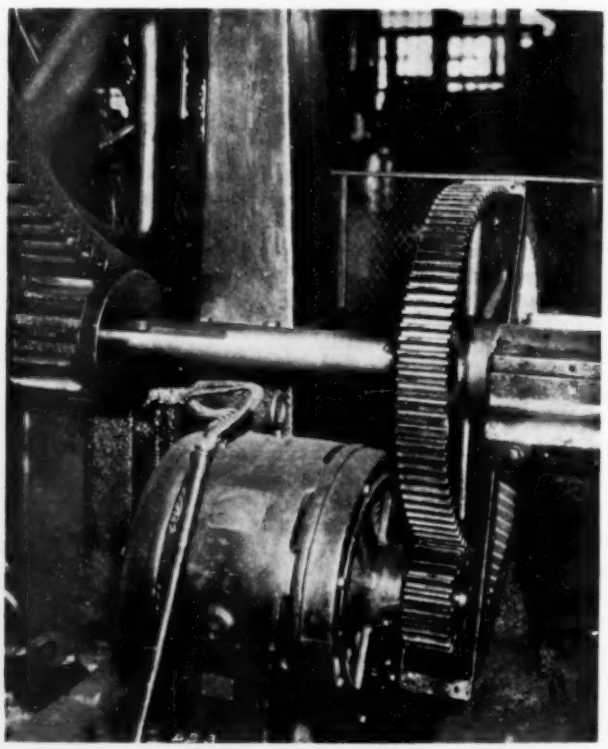

FIG. 14 SMALL BAKELITE GEARS USED FOR LIGHT-LOAD SERVICE
(The Bakelite pinion shown is mounted on a 100-hp. motor which drives a boring mill.)

(2) A molder who was producing jar covers was obtaining production of but 130 per day. A stopwatch study of loading and curing time made by a service engineer revealed that it was taking $7^1/_2$ min. for each cycle. The press platen was too high and the arbor press too far from the molding press for easy and efficient handling of the molds. A platform was built in front of the presses and the distance between arbor press and molding press was reduced. The result was that production was increased to 190 covers per day, a gain of 45 per cent.

(3) In molding phenol-resinoid materials gases are given off under the heat and pressure of the molding operation. If a ready escape is not provided for these gases, the molded piece is apt to have interior gas pockets and surface blisters. This trouble can be overcome readily by the practice known to the trade as "breathing" the mold; that is, releasing the pressure for a period of 3 or 4 sec. after the mold is first closed. Preheating the molding tablets for 10 or 15 min. at a temperature of 180 to 190 deg. fahr. will also be found a very effective means for checking the tendency to blister. An "air-bound" mold is

another fruitful cause of blistering. Such a mold is one in which the top force fits into the chase so snugly that there is no means of escape for the heated air or gases given off in molding. This occurs only in positive molds of the "straight-draw" type. To avoid air binding, the mold force should be made with a free sliding fit in the chase and should be provided with sprue grooves to allow for the escape of gases.

(4) In 1926 a company producing 5000 tube bases per day was using the following cycle: (*a*) Load, discharge, 1 min. 20 sec. (*b*) Closing mold, 40 sec. (*c*) Cure, 2 min. A service engineer demonstrated that the 2-min. cure could be reduced to $1^1/_4$ min. by puffing. Thus they included in their operation a slight opening, or release, of the mold about 10 sec. after the first closing, and standardized on a cure of $1^1/_2$ min. In 1930 the cure requires less than 1 min.

(5) Whenever possible the practice of using a small mold in a large press should be avoided. The excessive pressure applied on the small surface of the mold may drive the mold into the platen of the press and score it badly. When it is absolutely necessary to use a large press with a small mold, it is a wise precaution to place at the sides of the mold steel blocks of approximately the same height.

(6) One of the best speed records for hand-mold operation is 600 pieces per hour from a single press, using two nine-cavity molds. Time in the press is 40 sec.; transfer, 5 sec. Wall thickness of molded part is $^1/_{16}$ in. In considering molding speed records, it should always be remembered that excessively short curing time does not impart properties claimed for phenol-resinoid material.

(7) In an instance of alleged shrinkage, with finished piece undersize, it was found that the gas-heated presses were operated at too high a temperature. The alleged shrinkage was really warpage. The molded part had a sizeable central slot. Use of shrink plugs eliminated the trouble.

(8) The use of hard water will cause coating of the steam channels in the mold, and this, by interfering with the thermal conductivity of the metal, will influence the curing and chilling effect, and alteration in these factors will cause surface defects on the molded piece.

(9) In molding a typewriter space bar, poor surface, due to insufficient cure, caused by poor conduction, was traced to the fact that the mold had warped. A thin film of resinoid material had become located between the bed plate and the mold. This acted as a heat insulator. The die was machined, and relocated with good contact surface, and the trouble was eliminated.

(10) In molding a coil cap, a void was formed in the center of the molded section. Material was not flowing properly into place because the force of the mold having long pins in it was allowed to rest near an open window for several minutes during the loading operation; consequently it became so cooled that flow of material was retarded. The trouble was corrected by keeping both top and bottom mold parts hot. Proper molding was facilitated by heating preformed disks for one hour at 210 deg. fahr.

(11) It is good practice to use an air hose to clean off the mold between cycles. Care must be taken, however, not to blow impurities into the supply of molding material and not to blow contamination into recesses of the die. It is sometimes found that the pump supplying the air pressure has its intake located near the floor. An air filter should be included in the air supply line.

(12) In the molding of an electrical instrument case blistering occurred, but only on one side of the part. The material was blamed. A service engineer found that a small amount of snow was drifting through a ventilator in the roof and settling in the open cavities of a tilt-head press mold. When the ventilator was closed, the blistering trouble disappeared entirely.

(13) On a 12-cavity mold for a cylindrical automobile part, four cavities had been left empty because of broken pins. Operators were equipped with five sets of shrink plugs for each cavity, and they stated that on taking from a given cavity five successive parts, differences after shrinking on the plugs until cold were between 0.003 and 0.007 in. The die cavities differed slightly; hence the different sets of marked shrink plugs. In spite of marked indication, the operator was not taking any particular care to put the part from a given cavity on the right plug. Proper use of shrink plugs removed trouble.

(14) The manufacturer of an electrical device requiring exact dimension and high polish complained of steel particles in one drum of molding material. It was found that a workman had been using a steel screwdriver to clean mold cavities. Three cavities in the mold have been badly scored, and would require repolishing. Having ruined the finish the workmen had reported that the molding material contained metallic impurities.

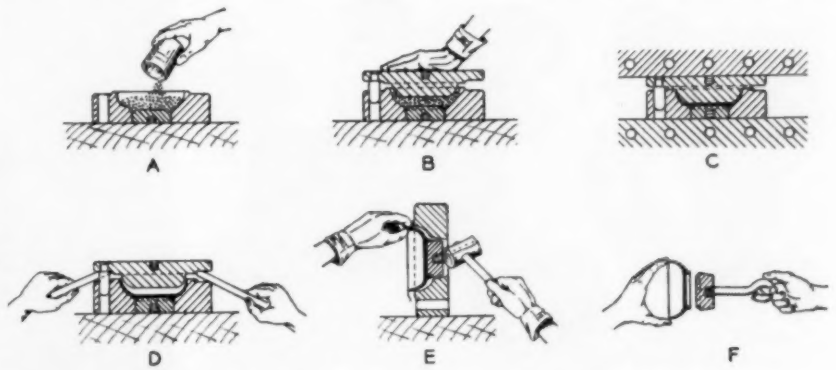

FIG. 15 THE MOLDING OF A RESINOID PART OF SIMPLE DESIGN

(The operations shown are analogous in principle with the machine methods involved in quantity production. *A*, fill mold with requisite amount of molding material; *B*, press down with hand; *C*, cure in hot-plate press for about 43 min.; *D*, remove the top force; *E*, tap the ejecting plug and the molding from the mold; *F*, remove molding from the ejecting plug.)

(15) Large silver-gray spots, appearing without apparent cause on surface of molded parts, were attributed to oil or water having passed through the air hose.

(16) A large three-cavity positive mold for the production of parts with thin, deep-wall section requires a "soft" material with quick flowing properties. In the instance reported, sticking occurred in the middle cavity. On checking with a pyrometer, it was found that after a period of 45 min. under steam, the end cavities were 300 to 325 deg. fahr. The center cavity registered 250 to 270 deg. fahr. These molds were being operated with chill, so the production temperatures would be still lower. It is essential that molds be designed so as to maintain the same temperature throughout all cavities.

(17) A fast-curing molding material was found to take an unusually long time to cure. Investigations showed that the drum was shipped and stored during a blizzard. When the material was put in the mold, a long time was required to heat it through. The material being a good heat-insulating medium, it was naturally slow in reaching room temperature before molding.

(18) Misaligned mold pins are always a source of molded part cracking or breaking.

(19) A molded tool handle was found to be breaking in service. Examination showed that the resinoid material was under-

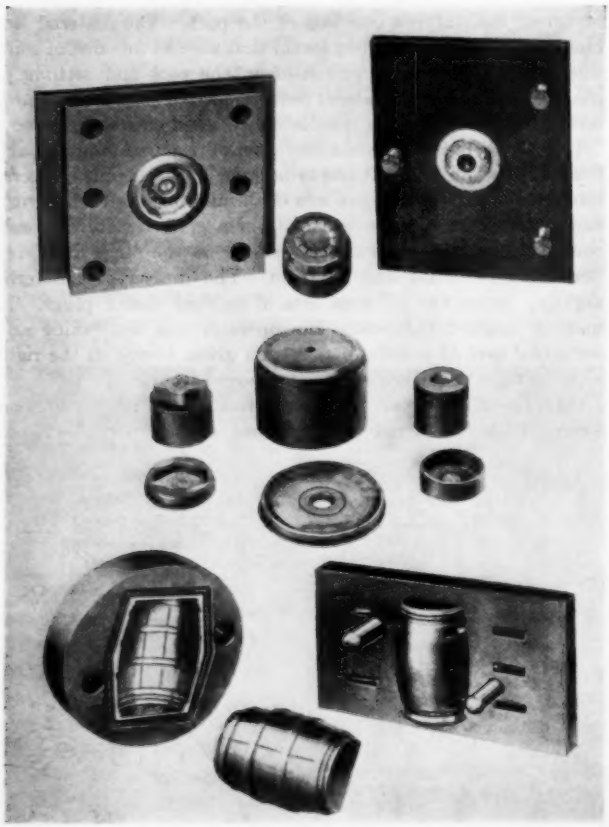

FIG. 16 GROUP OF MOLDS AND HOBS USED IN FORMING THEM

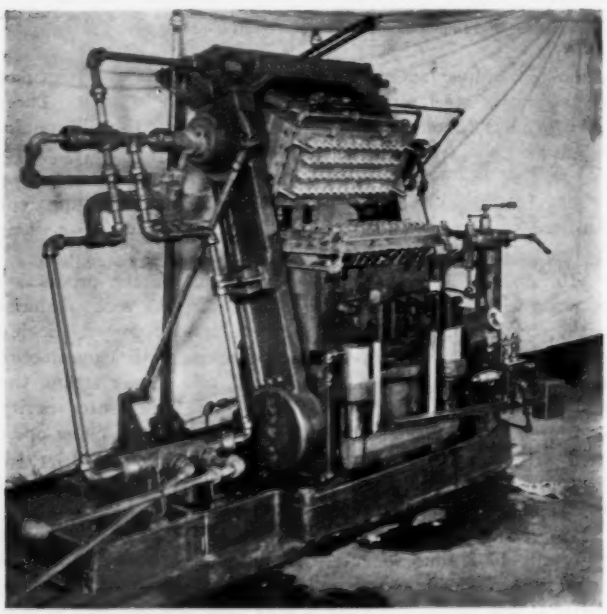

FIG. 17 TILTING-HEAD MOLDING PRESS

cured. Moreover, considerable material had escaped from the flash mold instead of being compressed into the finished handle. The shape of the preform was changed, and the time of cure was increased to 6 min. The tablets were pre-warmed, and the mold was closed slower to prevent escape of material. A handle, thus made, could be pounded on the floor until the metal part was seriously deformed, and the handle was unimpaired.

IMPROVED METHODS AND MATERIALS

Rather than discuss equipment and technique of the resinoid

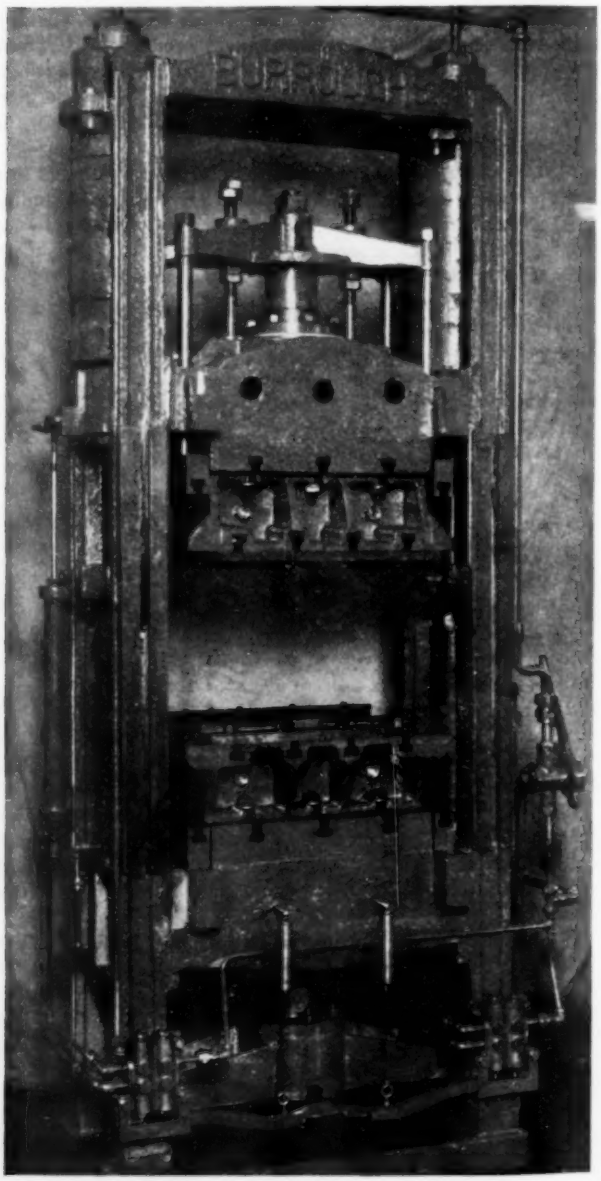

FIG. 18 HYDRAULIC SEMI-AUTOMATIC MOLDING PRESS

molding plant as if it were a new subject, some of the technical improvements which have been responsible for the remarkable advance in production and application during the past five years are listed.

1 Presses:
Automatic—increasing production speed; compared with hand molding.
Tilting head—permitting time saving and easier loading.
Rodless—minimizing danger of platen misalignment.
Mechanical (molding machines)—eliminating hydraulic system.
Duo—Turntable design permitting heating and chilling operations

quickly continuous without hand transfer. Hot and cold operation confined to respective press units.
Mechanisms, control—eliminating hand operation of press cycle.

2 Molds:
Multiple—molding a hundred parts instead of one in equal time.
Chromium plated—protecting surface, facilitating release of complex parts; also an aid to hobbing.
Hobbed—extending application for mass production of multiple cavities.
Design improvement—reducing flash to a minimum.

3 Preforming equipment:
Rotary—notably advancing tablet production per minute output.
Percussion—heavy construction eliminating frame breakage and producing tablets of larger size.

4 Plant:
Production line—sequence improved, and conveyor systems increasing speed and convenience.
Press tables—at same height with press, keeping work on same level.
Loading frames—permitting rapid charging of multiple molds.
Line connections—maintenance of standardized temperature and pressure minimizing leaks; copper pipe spiral connections sometimes preferable to swing joints.

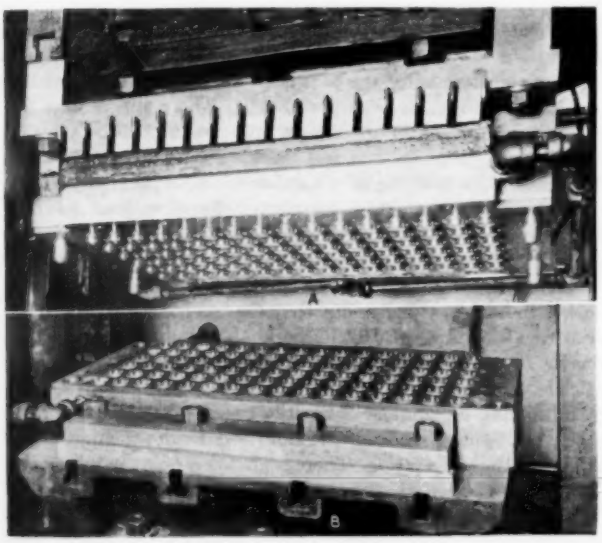

FIG. 19 UPPER AND LOWER DIES FOR PRODUCTION OF A BOTTLE CORK COVER

(*A*, upper die; *B*, lower die. These are mounted in a 100-ton semi-automatic press. Work is stripped from forces of the upper die by a stripper plate moved downward by the ejector cylinder. The mold is direct-heated and contains 96 cavities. The cup-shaped moldings produced are 1 in. diameter and 9/8 in. depth. Production is 23,000 pieces per day.)

Instruments—increasing use of indicating and recording types.
Measuring equipment—electric scales for accurate charge weighing; rotary measuring machines for preparation of identical charges of powder material.
Material-handling methods—involving segregation of colored materials, and the protection of molding material, generally, from contamination.
Safety devices—automatic press guards, etc., preventing injury of operators.
Air hose—slender neck type permitting insertion to reach die cavities; installation of dust filters.

5 Materials:
Development of a material possessing increased shock resistance—twelve times that of the regular molded product, itself a good shock-resisting material. Airplane pulleys and camera cases are typical applications.
Development of materials which can be drawn hot. Equal number of cold presses eliminated, doubling plant capacity. Time saving results because a 9-min. cycle may now be two. This latter point means that a molding plant of given size is capable of at least four times its former output.
Development of an entire color series supplementing the blacks and browns which long prevailed.
Development of an improved heat resistant material by which the heat resistant range of the molded piece has been raised from 250 deg. fahr. to 400 deg. fahr.
Development of material with increased resistance to the carbonizing effect of the electric arc. Endurance aircraft have used it for their magnetos.
Development of improved "low loss" material for radio. This yields a molded piece with very low power factor, and high resistance; suitable, therefore, as insulating parts of high frequency apparatus.
Development of a material offering increased flexibility. This seems to solve the problem arising from difference in expansion between a reinforcing metal core and its molded resinoid covering. An important use is found in the automobile steering wheel. Integrally molded, a resinoid steering wheel with metal spider is reported to be three times as strong as the rubber rim wheels, and from two to three times as strong as one made from wood.

6 Material application trend:
Coupled with shop-practice improvement and material development is the rapid extension of molded resinoid parts to mechanical uses involving relatively large forms. Instances include soda fountain ice-cream cabinet covers, lunch-counter stool tops, office-machine sides, electric-fan bases, subway-train coupler parts.

CONCLUSION

In this review an effort has been made to show the origin, comparative properties, and present industrial position of phenol-resinoid material. This resinoid class of substance which is a product of the research laboratory has been considered as a major class among materials of construction. It has been ranked, by reason of its versatility, with wood, stone, and metal. Resinoid has been so nominated, after consideration of its rapid advance, permanence of achievement, and future promise—particularly with regard to its unusual combination of properties adapting it to every field of engineering and in consideration of its thousands of important industrial applications.

Emphasis of the spectacular has been avoided. The best services of resinoid have been found to supplement metal and the older materials of construction. Every effort has been made

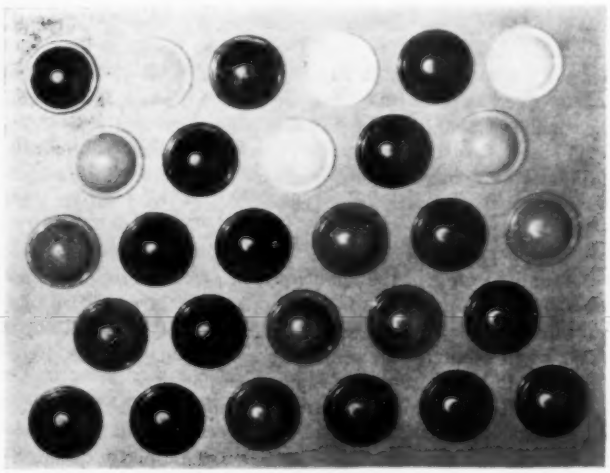

FIG. 20 RESINOID MOLDINGS IN A WIDE RANGE OF COLOR

(In addition to standard one-tone shades, wood finish mottles such as walnut and mahogany are available.)

to prevent overestimation or incorrect interpretation of the rôle of replacement. Resinoid is not a universal cure-all, but it is one of the most useful material allies of modern progress. Effort has been made to indicate and to discuss the engineering factors which govern its adoption in new fields.

One of the chief problems confronting twentieth century organization is that of coordinating the complex activities produced by the past generation of industrialism. Resinoid material, by reason of increasing use, is creating new departments in mechanical shop practice. Its fabrication, especially the unique process of molding, is a natural supplement to older operations of the metal trades.

The history of humanity is a record of transition no less in materials than in mankind. Particularly is this generation replete with change. There is unparalleled attention to research, which is deemed necessary to survival. Research is responsible for new materials and their application. The total effect of material transition, either upon industry or upon the workers, is impossible to assay. Sometimes resinoid replaces steel. Again conjoined with sheet steel, it replaces stone, and opens a new metal market. Gleaming corridors of mammoth buildings bear evidence. Optimum application of material must involve conservation as well as efficiency. A study of

the engineering factors involved in material replacement becomes, therefore, increasingly important.

Discussion

W. S. Huson.[2] This paper marks an unusual presentation of a very live subject, in that it enters so fully into intimate detail of manufacture and application and, too, because it is a material which at first glance would seem remote from a place usually assigned to the metals.

However, as the author has pointed out at length, where pieces formerly considered only from a metal base can now be made of a material so different and yet adaptable to many used heretofore considered as of metallic possibility only, the paper will undoubtedly broaden concept and use as study is given the material and its economic value in the industries.

There is a phase of production on which the author touches rather lightly, and that is the machining of resinoid materials and the effect on cutting tools. The material is very abrasive in its action on cutting edges, and while not seriously affecting machining, nevertheless retards it and is a factor in cost consideration. Here steps in another laboratory accomplishment, cemented-tungsten-carbide tools, which are so hard that the abrasive nature of resinoid has small detrimental effect on the cutting edges, so little that parts are produced much faster than when made of metal. It is well this paper has been presented, for it emphasizes how materials other than those customarily considered as being the only available are coming into larger use and in many ways better service.

W. F. Lent.[3] The paper is an able and comprehensive review of the fundamentals of the application of synthetic resins. The writer has some comments on the application of molded products which apply as well to the phenol-resinoid type mainly discussed as to other types of molding compounds such as urea, celluloid, cellulose acetate, cold molded, and others.

As the author brings out so clearly, in application engineering one must simultaneously consider both engineering and economics. And when these two phases are properly balanced there is truly an optimum application. The solution of the economic phase, which is perhaps the least understood and appreciated, will remove the most serious obstacle to more rapid expansion of applications.

The fundamental nature of the molding art demands a relatively high preparation cost (molds and fixtures) prior to the initiation of economical manufacture. The typical case therefore presents a problem of economic balance between high tool cost and savings in production. This is generally a complex balance and involves many considerations of apparently trivial details of design of molded parts as well as of the tools for making these parts.

First, regarding the design of molded parts, it should be realized that it is often very easy to produce a part by machine methods which it may be very difficult to mold. This involves a consideration of under-cuts, side holes, use of inserts molded in, dimensions of sections, location of holes, proportions, etc. These are the every-day problems of the molder and have been treated in detail in current literature. They are extremely important for successful and economical manufacture. The designer should realize that apparently slight concessions in these details have a powerful bearing on cost.

Second, regarding the tool equipment, there is always the economic balance, here stressed again, of the amount to be expended on tools versus a counterbalancing lower product cost. Here there are two considerations—how the mold unit is to be laid out most advantageously and how many units (or cavities) will be most economical over all.

The layout of the unit determines whether a positive, semi-positive, or flash type of construction will be used, in what position the part will be molded and how the fins will appear. Of course this problem must be considered in connection with the detailed design of the molded part, and it is mainly for this reason that the detailed design has so important a bearing on cost. Flash molds are cheap to construct and easy to operate, but they do not necessarily produce the best parts. The fins appear laterally, entail a slow operation for removal, and are apt to leave objectionable marks when removed. Contrast this to the vertical fin from a semi-positive or positive mold which may be removed by a simple rub on an abrasive surface. The cost is by no means all there after the part has been molded, although the most skillful work has been performed. There still remain the fin-removing (cleaning) operations, and possibly drilling, reaming, tapping, grinding, and inspecting—all classed as finishing operations. An analysis of a number of small molded parts in large quantity manufacture for electrical applications discloses aggregate cost of finishing operations ranging from 20 per cent below to 20 per cent above the molding cost. A prominent hot molder recently said that he had been employing about one finisher to one press hand, but that the tendency seemed to increase the ratio toward two finishers. The point to be noted is that the layout of the mold has a vital influence on finishing cost, which is an appreciable item in total cost.

Multiplying the number of cavities in a mold at least approximately multiplies the cost of the mold and divides the unit molding cost in the same ratio. There is always a point in number of mold cavities above which or below which the cost of total parts to be made plus tool cost is greater. More effort should be put into the correct determination of this most economical number of cavities. It is indeed surprising in studying proposals from different sources working with the same information, to note the great variation (often as much as three or four times) in number of cavities in molds.

Serious thought is apparently necessary in preparation to manufacture molded parts. The design of the part must be suitable and the layout of the tools correct. Once committed to a design and layout, a change is costly, as it may necessitate reconstruction of tools.

The problem of those interested in the sound expansion in the use of molded products is to get designers and development engineers to think in terms of the possibilities of the application of such parts. Effort is necessary to educate them in the physical properties of the materials and in the general methods of fabrication. The latter is not an easy matter and probably will never be wholly accomplished, as economical design is dependent on many fine points of technique, a complete knowledge of which can be had only by those in intimate contact with the design and production of molded parts.

The writer would say that the recommended procedure is to call in the molder in the early stages of the design. Give him all details of what is to be accomplished, particularly the relation of the molded parts to the complete assembly. Work the problem out with him frankly and do not withhold "secrets" for fear of trade information or patent data leaks. There is a well-defined code of ethics to be followed in such cases. Failure to be frank surely limits the possibility of material savings in adaptation of molded product design to specific conditions.

Repair of Worn Parts by Electrodeposition of Iron

By T. P. THOMAS,[1] EAST PITTSBURGH, PA.

In this paper a commercial method is described for salvaging worn or undersized steel parts, such as thread and plug gages, arbors, reamers, motor shafts, gear centers, etc., by electrodeposited iron. Details of the process have been worked out which provide a practicable set of instructions for shop use. The high current efficiency and rate of deposit of the warm concentrated sulphate bath will enable the plater to complete practically any salvage job in one working day.

IN THE past few years considerable attention has been given to a means of salvaging valuable machine parts in which certain critical dimensions were undersize, due either to wear in service or to errors in manufacture. The reclamation of such material by applying an adherent coating of electrolytic iron began in England and France during the recent World War. Those most concerned in this development were B. H. Thomas[2] and W. A. Macfadyen.[3] The British were the first to make practical application of the electrodeposition of iron for this purpose, applying it to the repair of worn automobile and aeroplane parts.

The Westinghouse Research Laboratory became interested in this problem and work has extended over a period of several years. Experimenting with different solutions, addition agents, current densities, etc., there has been developed a standard method of procedure using commercial salts and sufficiently high current density so that all ordinary repairs will not require more than two or three hours in the plating bath. The cost of building up and machining are thus kept low enough so that it will generally pay to reclaim a piece rather than use a new one.

For general repair work a plating bath made up in the following proportions is satisfactory: Commercial ferrous ammonium sulphate, or the proportional amount of ferrous sulphate and ammonium sulphate, 2.5 pounds per gallon of water plus five ounces of ferrous carbonate freshly precipitated and kept under water, plus a handful of powdered charcoal. The carbonate "mud" keeps the solution practically neutral. The charcoal prevents pitting at the cathode surface. The sulphate salts must be free from sulphocyanates.

All small pieces are plated in earthenware crocks and large pieces in lead-lined wood tanks or stoneware tanks. Difficulty is experienced in using the plating solution in a wood tank. Organic materials from the wood enter the plating solution and cause excessive pitting of the deposit. The anodes are made of Armco iron, cylindrical in shape. Micarta disks with a hole cut in the center are fitted in each end of the anodes. The pieces to be plated are made the cathode and held stationary as they extend into the plating solution through the holes in the micarta disks. The anodes are attached to a suitable device designed to move them up and down, thus keeping the plating solution agitated and the ferrous carbonate and charcoal in suspension. The temperature of the bath is held at approximately 60 deg. cent. A current density of 60 to 65 amperes per sq. ft. is used. This deposits metal at the rate of 0.006 in. in diameter per hour. This method of procedure applies to pieces such as shafts, plug gages, reamers, pins, etc. For pieces such as gear centers, where the inside diameter is to be reduced, the anode passes up and down through the center and micarta rings are attached to it to produce stirring.

Probably the most essential part of the process and the step which requires the most careful attention is the cleaning of the piece before plating. After trying different methods of cleaning to obtain good adherence of the deposited metal, the electrolytic process was adopted as follows: The piece to be plated is made the cathode in an alkaline solution consisting of 5–10 per cent of caustic soda and 5–10 per cent of commercial sodium carbonate, using a current density of 3 amperes per sq. in., for a period of three minutes. It is then washed in running water and transferred to a 30 per cent commercial sulphuric acid solution and given a high enough current density to make it passive. This treatment is continued for a period of three minutes or longer, according to the condition of the piece. If it is free of rust in starting, then three minutes is sufficient. The piece being cleaned should come out of the acid-cleaning solution bright and silvery except in the case of cast iron which will be black due to graphite. When taken from the acid-cleaning solution the piece is washed in running water and immediately transferred to the plating bath without the cleaned surface being touched. It is very essential that the current density be held high enough, at least 3 amperes per sq. in. in the acid solution, so that the piece being cleaned remains passive. When passive there is a rapid evolution of gas with the piece remaining bright, but if allowed to become active it has a dull black appearance. When a piece is coated with oil or grease it is cleaned with gasoline or benzene prior to cleaning electrolytically.

Portions of the work which are not to be plated, but which will come in contact with the solution, are brushed over with melted hydroline of a melting point sufficiently high to stand immersion at 60 deg. cent. without undue softening. After the piece is plated the protective coat can be readily removed by washing with benzene.

It is impossible to build up a piece accurately to size; therefore it is necessary to plate a few thousandths over and then grind to finish size. This method of recovery can be used with steel, cast-iron or case-hardened material. Press fit, severe bending, and forging tests with deposits $^1/_{16}$ in. or more thick, all indicate that platings produced in this manner are satisfactorily anchored to the base metal. Plug and thread gages have been repaired and have given satisfaction, although they are not as hard as heat-treated tool steel. It is, of course, possible to carburize such pieces, when they will compare favorably with the original gages. One of our prize exhibits is the shaft from a 3-hp. motor which was used on a six-spindle drill press with a rather short, very tight belt. This shaft was ground undersize to simulate wear, then plated oversize, ground, and reassembled. It ran steadily

on the day shift for eight months and was then taken out for inspection. No wear could be detected. As this shaft had had more than a thousand hours of actual service, it is quite evident that this material is all that can be desired for bearing service.

The limiting factor in the size of a plating plant is the amount of current needed for cleaning. At the rate of 3 amperes per sq. in., a 1000-ampere generator set would clean a piece having 333 sq. in. surface, the equivalent of a shaft 4 in. in diameter and 26 in. of plating length, or a shaft 6 in. in diameter and 17 in. of plating length. After a repair shop of this kind has been equipped the chief operating expense is labor. The plating baths should run 6 months at the least without any attention or addition of salts with the exception of adding water to replace that lost by evaporation and the addition of a small amount of ferrous carbonate and charcoal once a week. The cost of the current used in cleaning and plating is small. The anodes are gradually used up and have to be replaced by new ones; however, the initial cost of an anode is distributed over a number of repair jobs, making the amount added to an individual piece small. The laborer is chiefly concerned in getting pieces ready to be plated and cleaning the ones that have already been plated. As they require no attention while in the plating bath one man can handle enough pieces in a day to make such a shop a paying investment.

Discussion

H. A. Rohrich.[4] Have worn cast-iron parts been successfully salvaged by this process? There are a large number of slides and other parts in automatic bottle machines which wear rapidly and are now thrown away. Has there been enough experience with cast-iron parts salvaged in this way to show that they wear sufficiently well to justify the cost of salvaging as against replacement?

Our bottle machines are complicated and have a great many cast-iron parts, some of which pass through a series of machining operations. If local wear can be restored by electroplating, it will save considerable money, as the parts will last indefinitely otherwise. There must be many machines where local wear of expensive cast-iron pieces can be restored, and if the author can give additional information, it will be of great value to the industry. We expect to do some experimenting with Mr. Thomas' process and will report results.

Arc-Welded Jigs, Fixtures, and Machine Tools

By J. R. WEAVER,[1] EAST PITTSBURGH, PA.

Among the advantages of jigs and fixtures welded up from structural-steel shapes over those of cast construction, the author cites production on short notice, strength combined with comparative lightness in weight, ease of alteration, etc. He outlines the methods used in their manufacture, and gives examples of a wide variety of jigs and fixtures and of special machine tools embodying this form of construction.

THE application of welding to the building of jigs, fixtures, and machine tools, which the author proposes to discuss here, was practically forced upon the company with which he is connected about a year ago. Its business increased very rapidly about that time, so that in order to obtain all advantages possible in manufacturing, it was necessary to obtain jigs, fixtures, and special machine tools on very short notice.

It was quite noticeable in regard to new machine tools purchased from the machine-tool manufacturers that delay in receiving them was due in all cases to the time necessary to make the jigs and fixtures. Naturally, the machine tool was more or less of a standard product and could be delivered on comparatively short time.

When the idea was conceived of manufacturing jigs and fixtures from structural shapes welded together, several such jigs were built and put through a very thorough test to ascertain whether they would be suitable for the company's work. After testing them for all the inaccuracies that are liable to occur due to warpage, distortion, etc., a definite program of manufacture was then decided upon which has given extremely satisfactory results. The thought was advanced that the jigs and fixtures would not maintain their shape after a period of time, but they have been used for about a year and have required less maintenance than did similar cast-iron jigs.

As mentioned above, it became necessary to obtain jigs, fixtures, and machine tools on very short notice, and in checking deliveries of cast jigs versus structural jigs, it was found that when putting the orders through for cast jigs in the regular way, it required about four weeks to obtain castings. Of course, it was necessary to make patterns, core boxes, etc., and the castings had to be made, cleaned, etc., before being sent to the shop. In the case of welded structures, however, we can obtain the most complicated jig in not more than a week's time. The average time is about four days and it will readily be appreciated what a decided advantage this is in manufacture of any kind of product.

Construction of Welded Jigs

These jigs are made from hot-rolled steel of whatever shapes and sizes are necessary and welded together. Where hardened pieces are required, these are made from tool steel, hardened and attached to the jigs by means of screws, bolts, etc., or in the case of bushings, pressed in holes provided for them. Some trouble was experienced owing to the fact that after the jig had been annealed the feet were too soft and chips on machine tools would imbed themselves in them. In order to overcome this, the feet were made from tool steel and heat treated before being welded to the jig. They were then drawn to a scleroscope hardness of 45 to 50 and were of sufficient hardness but could still be machined. The results have been very satisfactory.

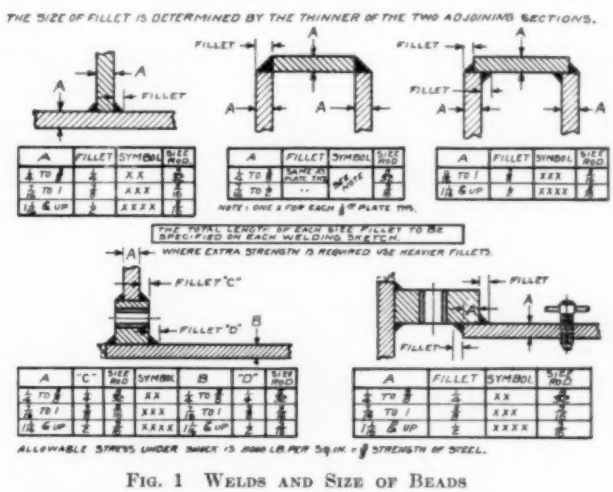

FIG. 1 WELDS AND SIZE OF BEADS

Of course, when welded jigs and fixtures were adopted, it was necessary to change the entire method of manufacturing jigs, fixtures, and machine tools. This not only included the actual manufacture of these jigs and fixtures in the shop but also their design. In order to have the proper information on the drawings and sketches which were sent to the shop, it was necessary to train the tool designers in the art of welding to a certain extent. To do this, the company incorporated in its standard book several sheets of instructions which, in addi-

[1] Superintendent, Manufacturing Equipment Department, Westinghouse Electric & Manufacturing Co. Assoc-Mem. A.S.M.E. The author was born in 1895 near Pittsburgh, Pa. Mr. Weaver spent all of his time since the age of 16, with the exception of the World War, when he served in the Navy as Ensign aboard the *U.S.S. Connecticut*, with Westinghouse, either engaging in the actual operations of manufacture or in their supervision. After serving his apprenticeship of four years at the Westinghouse Air Brake Company, he remained two years as master machinist. In 1919, he was made assistant superintendent of tools and later had charge of moving all tool equipment from East Pittsburgh to the South Philadelphia Works. In 1921 he became associated with the Westinghouse Electric and Manufacturing Company, of East Pittsburgh, in the capacity of mechanical engineer. In 1926, he was promoted to superintendent of machine tool equipment, and in 1928 he was again promoted to superintendent of manufacturing equipment, which position he now holds.

Presented at a meeting of the Metropolitan Section of the A.S.M.E., New York, N. Y., January 7, 1930, and at a meeting of the Cincinnati Section, Cincinnati, Ohio, January 23, 1930.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

tion to supplying the workmen in the shop with information, also standardized the manufacture of welded jigs and fixtures.

Fig. 1 shows the various types of welds and the size of bead which is used on welded jigs and fixtures. This is a standard throughout the shop, so that the workman is familiar with it and any reference to it is readily understood.

In order to avoid delays due to material being out of stock, there is included in the standard book a sheet showing the standard stock sizes of steel that are being used for this particular method of manufacture.

Fig. 2 shows such a sheet and gives the sizes of bar and plate stock. When bar stock is not suitable, the part is cut to size from a plate by means of an acetylene torch.

When the designer makes his drawings of a jig, he lays it out without showing any particular method of construction. Fig. 3 shows a milling fixture, and it will be noted that no reference is made to welding in it. Therefore it is necessary for the tool designer to make a separate sketch, which is shown in Fig. 4 and is called a welding and machining sketch. This gives the detail construction and indicates what material is to be ordered, and from the drawing can be obtained the information as to the shape desired. This material is then cut from the proper-sized stock with a saw in the case of bars, or with an acetylene torch in the case of a plate. The parts are then assembled and welded together. The title on this sketch states the total length of a certain-size weld necessary to completely weld this jig. This is done for the convenience of the time-study supervisor, who estimates and sets a value on the time it should take to manufacture the jig.

Figs. 5 and 6 show more in detail the various parts of a jig and the method of assembling and machining, and give a better idea of the extent to which information is given to the shop. In Fig. 6 the various sections are shown separately so that the shop will have no trouble to obtain the material and cut it to the proper shape and size. Fig. 5 also is used for machining purposes, giving the necessary dimensions, etc. that are required to properly machine this jig.

Of course, it is not possible to test a weld without destroying it, and the workman must be relied upon for good workmanship. In order to control this phase of the welding, all welders are required to stamp their work with a stencil. This stencil identifies the particular welder who performed the work and, in case there is any question, it can be readily traced back to him.

Periodically, a test is run on welds, and if any welding is dis-

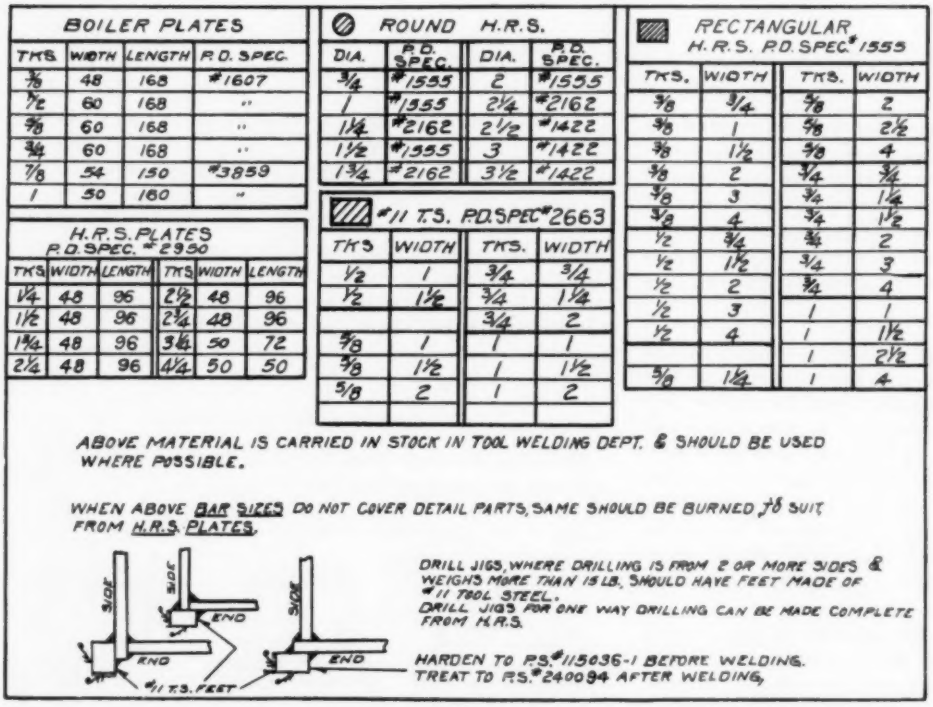

FIG. 2 MATERIAL TO BE USED IN WELDED JIGS AND FIXTURES

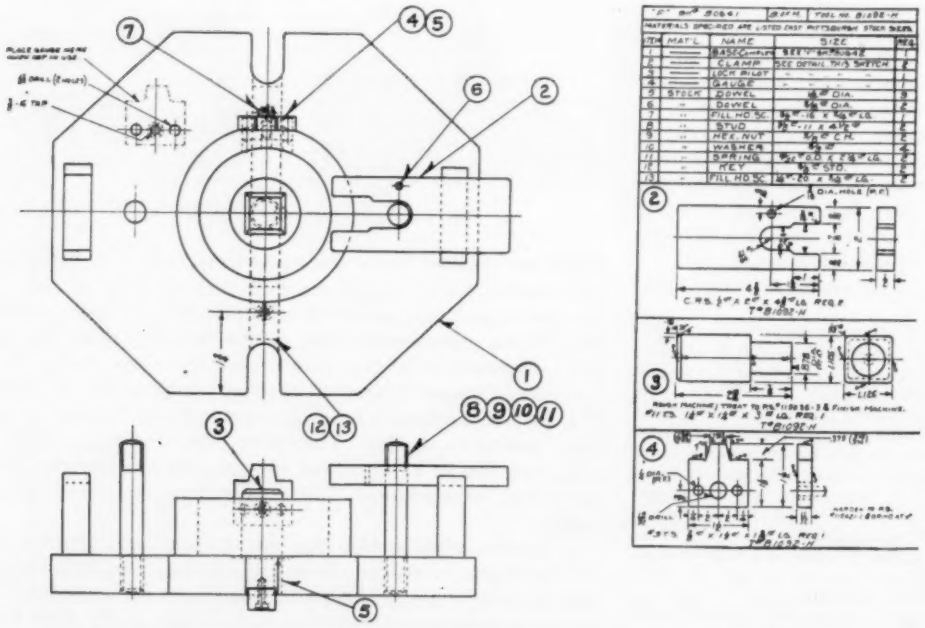

FIG. 3 MILLING FIXTURE FOR CLUTCH-TYPE OIL-IMMERSED CAM CONTROLLER

covered that is not satisfactory, the workman is required to take additional instruction; or, if he proves entirely unsatisfactory, he is taken off the job. The type of stencils used is shown in Fig. 7.

Fig. 8 shows a cutting machine which is used for cutting from plate stock the various parts that are required to make a jig. There are several different types of these machines in this department for cutting any shape or size necessary.

Fig. 9 shows a number of parts cut to size to make a jig. It will be noted that all the necessary large holes are cut in the plates by means of an acetylene torch before the parts are assembled into a jig.

These various detail parts are assembled and tack welded just sufficiently to hold them together (Fig. 10). This is done by a mechanic so that the parts will be properly located, also so that the jig will be squared up and be a good job when it is finally finished. After the tack welding the jig is passed to a welder, who completes the job by welding the jig as it should be.

Fig. 11 shows a jig completely welded. While this jig is fairly large, it weighs only 120 lb. It is used for drilling the bracket which is shown at the right of the jig.

Removing Strains From Jig Due to Welding

The fact that these jigs are made from hot-rolled steel, as well as the welding, detracts somewhat from the appearance of the completed jig. Certain strains due to the welding must be removed from the jig so that it will maintain its shape and size. This is done by heating the jigs in a furnace to a temperature of 1000 deg. fahr., after which they are allowed to cool in the air. Owing to the use of hot-rolled steel and this normalizing treatment, a certain amount of scale develops on these jigs, which is removed by means of a sand-blast machine as shown in Fig. 12. After the sand-blasting operation, which really improves the appearance of the jig, the jig is spray painted as shown in Fig. 13. It is sent to the shop for machining, which is no different from what it would be for a cast jig except that not as much material is allowed for finish as is ordinarily allowed on castings.

To give an idea of the extent to which welding has been applied in the manufacture of jigs and fixtures, Figs. 14 and 15 show a jig weighing 1300 lb., the overall dimensions being $39\frac{1}{2}$ in. $\times$ $51\frac{1}{2}$ in. $\times$ 21 in. This complicated jig is built entirely of steel, using hot-rolled bar stock and plates. The bosses shown in Fig. 14 are made from hot-rolled round steel cut off with a saw and welded in place.

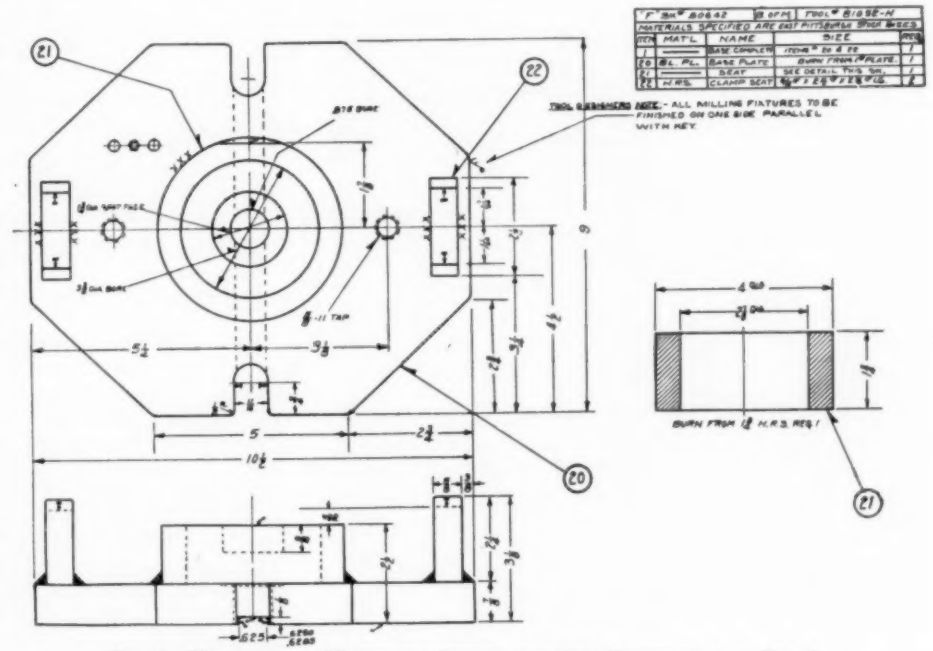

Fig. 4 Welding and Machining Sketch for Cam Controller of Fig. 3

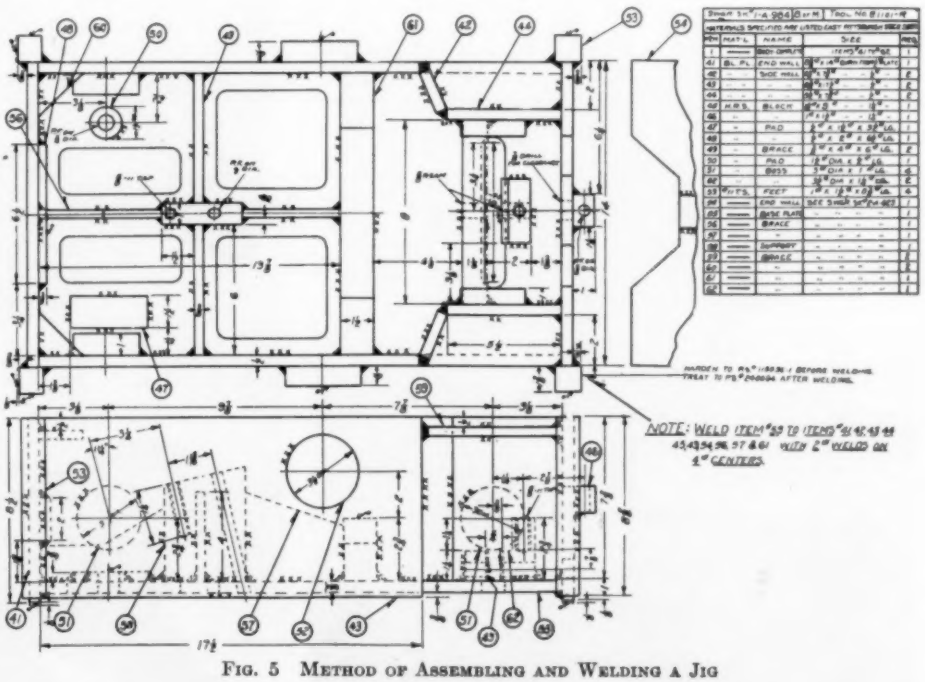

Fig. 5 Method of Assembling and Welding a Jig

Fig. 16 shows welded jig being used on a drill press. No difficulty has been experienced with these jigs due to inaccuracies, although they have been in use for approximately a year.

Figs. 17, 18, 19, and 20 show several other types of jigs that have been manufactured, and indicate that it is feasible to make any kind of a jig that is necessary by this method.

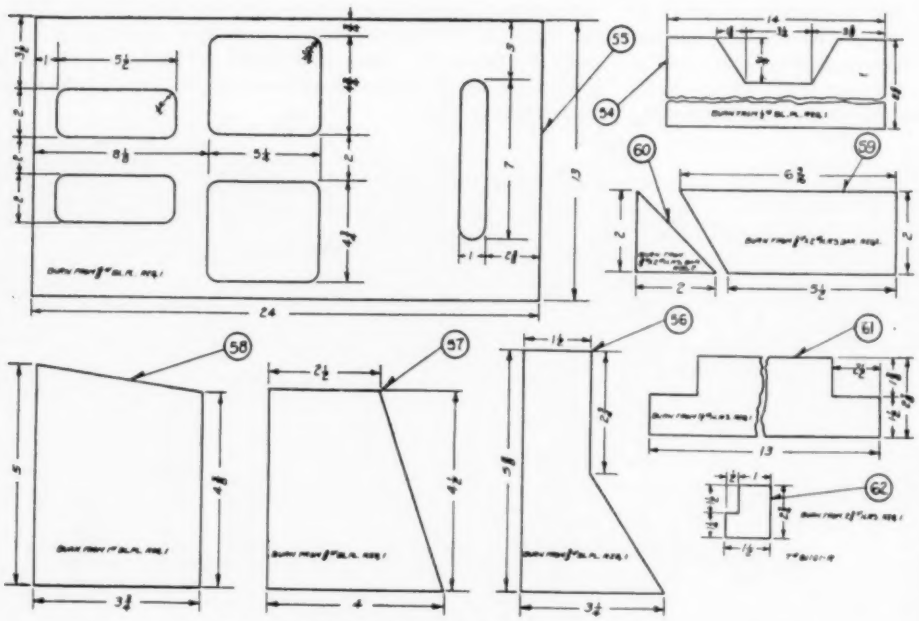

FIG. 6 SEPARATE PARTS OF JIG SHOWN IN FIG. 5

SEVERAL ADVANTAGES OF WELDED JIGS

In addition to other advantages set forth, jigs made from steel have considerable more strength and weigh less than cast jigs. This is because thinner material can be used and because it is not necessary to increase the sections to reduce casting difficulties, etc. It is also possible to place metal where it is most desired in order to make a stronger jig with the least amount of weight.

Also in the event that it should become necessary to make a change in the jig owing to the products being changed or for any other reason, it is very easy to remove any interference by means of an acetylene torch and reweld the parts in new locations if desired.

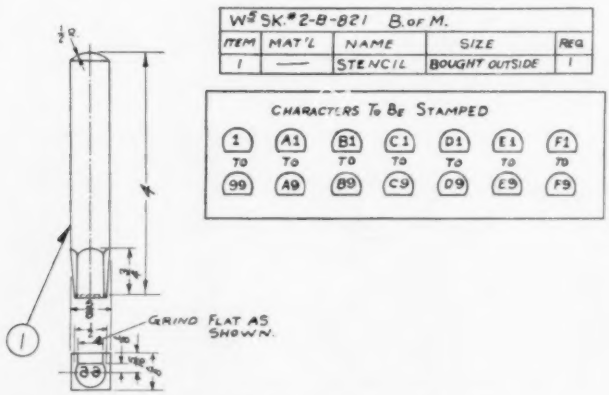

FIG. 7 WELDERS' IDENTIFICATION STAMP

MACHINE TOOLS OF WELDED CONSTRUCTION

Attention is called to another application and that is the design of special machine tools employing the same type of construction. The Westinghouse Company has applied this method of construction only to special machine tools such as it designs and builds itself, but the author believes it will be applied to all types of machines in the future. For example, the machine shown in Figs. 21 and 22 is a double-head oxygen-acetylene

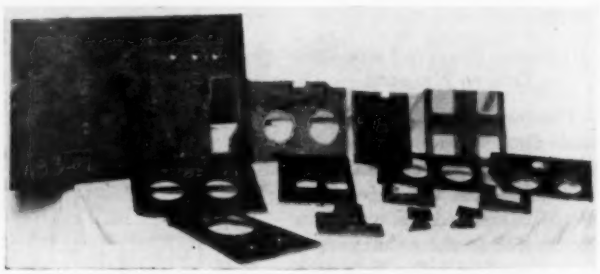

FIG. 9 VARIOUS DETAILS AS CUT WITH TORCH, SHOWING ALSO ONE SIDE MARKED OFF, AND DRILLED HOLES FOR STARTING THE CUT

from one position. This particular structure worked out very satisfactorily, and no troubles developed due to misalignment, vibration, or any of the things that may be found in the machines which are not properly designed or built.

FIG. 15 (LOWER RIGHT-HAND COLUMN) REAR VIEW OF DRILL JIG SHOWN IN FIG. 14 BREAKER TYPE "B-32"

FIG. 14 FRONT VIEW OF DRILL JIG FOR MAIN BASE OF OIL CIRCUIT BREAKER
(Weight, 1304 lb.; size, 39½ in. × 51½ in. × 21 in.)

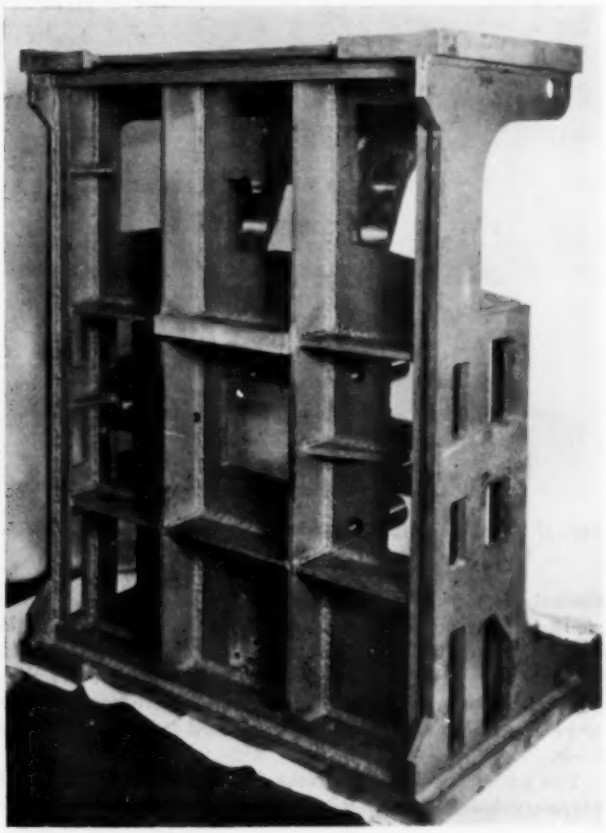

Fig. 23 shows a machine for testing mica sheets. With the exception of the worm-gear reduction unit, this is built entirely from structural steel and welded together.

Fig. 24 shows winding machines for winding mush-type coils for a.c. motors. These machines are entirely fabricated from structural steel and welded together, and attention is particularly called to the construction of the tailstock. This is similar to the general design of tailstocks, with the exception that this is welded from structural steel. It functions satisfactorily and, although the requirements here are not as rigid as they would be on metal-cutting machines, there does not seem to be any reason why it could not be used successfully on such tools.

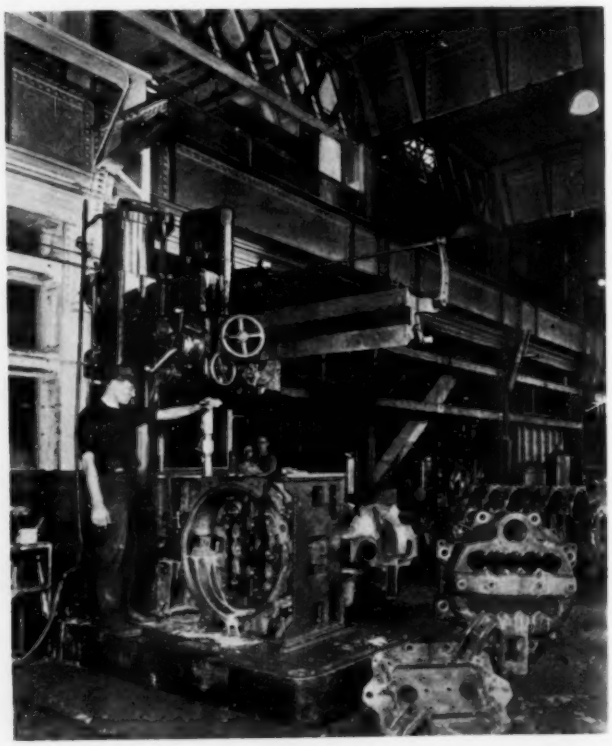

FIG. 16 DRILL JIG OF FIGS. 14 AND 15 IN USE

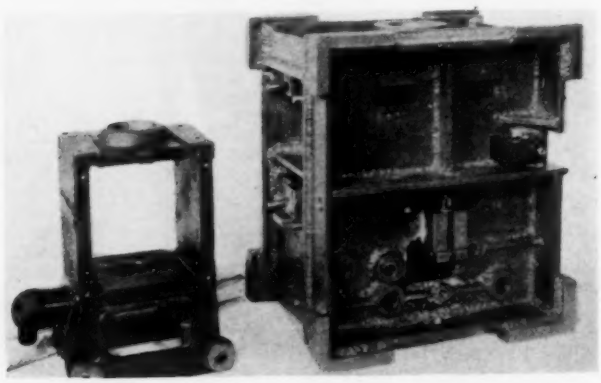

FIG. 17 SOLENOID MECHANISM FRAME AND 7-DRILL JIG FOR SAME
(Heavy boring is done in this jig.)

The author realizes that some further development will be necessary before this particular type of construction can be applied to general machine-tool construction, but he believes the facts he has brought out successfully demonstrate the practicability of welded jigs, fixtures, and machine tools. He is building from 200 to 400 welded jigs and from 3 to 6 special machines per month, and has been able to build them in a shorter time, to reduce the average cost approximately 25 per cent, and to produce jigs and fixtures that are more desirable due to the fact that they are lighter and at the same time of at least equal strength. The jigs and fixtures which have been built in this way have required less maintenance, and it is not believed that anything has been sacrificed that would result in misalign-

ment, warpage, distortion, vibration, etc., or detract from the appearance on this particular type of equipment. It is believed to be a practical idea and, owing to the advantages which have been set forth, it should be given serious consideration.

MSP-53-6

Machining Properties of Some Cold-Drawn Steels

By O. W. BOSTON,[1] ANN ARBOR, MICH.

This paper gives the results of a series of machining tests on 13 cold-drawn screw-stock steels and 2 cold-drawn stainless steels. Machinability values for standardized conditions are given for each steel as follows: The force required to remove a chip by a planer tool; the energy required to remove a chip by a single-tooth milling cutter; the torque and thrust developed by a 3/4 in. diameter drill; the penetration of a 1/4 in. diameter drill under a constant feeding load. An attempt is made to correlate the results of these various machining tests with the Brinell, Rockwell, and scleroscope hardness values, as well as the analysis and structure of each bar. Values representing the power required to cut 1 cu. in. of metal per minute under specific standardized conditions are given for planing, milling, and drilling the various steels.

THE object of this paper is to show the results of various metal-cutting tests on a variety of cold-drawn steels so as to indicate, if possible, the best method for determining whether the material is suitable for machining purposes and the relative advantages of one material over another from the standpoint of machining.

In a paper before the American Society for Steel Treating,[2] the author gave an outline of the various test methods which were used in determining machining properties and comparative values between 18 ferrous metals and 21 non-ferrous metals. This paper is a continuation of the tests made on cold-drawn steels.

The Tests

Each specimen was subjected to the following tests:

(1) The Brinell, Rockwell, and Shore scleroscope hardness readings were determined on a ground surface approximately 1/16 in. below the cylindrical surface, as follows:

In the Brinell test a 3000-kg. load and a 10-mm. ball were used. The readings were taken with the grain; that is, across the diameter of the impression lengthwise of the bar. The time of duration of the load was 30 sec., and measurements of the impressions on the ground surface were taken with a Brinell microscope.

The Rockwell reading was read on the B scale, using a 1/16 in. diameter ball and the 100-kg. load.

The scleroscope readings were obtained with a Shore scleroscope.

(2) The force developed in the direction of cut by a planer tool was measured. The tool was of the end-cutting type, 0.500 in. wide and provided with a 15-deg. front-rake, but no side-rake angle. The corners of the tool were beveled off, making a 1/64-in. flat at a 45-deg. angle, to insure greater endurance of the geometric shape of the high-speed-steel tool. After grinding to shape and size, the tool was honed. A depth of cut of 0.010 in. as measured on a dial gage was taken in all cases. An average was taken of from 6 to 12 consecutive readings, when cutting dry at a speed of 20 ft. per min.

(3) The torque and thrust developed by a 3/4 in. diameter high-speed-steel twist drill was determined. The drill had a helix angle of 30 deg. and a clearance angle of 3 deg. and 48 min. as measured at its periphery. The web thickness at the point was 0.095 in. and the outside diameter was 0.750 in. The drill was ground on a drill grinder with a drill overhang from the jaws of 3/8 in. The grinder forms the drill point so that it has a conical surface back of the cutting edge. The drill was measured on a special measuring instrument to make sure that the cutting edges were of the same length and position to cut chips of equal thickness. This drill was rotated at 153 r.p.m. and was given a feed of 0.012 in. per revolution.

(4) The drill penetration or the distance traveled by a 1/4 in. diameter twist drill for 100 revolutions when rotating at 504 r.p.m. under a dead load, including the weight of the drill and drill spindle of 93.75 lb., was determined. The twist drill had an outside diameter of 0.250 in., a web thickness at the point of 0.0269 in., and a helix angle of 24 deg. The clearance angle was about 6 deg. and 30 min. at the periphery of the drill. This drill was ground on a drill grinder which formed a cylindrical surface back of the cutting edge.

(5) The energy absorbed by a single-tooth milling cutter of the side-cutting type—that is, similar to a cutting-off tool—was determined. The tool had a width of 0.250 in., a 15-deg. front-rake, but no side-rake angle, and a 4-deg. clearance angle on the end and sides. The edges of the cutter were beveled to 1/64-in. flat at an angle of 45 deg., and the tool point finally was honed all over. The cut taken had a radius of 1 3/4 in., a depth of 0.125 in., and a feed of 0.010 in. per chip.

(6) The influence as shown by photographs of the cut surface as made by a shaper tool when having various front- and side-rake angles and when operating at light and heavy depths of cut and feeds, as well as two different speeds, are described below in connection with the tests.

It is realized that the influence of the material on the "tool life" under standardized conditions is of real commercial value. Such tests were not included with those described, as there was

insufficient material of each type on hand to make it possible to obtain any information of value.

It is further realized that, when various metals are compared, the metals themselves should be the only variables. In commercial practice a tool usually is ground to such a shape that satisfactory tool life is obtained in conjunction with finish and size. If the tool shape is changed, the tool life will be changed and also the finish on the cut surface will be different. The different degrees of roughness will in themselves alter the size of the finished piece or the size may be varied by changing tool shape, which affects pressures on the tool and thereby causes it to spring more under one condition than under another. No attempt is made in this paper to present the optimum tool form for the materials studied in order that maximum tool life, least power, and best finish may be obtained simultaneously.

The Testing Machines

The testing machines used in conducting the tests for machinability, as outlined, may be described briefly as follows: A specially designed dynamometer for measuring the force on a planer tool in the direction of cut was mounted on the 30-in.

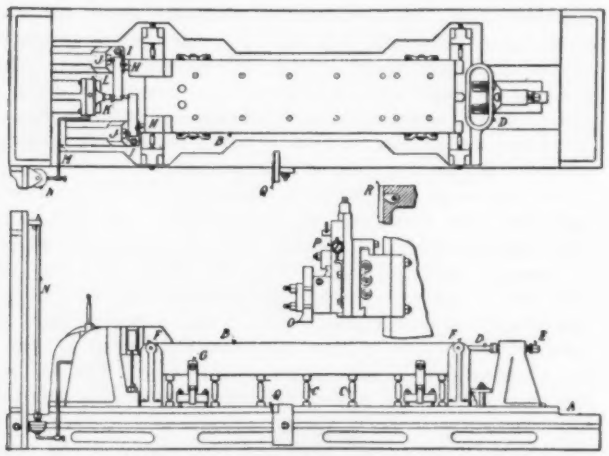

Fig. 1 Line Diagram of Planer Dynamometer

by 36-in. by 8-ft. planer. Power was furnished to the planer from a main drive shaft, a satisfactory arrangement in that the horsepower output of the machine was measured rather than the input. The cutting speed for all of these tests was 20 f.p.m. No cutting fluid was used.

Fig. 1 shows a line diagram of the dynamometer which consists essentially of a cast-iron bed *B*, weighing about 1300 lb., mounted on seven 14 in. long horizontal knife edges *C*. The bed is prevented from moving sideways when a side-rake angle on the tool is used by the four horizontal floating pins shown in the plan view, supported by the brackets *F*. The bed is kept from being lifted by four knife edges shown at *G*. An initial load of 2000 lb., tending to force the bed to the left was put on the bed by compressing the loop spring *D*. This load keeps the whole mechanism in compression, thereby eliminating chatter during a cut, and also keeps the mercury-column gage under an initial load which is indicated as a zero point on the scale. The loop spring was made of $^3/_4$ in. square spring steel having major and minor axes to center of bar of $11^1/_2$ in. and $4^3/_4$ in., respectively. It had previously been calibrated on a Universal testing machine. This spring also served for calibrating the mercury-column gage *N*. For more detailed description of this equipment, see Trans. A.S.M.E., 1926, Vol. 48, p. 749. The depth of each cut in these tests was secured by lowering the planer head and tool vertically 0.010 in. as measured on the dial indicator *P* mounted on the right-hand side of the head. There were 6 to 12 consecutive cuts taken on each test piece, and an average was determined. This eliminated even very slight deviation from the 0.010-in. feed per cut which might occur for a single chip.

The torque and thrust developed by the $^3/_4$-in. drill were determined by means of a torque and thrust dynamometer mounted on a manufacturing-type drill press. For detailed description, see Trans. A.S.M.E., Paper No. MSP-52-2. The press was driven by a 5-hp., 220-volt, 3-phase, 60-cycle motor through a short belt. The motor was mounted directly on the press column. All tests were run without a coolant or lubricant on the drill.

The thrust on the drill was measured on a recording chart of a gage. This pressure was exerted directly on a steel plate bearing on a rubber diaphragm just above the dynamometer base. Water underneath this rubber diaphragm was compressed and the pressure was transmitted to the gage thrust pen through a $^1/_8$-in. pipe. The plate resting on the rubber diaphragm which carried the thrust load was made to form the lower race of a large ball bearing consisting of 64 $^1/_2$-in. balls, so that the table of the dynamometer was free to rotate except for an extending arm which had a bearing against a piston resting on a second rubber diaphragm. The horizontal distance from the center of the drill to the support on the end of this arm was just 1 ft. The pressure on this torque rubber diaphragm compressed water back of it. This pressure was transmitted through a $^1/_8$-in. pipe leading both to a mercury column and the gage. The mercury column calibrated against the gage gave a scale reading for check purposes somewhat larger than that obtained on the gage.

To register the travel of the spindle the chart of the recording gage was made to rotate by means of a fine wire which passed from the upper end of the drill-press spindle over pulleys to a position vertically above the recording gage, thence downward making one turn about a special pulley on the shaft of the gage to a counterweight located below.

For determining the drill penetration under a given load, a sensitive drill press was remodeled so as to carry on the upper end of the rotating spindle a weight of sufficient amount to cause the tool to dig in when the spindle was rotated. By trial and error, the weight of 93.75 lb., including the drill spindle and drill, was arrived at in order to cause a $^1/_4$-in. twist drill to cut freely in various metals. A lighter load on the spindle or a larger size drill did not seem to give satisfactory results, as the drill could not be made to bite on some of the harder materials. This drill press also was driven through a short belt by a 5-hp. motor, a tight and loose pulley being provided. After mounting the specimen to be tested on the drill-press table or in a vise, the drill was first allowed to penetrate about $^1/_8$-in. By means of a beam-type indicator attached to a vernier height gage, the height of a particular point on the spindle was measured. With a speed counter attached to the spindle, the belt next was shifted from the loose to the tight pulley, causing the spindle to rotate. After 100 revolutions plus or minus, the spindle was stopped, and the height of the point on the spindle was again measured. The difference in measurements gave the penetration of the drill for the actual number of revolutions shown on the speed indicator. This was then reduced to 100 r.p.m.

This method of measuring the drill penetration was rather tedious and required considerable time; so in some subsequent tests the following method was used: Two beam-type indicators were mounted on a vernier height gage so that the vertical distance between the two, as measured with Johansson blocks, was just 0.250 in. The slide on the vernier scale was

so adjusted that, after the drill had penetrated about 1/8 in. the upper beam indicator bearing on the end of the drill sleeve would indicate zero, at which time a stop-watch would be started. After drilling continuously until the second indicator showed zero, the stop-watch was stopped. This gave the lapsed time for the drill to penetrate the 1/4 in. These results checked remarkably well with those obtained by the first method outlined. Averages of four to eight readings were taken for each test specimen.

All of the drill-penetration tests related in this paper were obtained with the same drill and with one grinding, as it was found almost impossible to regrind the drill, even on a machine, to give results comparable with those of the first grinding. After all tests were completed, many duplicate tests were run to check the influence of the dulling of the drill. It was concluded, however, that the dulling from all of the tests was insufficient to affect materially the results.

The energy absorbed by the single-tooth milling cutter, side-cutting (end-cutting) type, was measured on the machinability tester. This was constructed by Carl Oxford[1] and is described in detail in the Trans. A.S.M.E., 1921, Vol. 43, p. 549. If the pendulum be allowed to fall freely from the top vertical position it will rise almost to the same height. A freely rotating pointer is carried forward with the pendulum and indicates on a steel disk the highest position to which the weight rises. This position is taken as the zero reading to allow for friction of the bearings. If the material is bolted to the bed and adjusted for depth of cut and feed, a subsequent fall of the pendulum will form a chip, and the pendulum will not swing as high after taking the chip as when taking no chip. This change in height is a measure of the energy in foot-pounds given up in forming the chip. It is the same principle as is used in impact testing machines. The face of the steel disk is graduated at the periphery, so that the reading of the energy absorbed by taking a chip of any given material is read directly. Ten readings for each test specimen were averaged for the final value.

[1] Chief Engineer, National Twist Drill and Tool Company, Detroit, Mich.

The Materials Tested

The materials tested consisted of a variety of cold-drawn steels for use primarily in automatic screw machines. The bar numbers, together with the sizes and chemical analyses, are listed in Table 1. Table 2 shows the Brinell, Rockwell, and Shore scleroscope hardness values of the bars tested.

The exact analysis of bar 414 is as given. The tensile strength of this particular specimen was 86,100 lb. per sq. in. This material is purchased in accordance with the following specifications:

"Cold-drawn super free-cutting steel for screw-machine work. Carbon not over 0.18 per cent, with 0.10 to 0.18 per cent preferred. Manganese not over 0.90 per cent, with 0.60 to 0.90 per cent preferred. Sulphur not under 0.17 per cent, with over 0.18 per cent preferred. Phosphorus not over 0.13 per cent, with 0.07 to 0.09 per cent preferred. Tensile strength to be not less than 95,000 lb. per sq. in. for sizes 3/8 in. and under; to be not less than 90,000 lb. per sq. in. for sizes 3/8 to 5/8 in.; to be not less than 85,000 lb. per sq. in. for sizes 5/8 to 1 in. The material must be sound with surface suitable for screw-machine manufacturing operations."

Bar 415 also has the exact chemical analysis given, but has additional physical properties as follows: Proportional limit 65,600 lb. per sq. in.; tensile strength 92,050 lb. per sq. in., elongation in 2 in. 11.5 per cent, and reduction of area 44.8 per cent. This steel was found by a large user to stand machining at 100 per cent faster speed than the usual commercial stock. An attempt was made to have steel made to this analysis, but its machining properties were greatly inferior to the imported steel.

The carbon content of bars 422 and 424 appeared, from the photomicrographs, to be questionable, so that carbon analyses of these two bars were determined and found to be 0.336 per cent for bar 422 and 0.365 for bar 424, which conforms with the carbon range specified in Table 1.

Photomicrographs at 100 magnifications of steel bars Nos. 414 to 426, inclusive, are shown in Figs. 2 to 16, inclusive, except that Figs. 11 and 15 are of bars 422 and 424, respectively, at 1000 magnifications. This higher magnification was used in these two instances better to show the structure involved, which was not clear at 100 magnifications. All of these specimens were etched in a 4 per cent nital solution. All photomicrographs were taken on a surface approximately 3/16 in. from the outside, running parallel to the length of the bar. These photomicrographs represent fairly well the structure of the metal from

which the majority of the experimental data was obtained. Comments as to each photomicrograph are given in the caption of each figure.

Machinability Data

The results of the various machinability tests are shown for the steel screw stock in Table 3. These data were determined by measuring the force on a planer tool, the torque and thrust of a $^3/_4$ in. diameter drill, the penetration in inches per 100 revolutions of a $^1/_4$ in. diameter drill, and the energy in foot-pounds required to remove a chip by milling, as described.

The total force F on a planer tool is the value in pounds actually exerted in the direction of cut on the planer tool $^1/_2$ in. wide

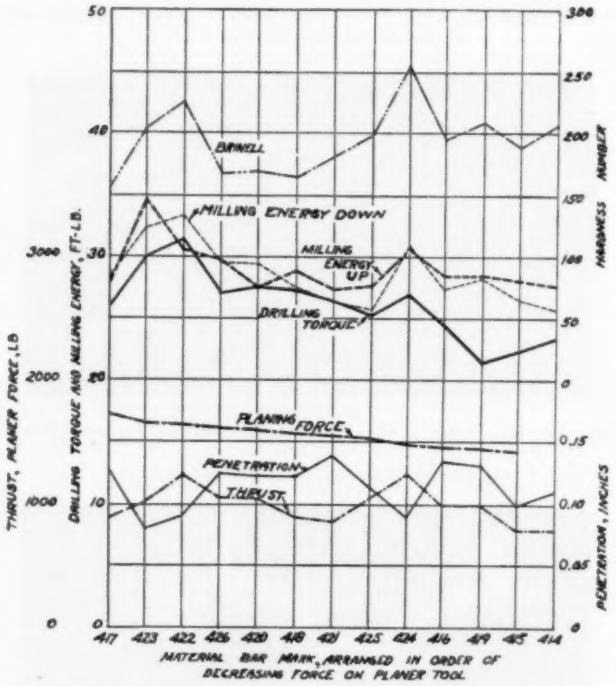

Fig. 17 Machining Properties of Screw-Stock Steels

when taking a depth of cut of 0.010 in. at a cutting speed of 20 f.p.m. The unit force U is the number of pounds exerted on 0.001 sq. in. of cross-sectional area of the chip.

$$U = \frac{F}{1000\ WD} = \frac{F}{5}$$

in which W = width of cut 0.5 in. and D the depth of cut 0.010 in.

For bar 419, SAE 1112,

$$U = \frac{1444}{5} = 288.8 \text{ lb.}$$

This unit force of 288.8 lb. is equivalent to 288,800 lb. per sq. in. of chip area. The horsepower developed by the planer tool equals $FS/33{,}000$, in which F is the total force on the tool in the direction of the cut in pounds and S is the cutting speed in feet per minute. As S equals 20,

$$\text{Hp.} = \frac{20F}{33{,}000} = \frac{F}{1650}$$

For SAE 1112, bar 419, the developed

$$\text{Hp.} = \frac{1444}{1650} = 0.875$$

The cubic inches of metal removed per minute = WDL = $0.5 \times 0.010 \times 20 \times 12 = 1.2$, in which L is the length of cut per minute in inches and equals $12S$. The horsepower per cubic inch of metal removed per minute equals the total power developed divided by the cubic inches of metal removed per minute, or

$$\frac{F}{1.2 \times 1650} = \frac{F}{1980}$$

For SAE 1112, bar 419, the horsepower per cubic inch of metal removed per minute is then 1444/1980, or 0.729.

To reduce the experimental data for the drill torque and thrust to net horsepower per cubic inch of metal removed per minute, the following method may be used. The total horsepower developed at the point of drill is the sum of that due to torque and thrust. The horsepower of the torque

$$\text{Hp.}_t = \frac{2\pi TN}{33{,}000} = \frac{2\pi \times 152T}{33{,}000} = 0.02894\ T$$

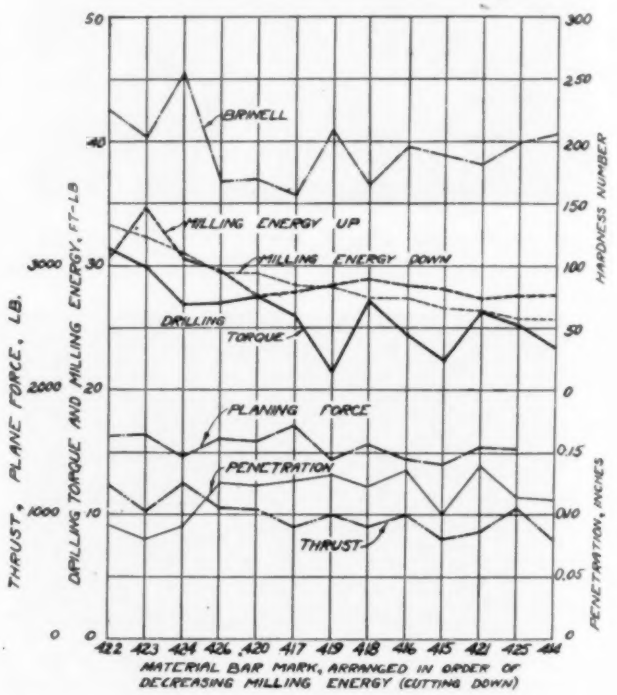

Fig. 17-a Machining Properties of Screw-Stock Steels

in which T equals the torque in foot-pounds and N equals the actual revolutions per minute of the drill. The horsepower of the thrust equals the thrust times the distance traveled per minute divided by 33,000, or

$$\text{Hp.}_{th} = \frac{fN\ Th}{33{,}000} = \frac{0.012 \times 152\ Th}{33{,}000 \times 12} = 0.000004606\ Th.$$

in which Th equals the thrust in pounds, f equals the feed in inches per revolution of the drill, and N equals the revolutions per minute of the drill. The total net horsepower Hp. = $0.02893\ T + 0.000004606\ Th$.

The cubic inches of metal removed per minute equal

$$\frac{\pi d^2}{4} fN = \frac{\pi(^3/_4)^2}{4} \times 0.012 \times 152 = 0.8068$$

in which d is the diameter in inches of the hole drilled, f is 0.012 the feed in inches per revolution, and N is 152 the revolutions per minute of the drill.

The net horsepower per cubic inch of metal removed per minute in drilling with a $^3/_4$-in. drill rotating at 152 r.p.m. and having a feed of 0.012 in. per revolution, for SAE 1112, bar 419, of Table 3, for which there is a torque of 21.5 ft-lb. and a thrust of 1000 lb., is

$$\frac{0.02894T + 0.000004606Th}{0.8068} = \frac{0.622 + 0.0046}{0.8068} = \frac{0.6266}{0.8068} = 0.777$$

The influence of the thrust on power is so small that it may be omitted.

For determining the horsepower per cubic inch of metal removed per minute in milling, using the experimental data, it is necessary to make the following assumptions, which include the conditions under which the experiments were run:

d = the depth of cut = 0.125 in.
w = the width of cut = 0.250 in.
f = the feed per tooth = 0.010 in.

A cutter is assumed to have 14 teeth and to rotate at 58.3 r.p.m., giving 816.2 chips per minute. The horsepower developed equals

$$\frac{816.2}{33{,}000} \times E = 0.024733\,E$$

in which E is the energy in foot-pounds required to remove one chip. For SAE 1112, bar 419, the horsepower developed is $0.024733 \times 28.5 = 0.705$.

The cubic inches of metal removed per minute equals $dwftN = 0.125 \times 0.250 \times 0.010 \times 14 \times 58.3 = 0.255$, in which t is the number of teeth in the cutter and N is the revolutions per minute of the cutter.

Therefore, the horsepower per cubic inch of metal removed per minute $= 0.024733E/0.255 = 0.097\,E$. For SAE 1119, bar 419, this becomes $0.097 \times 28.5 = 2.76$, as shown in Table 3.

Discussion of Machinability Data

Certain machinability data on the steel screw-stock bars tabulated in Table 3 are shown graphically in Figs. 17, 17*a*, and 18. In Fig. 17 the Brinell hardness numbers, the drilling torque and thrust, the planing force, the drill penetration, and two milling-energy values, for each bar, are plotted over that bar number. The bar numbers are arranged from left to right in order of decreasing force on the planer tool.

In Fig. 17*a* the same values as represented in Fig. 17 are shown plotted over the bar numbers arranged from left to right in order of reducing "milling energy down." The respective values have been joined by lines to indicate continuity.

At first only the "milling-energy-up" curve was prepared. The cut by the milling cutter was taken upward or against the feeding motion of the specimen. Subsequent tests on another project, however, showed that some materials yielded greater, equal, or smaller energy values when the direction of cut was reversed; that is, the cut taken down or with the feed of the material. It was thought desirable, therefore, to determine the values of milling energy on a down cut for these cold-drawn steels so as to make the information a little more complete. There are then two milling-energy curves, one

indicated by "up" and the other by "down," indicating the method by which the values are obtained.

In connection with another investigation, it has been found that, by tests cutting dry, some metals require as much as 30 per cent less energy when the cut is taken down or with the feed than when against it. The power for feeding is not included. On the other hand, other metals require as much as 25 per cent more energy when the cut is down or with the feed. A wide variety of metals fill in the range between these two extremes and some show no difference in energy for the two types of cuts.

It also has been found that the introduction of a coolant or lubricant complicates this situation still further, as the saving in energy between dry and wet cutting accomplished on an up stroke frequently does not compare favorably with a similar saving between dry and wet cutting on the down stroke.

Fig. 17 shows that in general the Brinell curve slopes upward to the right, which indicates that the greater the Brinell number the lower is the planing force. The "milling-energy-down" curve slopes downward to the left to bar 424, for which there is a rise, after which the curve again slopes to the right. The "milling-energy-up" curve slopes downward to the right up to bar 425 and is practically horizontal to the right of bar 416. The drilling-torque curve, with a few inconsistent points, also slopes to the right. The thrust curve shows no particular trend, but might be considered as a horizontal line. The penetration curve shows perhaps a slight trend to increase to the right as might be expected in that the softer the metal the greater would be the drill penetration. In general, the various machinability and hardness curves of Fig. 17 do not agree favorably with the "planing-force" curve, as there are too many exceptional points on each curve.

In Fig. 17*a* the machinability and hardness values have been plotted over the bar numbers arranged from left to right in order of reducing "milling energy down." On this new basis a general curve, representing Brinell numbers, may take two forms: the first, excepting values for bars 426, 420, and 417, a straight line would be obtained sloping downward from left to right; the second, if values for bars 422, 423, and 424 are omitted, would give a straight line sloping from bar 426 upward to the right. The "milling-energy-up" curve slopes downward from left to right across the figure, except for the low values for bars 420, 417, and 419. Neglecting the first four points, however, would leave a horizontal line representing the values of bars 420 and those to the right.

Excepting points for bars 419 and 416, the drill-torque curve would slope gradually from left to right. The planing-force curve, excepting the values for bar 424 and 417, gives a satisfactory straight line sloping from left to right across the figure. The drill-thrust curve also gives a satisfactory general slope from left to right. The $^1/_4$ in. diameter drill-penetration curve, however, seems to follow more closely the Brinell curve in that two possible curved lines may be obtained as representing smoothed-out values: the first, for bars 422 to 421, inclusive, omitting the low values of bars 415, 424, and 423; or a second curve sloping from left to right for bars 426 to 414, inclusive, with values for bars 416, 415, and 421 omitted. This second curve of drill penetration, sloping from left to right for bars 426 to 414, inclusive, agrees favorably with a Brinell curve sloping upward from left to right for bars 426 to 414, inclusive. This is a satisfactory relation in that it naturally would be expected that the harder the material the less would be the penetration per hundred revolutions. This, then, indicates that bars 422, 423, and 424 are out of order.

Bar 422, SAE 6140, is shown in Fig. 10 to be not fully annealed before cold drawing. This structure undoubtedly plays some part in the odd results obtained. Bar 423 is the only $3^1/_2$ per cent nickel low-carbon steel bar in the group. This, too, may account for its unusual properties. Bar 424, a manganese-carbon steel bar, also appears not fully annealed before cold drawing, as shown in the photomicrographs in Figs. 14 and 15.

Fig. 17*a* shows an interesting relation between bars 417 and 418, each an SAE 1120 steel. It is seen that bar 417, which is cold-drawn to $^3/_4$ in. sq., has machining properties greater than 418, which is cold-drawn to $1^1/_2$ in. sq. The photomicrographs Figs. 5 and 6 indicate that bar 417 has received more cold drawing than bar 418. Similarly comparing bars 419 and 416, both SAE 1112 steels, it is seen that bar 419, cold drawn to $^3/_4$ in. sq., has higher machining properties than bar 416, which is cold-drawn to $1^1/_4$ in. sq. The drill torque, however, is higher for bar 416 than for bar 419. The same relation holds for bars 417 and 418, which might indicate that the drilling torque is less the finer the grain structure. The planing force for these two sets of bars is just the reverse, being higher for the smaller bars. The Brinell numbers are inversely proportional to the torque and planing force for these four bars and vary directly with the thrust and penetration.

Bar 417, SAE 1112, $^3/_4$ in. sq., is shown in Table 2 and in Figs. 17 and 17*a* as having the highest planing force. The value of 1717 lb. is high and apparently out of order. There may have been an error in copying this value from the data sheet, as it appears that 1517 lb. would be much more appropriate. There was not enough material left in the bar to run check tests, however, so that no further light can be gained on this point.

It is of interest to note the relative positions of bars 415 and 414, supposedly super-free-cutting screw-stock steel. Bar 415 has a low thrust, a low planing force, a low drill torque, an average "milling energy down" value, and an average Brinell for its position. The penetration, however, is low, whereas it should be high. Bar 414 has a Brinell number above the average for its position and has a low penetration.

Fig. 18 shows, more for commercial use, the value of horsepower per cubic inch of metal cut per minute by milling, drilling, and planing, of the various steel screw-stock bars. These curves show the same general tendency as the force or energy curves of Fig. 17.

It is realized that these tests have been performed somewhat contrary to actual commercial practice. Drilling for torque and thrust with a $^3/_4$-in. drill, for instance, has been done crosswise of the bars, whereas in most screw-machine work it is done lengthwise. The results of similar tests in drilling, however, have shown that the results in cross-drilling compare quite favorably with those of end-drilling. The force on the planer tool has been determined from a cut running lengthwise of the bar, whereas in turning the cuts are at right angles to the axis of the bar. No data are available to indicate whether one is higher than the other. All milling-energy values have been determined by taking cuts lengthwise of the bar. In several instances check tests have been made to show that the energy required to remove a chip lengthwise of the bar is equal almost exactly to that required when taking a cut at right angles to the bar. For example, Table 3 shows the milling-energy value for the cut lengthwise of bar 418 to be 28.86 ft-lb. per chip. Tests taken crosswise at the same time show the results to be 28.95 ft-lb. per chip, or about one-third of 1 per cent greater.

Chips From the $^3/_4$-In. Drill and Planer Tool. All chips from the cold-drawn steels numbered 416 to 425, inclusive, for the $^3/_4$-in. drill and the planer tool were retained and compared.

The torque chips for bars 422, SAE 6140 steel, 423, SAE

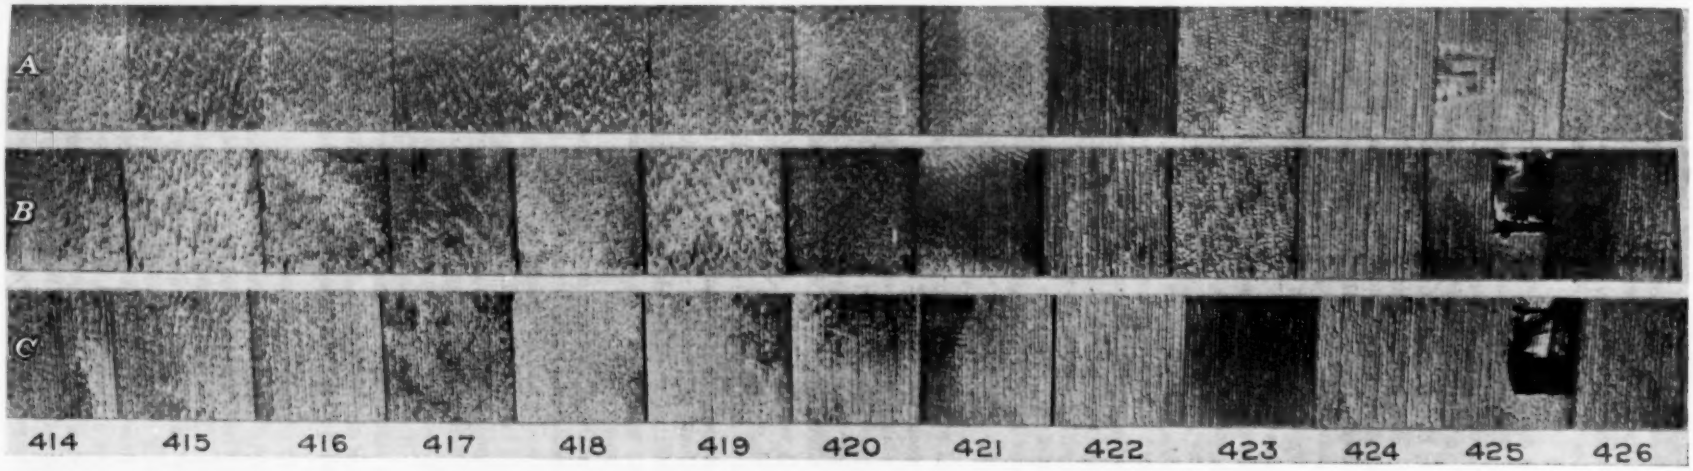

FIG. 19 FINISHED SURFACE ON RESPECTIVE SPECIMENS LEFT BY SHAPER TOOL × 1.8

(*A*, Tool 0 deg. front and 0 deg. side rake and 1/16 in. nose radius, the cut 0.005 in. deep, with 0.013 in. feed, 40 3-in. strokes per minute. *B*, same as *A*, but with 0.015 in. depth of cut. *C*, same as *A*, but tool 13 deg. front and 16 deg. side rake and 1/16 in. nose radius and 0.005 in. depth of cut.)

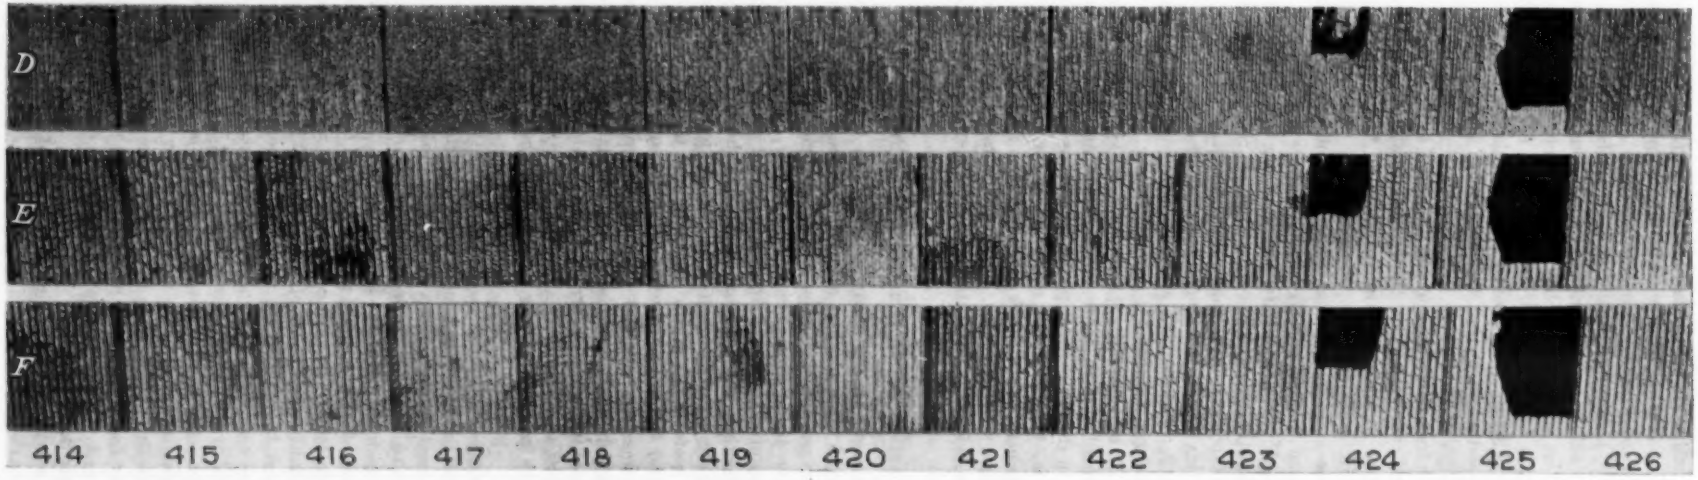

FIG. 20 FINISHED SURFACE ON RESPECTIVE SPECIMENS LEFT BY SHAPER TOOL × 1.8

(*D*, Tool 13 deg. front and 16 deg. side rake and 1/16 in. nose radius, the cut 0.015 in. deep, with 0.013 in. feed, 40 3-in. strokes per minute. *E*, same as *D*, but with 0.010 in. depth of cut and 0.027 in. feed. *F*, same as *E* except that speed of shaper was increased from 40 3-in. strokes to 82 3-in. strokes per minute.)

2320 steel, and 424, manganese-carbon, were in the form of coils from 1 to 3 in. in length. All three chips were somewhat blued, indicating the development of heat. While all tests were run dry, none of the other chips was blue. The drilling chip of bar 425, a special manganese-carbon steel, was well broken up, but some of the chip particles were slightly blued. The drill chips from bars 416, SAE 1120 (3/4 in. sq.), and 419, SAE 1112 (3/4 in. sq.), were coiled up to 1 in. in length, whereas the balance of the chips were well broken up into parts not to exceed 1/4 to 3/8 in. in length.

The planer tool gave chips on bar 422, SAE 6140, which were slightly blued, very rough on the bottom, and compact into a coil 3/4 inches in diameter and spiralled to 3/4 in. in length. The length of each cut was about 12 in. Bar 424, manganese-carbon steel, had planer chips not colored, rough and in the form of a small coil 5/8 in. in diameter and spiralled to 1 in. in length. The planer-tool chip of bar 423, SAE 2320, was very slightly blued and very rough on the bottom (next to the tool face). It was small and compact, a coil 7/8 in. in diameter. Bar 416, 1 1/4 in. sq. SAE 1112, and bar 419, 3/4 in. sq. SAE 1112, produced the smallest planer-tool chips of all, being in the form of a spiral 1/2 in. in diameter. Bar 417, 3/4 in. sq. SAE 1120, and bar 418, 1 1/2 in. sq. SAE 1120, gave planer-tool chips rougher than those for bars 416 and 419 and in a coil 7/8 in. in diameter. All planer-tool chips were continuous for the 12 in. length of cut, except those for bar 420, 1 1/8 in. round manganese screw stock. These were broken into two and sometimes three sections. In every instance there was a built-up nose left attached to the chip at the end of the cut for all bars.

Comparison of Surfaces Left by Shaper Tools

It was thought that a study of the finish left on each bar might prove of interest when a finish produced under a given condition on one bar was compared with that similarly produced on the other bars. Specimens of each bar, therefore, were prepared, approximately 1/2 in. thick and 2 in. long. These small sections then were clamped together in the vise of a shaper and a roughing cut was taken across all sections so as to present a flat surface, the width of which was the length of the specimens and the length of which was the sum of the widths of the specimens. The cuts were taken lengthwise of each specimen, which was lengthwise of the original bar. The bars were arranged in numerical order, with bar 414 at the left end and bar 426 at the right end. For each test cut the pieces were clamped with parallels on the bottom and the front to insure rigidity.

Fig. 19 shows the finished surface (× 1.8) on the various specimens left by a shaper tool. For the surfaces shown at *A* a tool was used having a zero degree front rake, a zero degree side rake, and a 1/16 in. nose radius. The cut was 0.005 in. deep and the feed was 0.013 in. per stroke. The shaper was set up to make 40 3-in. strokes per minute and the cut was made from right to left. The surfaces shown at *B* were made under the same conditions as those of *A*, except that the depth of cut was increased from 0.005 in. to 0.015 in. per stroke. There appears to be very little difference in the surfaces of cuts *A* and *B* for a single bar. Whether the surface *B* for bar 417 actually is smoother than that of *A* for the same bar is difficult to say. The photographs did indicate that *B* was the smoother. Also surface *B* of bar 418 appears to be smoother than surface *A*. On the other hand, surface *B* of bar 419 appears to be rougher than surface *A* for that bar, which might be expected because of the greater depth of cut.

It was noticed that, in taking the depth of cut of 0.005 in. with the zero degree front- and side-rake tool, the chips of bar 424 were of the curled type, being approximately 3/8 in. in diameter. The chips from all other bars, however, were straight and came off in one piece. When the depth of cut was increased to 0.015 in., using the same zero degree front- and side-rake tool, the chips from bars 422 and 424 were curled, while the rest were straight.

Cut *C* was made following cut *B*, in which a 13-deg. front-rake- and a 16-deg. side-rake-angle tool having a 1/16 in. nose radius was used with 0.005 in. depth of cut. This surface is shown at *C* in Fig. 19. Surfaces *C* are directly comparable to surfaces *A*, Fig. 19, except for the front- and side-rake angles on the tool. The surfaces shown for cut *C* give, in general, a smoother appearance than those for *A*. Bar 424 is a notable exception, whereas bars 414, 415, 418, 419, and 423 show considerable improvement.

The chips from cut *C* were curled for bars 424 and 425, whereas all others were straight.

Fig. 20 shows the finished surfaces at 1.8 magnifications on the various specimens left by a shaper tool. At *D* is shown the surface left by the 13-deg. front-rake and 16-deg. side-rake tool having 1/16 in. nose radius with a feed of 0.013 in., a depth of cut of 0.015 in., while the shaper provided 40 3-in. length strokes per minute. The surfaces from cut *D* correspond quite favorably with those of cut *C* for the same tool, although cut D was taken with a depth three times greater than that for cut *C*. The surfaces of cut *D* show a marked improvement over the surfaces of cut *B*. This improvement is due to the front and side rake of the tool, as otherwise the cutting conditions were identical.

Cuts *E* and *F*, shown in Fig. 20, were taken under the same conditions, except that in cut *E* the shaper made 40 3-in. strokes per minute, while in cut *F* 82 3-in. strokes per minute were made. In both instances the depth of cut was 0.010 in. and the feed was 0.027 in. The 13-deg. front-rake- and 16-deg. side-rake-angle tool having a 1/16 in. nose radius was used in both instances. It seems apparent that the finish of cut *F* is better than that of cut *E* taken at the slower speed. The surfaces of cuts *D* and *F* were enlarged another five times, making nine times natural size. It was thought that this magnification would bring out features of the surface not evident at the lower magnification. The results, however, were disappointing in that detail was lost due to the poor focus on the surfaces at different elevations.

It also is realized that the method of securing finished surfaces on these various bars by taking cuts 2 in. in length in a shaper was not the most desirable. Continuous cutting by turning would have been used had the specimens been adequate in size and amount for this purpose. This was not the case, however, so that the shaper had to be used. Just why some of the chips were curled while most of them were straight is not known. It is presumed that the formation of a built-up nose on the cutting edge of the tool varies with the material. The nature of the surfaces in all cases indicates the presence of this so-called built-up nose.

Stainless Steel

In addition to the 13 cold-drawn steel bars reported on, various machinability tests also were run on two stainless-steel or stainless-iron bars. Table 4 shows the chemical and physical properties of these bars, which were numbered 412 and 413. Bar 412 is called a stainless chromium iron and is in an annealed condition. Bar 413 is a free-machining rustless steel. The carbon content of both bars is low.

Photomicrographs of these two bars are shown in Figs. 21 and 22 at 100 magnifications. Bar 412, stainless chromium iron, has a very fine grain size and shows the results of the annealing,

while bar 413, the free-machining rustless steel, has the appearance of being cold drawn and has considerable banded sulphides. These specimens were etched with a standard ferric-chloride and hydrochloric-acid etch.

The results of the machinability data on these stainless-steel bars are given in Table 5. The force on the planer tool for the chromium-iron bar 412 was found to be 1586 lb., which compares favorably with the force for bar 418, the $1^1/_2$ in. sq. SAE 1120 steel. The chips from the $^1/_2$ in. wide planer tool, in making this cut, resembled very closely the chip of a fully annealed low-carbon steel. There was a built-up nose on the cutting edge of the tool, causing the under surface of the chip to be rough with rather parallel continuous cross ridges (resembling the teeth of a file) approximately $^1/_{16}$ in. or more apart. The surface left on the bar was very rough and showed slip lines quite similar to those on the bottom of the chip; that is, rather parallel ridges running crosswise of the cut approximately $^1/_{16}$ in. apart. The force on the planer tool for the free-machining rustless steel, bar 413, is only 1245 lb., which is lower than those for any of the cold-drawn screw-stock steels reported on. These chips were spiral in shape with the whole length of cut in one piece. The chip itself was burnished smooth on the bottom where it rubbed over the face of the tool, but was built up of chip sections slightly less than $^1/_{16}$ in. in width, which in themselves were made up of numerous shear elements. The sections were jointed only at their ends into the whole chip which gave a ladder-like construction. The surface of the chip away from the tool face was rough and made up of definite sections considerably larger than those for the annealed chromium-iron bar 412. A close examination of the chip from the planer tool for bar 413 does not show clearly any built-up nose on the cutting-tool edge. The surface left by the tool on bar 413 was considerably smoother than that on bar 412, but showed burnished lines, quite parallel across the cut $^1/_8$ in. apart.

TABLE 4 CHEMICAL AND PHYSICAL PROPERTIES OF STAINLESS STEEL

Bar No.	Material	Chemical analysis C	Mn	Phos	S	Si	Cr	Mo	Physical properties Tensile	Yield point	Elongation	Reduction area
412	Stainless chromium iron annealed.	0.06	0.31	0.012	0.022	0.18	13.35	..	90,000	50,000	30.0	60.0

413	Free-machining rustless steel.....	1245	249.0	0.754	25	800	0.900	0.0837	34.16	3.304	....

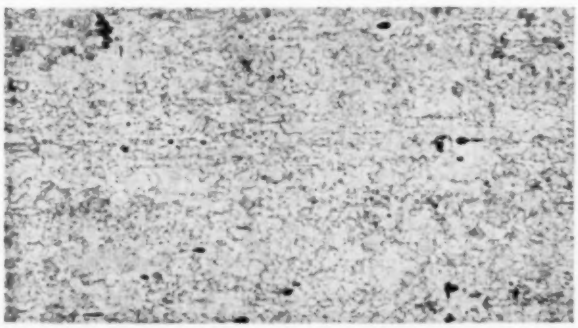

FIG. 21 BAR 412, STAINLESS CHROMIUM IRON × 100
(Very fine grain size; shows results of annealing.)

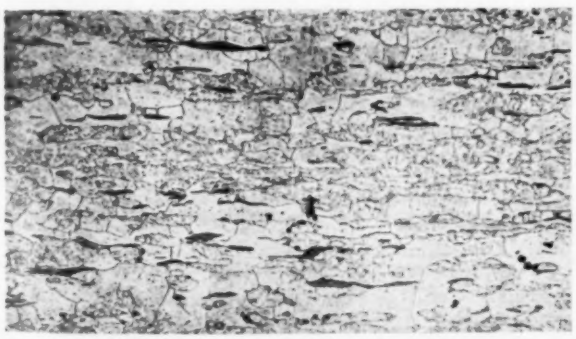

FIG. 22 BAR 413, FREE-MACHINING RUSTLESS STEEL × 100
(Has appearance of being cold-drawn; considerable banded inclusions.)

The torque for bars 412 and 413 is seen to be 49 and 25 foot-pounds, respectively. The value of 49 for bar 412 is considerably higher than the drilling torque for any of the cold-drawn steels reported on, as seen in Fig. 17, while 25 ft-lb. for bar 413 is rather an average value. The drill penetration of the stainless chromium-iron bar 412 is only 0.044 as compared with 0.081 for bar 423 which is the lowest in the group of steels. The drill penetration for bar 413, free-machining rustless steel, is 0.0837, which is in the range of bars 422, 423, and 424 of Fig. 17, the hardest of the group. The "milling energy up" for bars 412 and 413 is 59.1 and 34.16 ft-lb., respectively. The first value is much higher than any of the values for steel, while the second compares favorably with the values for the hardest steels.

CONCLUSIONS

The primary object of this paper has been to present certain machinability data obtained from a variety of cold-drawn steels, including two stainless steels. Because of the varied conditions under which these bars were manufactured and because of the differences in chemical analyses of supposedly similar bars, it is difficult to draw definite conclusions as to correlation between the machinability data, the structure, and the type of steel involved. Only by reference to the various tables and the texts can completely satisfactory conclusions be presented. Some conclusions, however, may be mentioned as follows:

(1) Data as to cutting force or energy required in planing, milling, and drilling, under similar standardized conditions, for 15 different kinds of cold-drawn steels are given. These data are directly comparable with similar data obtained from 18 ferrous metals and 21 non-ferrous metals, previously reported on in Trans. A.S.S.T., November, Vol. 16, pp. 659 to 710.

(2) Data as to horsepower per cubic inch of metal per minute are presented for each of the 15 cold-drawn steels.

(3) An attempt is made to determine the correlation between the machining properties of each cold-drawn steel and its hardness. A satisfactory correlation is obtained for some steels, but many show inconsistencies.

(*a*) The machining properties of each steel depend upon

its chemical composition, its heat treatment and method and degree of cold working, as shown finally by the resulting structure, and by its carbon content.

(*b*) The alloy steel bars 422, SAE 6140, and 423, SAE 2320, obviously do not belong in the family of plain carbon or manganese steels so far as their position on the machinability diagram is concerned.

(*c*) There appears to be little consistent correlation between the various machining properties of the steels as shown in Fig. 17*a*. One bar may show a low torque but high milling energy or a low penetration and low planing force, etc. The size of the bar, resulting from more intensive cold working for materials of similar chemical analysis, does not seem to cause wide variations in machining properties. Fig. 17*a* shows that bars 417 and 418, which are SAE 1120 steels $^3/_4$ in. sq. and $1^1/_2$ in. sq., respectively, have approximately the same machining and hardness values, in spite of their difference in size. Bar 417 has small grain size while bar 418 has medium grain size, which shows the effect of cold working. Also bars 416 and 419, which are $1^1/_4$ in. sq. and $^3/_4$ in. sq., respectively, SAE 1112 steel, show practically the same machining properties and hardness properties in spite of their difference in size. Bar 416 has medium grain size while bar 419 has small grain size, which shows the effect of cold working. The torque on bar 419, the smaller bar, is less than that for bar 416. The influence of size on tool life has not been investigated in this paper.

(*d*) The finish produced on the high-sulphur screw-stock steels appears to be better (than the finish on the alloy steels or manganese steels) for both the tools having 0-deg. front rake and 0-deg. side rake and 13-deg. front rake and 16-deg. side rake. Under the same cutting conditions, the high-sulphur and high-manganese steels have the best finish, the SAE 6140, bar 422, and SAE 2320, bar 423, being the poorest with the 0-deg. front-rake and 0-deg. side-rake tool, while bar 424, manganese-carbon steel, has the poorest finish, with the 13-deg. front-rake and 16-deg. side-rake tool.

(*e*) From Fig. 17*a* it is seen that, by omitting the first three steels at the right, which are SAE 6140, SAE 2320, and manganese-carbon steels, the Brinell curve slopes upward to the right, while the thrust curve slopes downward to the right; the penetration curve slopes downward to the right; the planing-force curve slopes downward to the right; the drilling-torque curve slopes downward to the right; and the "milling-energy-down" curve slopes downward to the right. This indicates that the higher the Brinell hardness the easier the bar machines.

(4) It is seen from Fig. 17*a* that each bar gives a certain energy required to remove a given chip by milling when the cut is "up" and a higher, equal, or lower value when the cut is "down." This indicates that the chemical analysis and structure influence the energy required to remove a chip, rather than any inherent difference in cutting process. The "milling-energy-up" curve in Fig. 17*a* seems to indicate no correlation with other machining or hardness values.

(5) The thrust curve seems to follow the Brinell curve almost exactly from point to point, as shown in Fig. 17*a*.

(6) The planing curve seems to follow the Brinell curve inversely from point to point, as shown in Fig. 17*a*, as does the penetration curve with a few exceptional points.

(7) The drilling-torque curve shows a reverse characteristic of the Brinell curve from point to point, as shown in Fig. 17*a*.

Acknowledgments

Grateful acknowledgment is made for the assistance of the Department of Engineering Research for meeting the expense of making the photomicrographs and various chemical analyses. The photomicrographs were made by Mr. Richard Schneidewind, of the Department of Engineering Research, and they were reviewed by Professor Claire Upthegrove, of the Department of Chemical Engineering. The machinability tests were made in most part by Mr. Charles E. Kraus and other former student assistants.

Most of the steel bars, together with the chemical analyses, were furnished by Mr. M. N. Landis, of Landis & Landis, chemists and metallurgists, Chicago, Ill., while the balance have been furnished by various users and manufacturers.

Discussion

M. N. Landis.[4] The writer has made a survey of the results obtained, taking into consideration a general knowledge of their

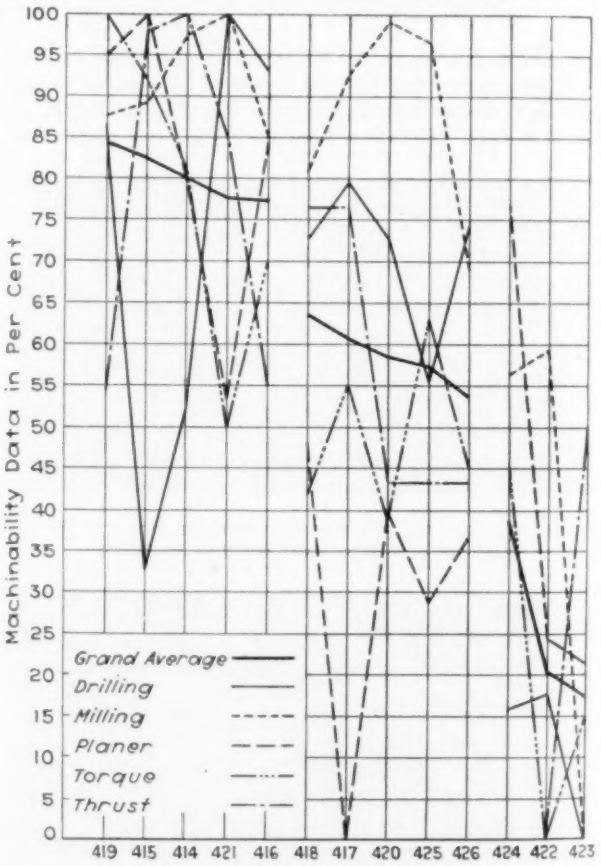

Fig. 23 Machining Properties

comparative machining properties from a production standpoint and has divided them into three groups:

First Group. Bessemer steels with low carbon and high sulphur:

414, $1^1/_{16}$-in. round super-free cutting.

415, 1 in. round (imported).

416, $1^1/_4$-in. square S.A.E. 1112 cold-drawn, $^1/_{16}$-in. draft.

419, $^3/_4$-in. square S.A.E. 1112 cold-drawn, $^1/_{16}$-in. draft.

Second Group. Open-hearth steels with high sulphur:

417, $^3/_4$-in. square S.A.E. 1120 cold-drawn, $^1/_{16}$-in. draft.

418, $1^1/_2$ in. square S.A.E. 1120 cold-drawn, $^1/_{16}$ in. draft.

420, $1^1/_8$-in. round manganese screw stock cold-drawn, $^1/_{16}$-in. draft.

424, 1 1/4-in. round manganese carbon alloy cold-drawn, 1/16-in. draft.

Recapitulation of the machinability data obtained in the various tests has been made on the basis of the best machining specimen being rated 100 per cent, the poorest 0 per cent, and the others graded between. These results are arranged in Table 6 in the order of their comparative ratings.

Analysis of these results, with the machinability calculated in percentages, indicates that the averages of the various tests follow very closely the generally accepted production machinability rating. There is the exception of No. 421, which apparently has a high rating, but it has been the writer's experience that certain items of the manganese screw-stock steels machine exceptionally well. In any one of the types of steel tested considerable variation in machinability rating will be encountered, such as is displayed by the two samples of S.A.E. 1112.

Analysis of the tests conducted, calculated by determining their variation from the average machinability rating for each specimen, indicates that the torque results more nearly approach the grand average, and the milling results are farthest from the average. These results are arranged in Table 7.

The hardness tests have not been considered in analyzing the results, as it has been the writer's experience that they are not sufficiently indicative of the degree of machinability in testing screw stocks. The drilling tests, unfortunately, are dependent on the grinding, and, as stated by the author, it is "almost impossible to regrind the drill, even on a machine, to give results comparable with those of first grinding." If this variable could be overcome, the writer feels that the drilling tests should give a very desirable indication of machinability.

Alvan L. Davis.[5] It would be interesting, and the writer believes valuable, if the author would add a brief appendix showing the maximum deviation and also the average deviation from the mean for a series of, say, ten determinations, all on the same test material, for the planer, for drill torque, and for the miller. Such maximum and average deviations would allow an estimate of the probable error pertaining to the mean figures in the paper.

In the absence of such means of arriving at the probable error, the writer has assumed that the figures are not to be relied upon further than two significant figures, and in order to simplify discussion as much as possible, has used two significant places only in preparing the tabulation of horsepower per cubic inch of metal removed per minute. (See Table 8.) An arbitrary separation of the materials has been attempted into classes, according to the power required for machining. The idea of this simplified table is to attempt to bring out more clearly the extent to which the different kinds of machinability tests are in accord with each other, in classifying various steels as to machinability.

The writer attaches relatively small importance to the drill-penetration tests, because considerable experience with this type of test has led him to conclude that it is subject to rather wide variations due to the metal loading on the bottom of the drill and altering its rate of cutting. Nevertheless, the last column of the table does show the penetration, thus permitting comparison with the "horsepower required to remove 1 cubic inch per minute."

Table 8 shows that all four methods of test are in agreement; that class 1 (which is ordinary stainless chrome iron) requires the greatest power for machining, and that it yields the shallowest penetration under constant load. Likewise, all four tests agree that class 2 (comprising S.A.E. steels 2330 and 6140) stands next in point of resistance to machining operations; also, class 3 (made up of the high-manganese steels and the open-hearth screw stocks) requires still less power and yields deeper penetration under constant load. Passing by class 4 for a moment and

[5] Research Engineer, Scovill Manufacturing Company, Waterbury, Conn. Mem. A.S.M.E.

TABLE 8 HORSEPOWER PER CUBIC INCH OF METAL REMOVED PER MINUTE

Class	Type of steel	Bar No.	Planer	Drill	Miller	Penetration of drill under constant load
1	Ordinary stainless chrome iron	412	0.96	1.76	5.7	0.044
2	S.A.E. 2320	423	0.94	1.08	3.4	0.081
	S.A.E 6140	422	0.93	1.14	3.0	0.091
3	S.A.E. 1320	426	0.81	0.98	2.9	0.124
	S.A.E. 1310	420	0.81	1.00	2.7	0.139
	S.A.E. 1315	421	0.79	0.96	2.8	0.139
	S.A.E. 1340	424	0.76	0.98	3.0	0.090
	S.A.E. 1120	418	0.80	0.98	2.8	0.123
	S.A.E. 1120	425	0.78	0.92	2.7	0.113
			0.76-0.81	0.92-1.00	2.7-3.0	0.090-0.139
4	Free-cutting stainless chrome iron	413	0.75	0.90	3.3	0.084
5	S.A.E. 1112	416	0.75	0.89	2.8	0.135
	S.A.E. 1112	419	0.73	0.78	2.8	0.131
	Super-free cutting, imported	415	0.72	0.81	2.7	0.100
	Super-free cutting, domestic	414	0.00	0.84	2.7	0.111
			0.70-0.75	0.78-0.89	2.7-2.8	0.100-0.135

considering class 5 (which comprises Bessemer screw stock and also more particularly the super-free-cutting steels, both imported and domestic), the table shows planer and drill in agreement in grading these steels as easier to cut than any of the foregoing classifications. The miller shows only very slight improvement, however, over class 3 steels, and the penetration test here fails wholly to denote the relative machinability.

Class 4, the free-cutting stainless chrome iron, appears to be intermediate between classes 3 and 5 as measured by planer and drill. The miller, however, is not in accord in this respect, and would place this material along with S.A.E. steels 2320 and 6140 in class 2. Why this should be so the writer is not in a position to state, but it presumably arises from the nature of the milling test itself, which apparently is influenced by other properties than those which control the results in planing and drilling. In commercial machining it has been observed (in the case of certain alloy steels and also tool steels) that the degree of annealing giving optimum results for drilling and planing will not always give the best results for milling. Also, thread tapping sometimes requires a still different degree of annealing to give the best results.

Thus there is found quite general agreement between the three tests based on cubic inches of metal cut. However, it is disappointing that there should be so little difference between the super-free-cutting steels (bars 414 and 415) and the ordinary open-hearth screw stock (bars 418 and 425), especially in view of the fact that actual shop tests have proved these two super-free-cutting steels to give about 100 per cent greater production on automatic screw machines than is possible with ordinary open-hearth screw stock.

No stress in this résumé is placed upon hardness as indicated by the various tests recorded. This is partly because there is not complete uniformity in the different hardness tests reported for some of the specimens, but also because in the case of cold-drawn bars the hardness is built up out of two factors: first, the hardness of the bar before being subjected to cold drawing, and, second, the amount of hardness conferred by cold drawing. While the hardness resulting from cold drawing seems to promote free cutting, the initial hardness acts in the reverse direction. Therefore, no consistent results can be looked for, unless it is known how much of the final hardness is due to cold work and how much to initial hardness of the steel.

The writer's experience in testing machinability shows it to be an elusive factor, and he is not surprised to find lack of complete accord between different methods of measuring it.

ALFRED V. DE FOREST.[6] This paper, as well as the author's previous one on machining properties, well deserves the full attention of all those interested in problems of machinability. Speaking from the standpoint of the steel maker, particularly the cold-drawn and free-cutting steel industry, the question as to whether an intrinsic property of the steel loosely covered by the term machinability can be reduced to some system of measurement is of great consequence. The measurements made by the author undoubtedly have a bearing on the problem, but the factors which cause a steel to be successful or the reverse in actual practice are usually more complicated than questions of energy absorption. To get the best results out of a given steel, the shape and material of the cutting tools, the lubricant, and the type of machine used all play a very vital part, and usually in actual practice the machinability of a steel is judged by whether it works well under the cutting conditions which have been established by custom for some other materials. The supplier of steel must then endeavor to change the operation of the machine tool so as to get the best out of the material he supplies. In some cases this can be done. Frequently it cannot even be attempted, and the steel is blamed for any failure.

The writer recently came across a good example of a case in which machinability was important. A vital part was being manufactured from screw stock on screw machines. Complaints as to quality caused the substitution of a low-carbon alloy steel without free-machining properties. Production immediately dropped to almost nothing, and the steel was pronounced unmachinable. However, with assistance and encouragement, it developed that if the steel were given an extra draft of cold work and the tooling and lubrication were changed, almost the same production could be obtained as with the free-machining steel previously used. In this case it is not doubted that a similar amount of attention bestowed on the free-machining steel would have raised the original rate of production far above that obtainable by the alloy steel, but in this case a little attention and perseverance saved a job which from the protests of the manufacturer appeared to be impossible.

This case also brings out a point not very well covered in the paper, and that is that under certain conditions the additional hardness due to cold work is of advantage in machining operations. Probably conditions of this kind have discredited hardness tests as having any bearing on the machinability problem.

If one separates hardness due to chemical constitution from hardness due to cold work and heat treatment, it is possible that a better correlation can be obtained. Hardness, however, is rather remote from the strength, hardness, and ductility of the metal just beyond the tool point at the temperature which exists during the cutting operation, and the properties at this point are undoubtedly those which control machinability.

It is very much to be hoped that the machine-tool industry, the tool-steel manufacturer, and those interested in supplying steels for machining join together and clear up the lack of knowledge surrounding the whole subject.

AUTHOR'S CLOSURE

The author is grateful indeed to those who have discussed this paper, as each discusser added a new viewpoint, together with

[6] Consultant, Wyckoff Drawn Steel Company, Pittsburgh, Pa.

his different method of analysis of the experimental data. Each discusser is well qualified to make comments in view of his years of experience with these problems.

The author fully appreciates that the experiments involved in this study of machinability do not include all desirable methods of tests. This work was done by the author and a few students with practically no financial assistance.

The analysis by Mr. Landis is extremely interesting and valuable. It would seem to the author in considering equipment, condition of tools, etc., that the planer tests would represent more nearly the machining properties, as far as power is concerned, of the various metals. The drilling tests, also, would seem to be quite reliable, inasmuch as a drill of a size of $^3/_4$ in. diameter can be reground on our grinding machine so that tests can be duplicated with a great deal of satisfaction.

The author believes the quotation of Mr. Landis regarding the impossibility of regrinding a drill to give the same results with different grinds was made in the paper to apply particularly to the $^1/_4$-in.-diameter drill as used in the penetration test. The $^3/_4$-in. drill can be reground repeatedly to give practically the same experimental results. The author has conducted tests as to the influence of dulling on a drill in use and has found that, when cutting dry, after the first few inches drilled, there is little difference in the torque and thrust values in drilling an additional 60 or 70 in. of metal. This dulling effect seems to be more perceptible, however, when a coolant is used. The cutting actions of the $^3/_4$-in.-diameter drill and the planer tool seem to be quite similar and the results of the test in quite satisfactory agreement. The drill penetration test, however, is obviously a different principle, as is that of milling. The author has considerable information dealing with the results of milling different metals when the cut is with the feed and against the feed of the work. For some metals the results are practically the same; on other metals there is quite a divergence. Some metals require as much as 25 per cent less power when the milling cut is taken with the feed rather than against the feed, while other metals require as much as 25 per cent more. This is brought out in Figs. 17 and 17-*a* in which the milling-energy values for each material are shown when cutting up and when cutting down. By cutting down is meant cutting with the feed.

These differences are not as outstanding in Figs. 17 and 17-*a* as though there were a greater divergence in types of materials, although the divergence is due, in the author's opinion, to the influence of the material characteristic rather than through inaccuracy of the test methods.

Mr. Davis raises the question as to the maximum deviation from the average of the results obtained by the different machinability tests. In determining torque and thrust with the $^3/_4$-in.-diameter machinability drill, torque values from individual tests may vary 2 or 3 per cent in the same material. An average of three or four tests, however, will agree with the average of two or three other similar tests run at another time within 1 per cent. In obtaining the torque values for bars 417 and 419, each of which was $^3/_4$ in. square, two pieces of the same bar were clamped together and then drilled with the point of the drill to one side of the separating plane. The area of the cut, however, was approximately two-thirds in one piece and one-third in the second piece. This would lead to a condition approximating intermittent cutting with the bumping effect eliminated. While the author has made no tests to compare the results obtained by this method of drilling with those obtained when drilling into one solid piece, yet it is believed that the error is not appreciable.

The planer-force values tabulated here are an average of the readings on 10 successive cuts. The tool was fed 0.010 in. downward for each cut, using a dial gage attached to the planer head. While each cut was supposed to be 0.010 in. in depth, it may have been slightly less in one cut and slightly more in the following cut, so that maximum deviations between individual readings may be 4 or 5 per cent. In taking 10 cuts, however, the accumulated depth of cut would be 0.100 in., as close as could be read on the dial indicator. The average of one set of 10 readings, however, will agree with the average of another set of 10 readings within $^1/_2$ to 1 per cent. The drill penetrator tests will vary possibly 12 or 14 per cent between individual tests, as a small error in time of starting and stopping the watch during the 0.15 to 0.20 minute required to penetrate the 0.100 in. amounts to a large percentage. But again an average of 6 or 12 tests will agree with the average of another set of 6 or 12 readings within 2 or 3 per cent.

In obtaining the milling data, individual tests on these cold-drawn steels varied as much as 6 per cent, but by taking 10 consecutive readings an average would be obtained which would agree within $^1/_2$ to 2 per cent of similar average readings obtained from another set of tests on another bar. It seems, therefore, that where these different methods fail to confirm machining characteristics of a metal, the difference is due to the reaction of that metal to the particular machining process rather than excessive errors in the test data. It is for just this reason that these four different methods of tests were all used in obtaining the information reported on in this paper.

The point brought out by Mr. Davis dealing with optimum heat treatment for best machining purposes is one on which further accurate information is needed. The influence of structure and grain size appears to be a point on which little agreement exists. Just why the methods of tests employed in this paper do not agree with the results of tool life cannot be explained here, inasmuch as the author has no definite information on tool life. Not enough material was available to obtain data of this nature.

Mr. Davis and Mr. De Forest both refer to the hardness of a piece of cold-worked steel as consisting of two factors: the initial hardness of the steel and the final hardness after being cold-worked. The author has no information to throw light on this complicated subject, but appreciates the value of more detailed information dealing with this subject. Mr. De Forest has raised the question of optimum tool size and shape and condition of the material being cut, as well as the best lubricant or coolant to be used. Data are now being accumulated dealing with the performance of various types of cutting fluids, which may help to explain some of these factors. Optimum conditions for cutting by any process do not seem to be available.

MSP-53-7

Mechanical Design of Electric Motors as Regards Standardization Interchangeability

By J. L. BROWN,[1] EAST PITTSBURGH, PA.

The electric motor has become a machine simply to do a job, and yet because it is vital and because the failure of a unit means its immediate replacement with a new one, there has been a growing need for uniformity in physical dimensions of units. The rapidity with which uses for electric motors are multiplying calls for the lowest possible cost of manufacture of what may be called the standard type, but also of the many variations necessary to meet various conditions. This dictates uniformity also of the many accessory parts.

TIMES have changed for the electric motor. The halo which it wore as it assumed form out of the mists of the nineteenth century has faded. The mantle of mystery has been transformed into the tunic of service. The child of the scientists has become the patient ox of industry. No longer is the electric motor given a place of prominence and consideration, having subordinated to it the structure and characteristics of the driven machinery. It has become simply a machine to do a job—any job; a tool for use—and abuse. In the vast variety of elements making up the modern world, it is but a cog in the wheels of industry—a thread in the fabric, a link in the chain, a bolt in the structure. Perhaps the keystone of the arch, but still only one stone among many.

Yet because it is vital, and the failure of one unit grown old in service must be remedied instantly by replacing it with a new, there has been a growing need for a greater measure of uniformity in physical dimensions of units, which are otherwise sufficiently similar to do the same job, irrespective of the manufacturing plant in which they originate. Not only so, but the rapidity with which uses for electric motors are multiplying calls for the lowest possible cost of manufacture of not only what might be regarded as the standard type, but the many variations from this standard that are necessary to meet the various conditions of service. This dictates every possible measure of uniformity among the various standard and semi-standard accessory parts composing the variations of any given motor unit, in the interest of both the tooling equipment used in manufacture and the ease and rapidity of assembling from a given set of parts any type of unit which may be required for any particular class of service.

Standardization of a simple line of hardware such as bolts and nuts, though attended with many difficulties, is by no means the complex problem encountered in the standardization of motor dimensions. In addition to the necessity of effecting an agreement among motor manufacturers, it is necessary also to effect a compromise among types of motors which in many of their detail parts are essentially dissimilar. Consideration of details regarding the possible extent of standardization of external mounting dimensions of electric motors is beyond the scope of this paper. Nevertheless, it may be interesting and profitable to consider briefly the development of one of the newer lines of motors which demonstrates to what extent standardization as among dissimilar detail motor parts may be effected, thus resulting in great flexibility in machining and assembly methods when producing units which, although similar in external dimensions, are essentially different in type.

The simplest form of electric motor, and at the same time the one most widely used and manufactured in the largest quantities, is the so-called squirrel-cage induction type. The rotating element of this motor has been brought to the irreducible minimum in simplicity and economy of manufacture. Fig. 1 shows such a rotating element consisting of a shaft *a*, a stack of sheet-steel laminae *b*, and a grid of aluminum alloy *c* passing through slotted openings in the laminae and forming, with the continuous end-ring portions, the whole system of electrical conductors in the rotating element, as well as the necessary ventilating means, in the form of axially extending blades of the same die-cast structure. It will thus be seen that there are three principal parts only —no commutator, no collector rings, no wire windings, no insulation, no band wires or slot wedges to retain otherwise unsupported parts of the structure, no supporting plates for the sheet-steel laminae; even core rivets to hold them in assembly are a superfluity.

Not all applications for electric motors, however, are most satisfactorily served by a constant-speed, polyphase, alternating-current motor, and in meeting the requirements of certain applications, types of motors must be used in which the simplicity of the squirrel-cage induction type is to some extent lost. Variable-speed induction motors, for example, require the insertion of resistance into the rotor winding circuit necessitating that these windings be insulated from each other and the core and connected together in such a way that terminals may be brought out and connected to the necessary resistance through collector rings and brushes. This change in the type of winding involves the addition of insulation, band wire, and slot wedges to hold the coils in place, separate clamping means for the core of sheet-steel laminae, and separate blowing means to secure ventilation, while the addition of the collector rings makes the rotor unsymmetrical about the center line.

For a number of purposes the characteristics of direct-current motors outweigh in importance the simplicity and low cost of the induction motor. In this type the rotor windings are arranged much as are those of the variable-speed induction type, but are attached to a commutator instead of to collector rings. Fig. 2 gives a comparison of the three types of rotors. It should be noted that in spite of their dissimilar electrical features, the

[1] Mechanical Engineer, Industrial Motor Engineering Department, Westinghouse Elec. & Mfg. Co. Mr. Brown was born near Clinton, Ontario, Canada, in July, 1891. He received his early elementary education at country school, and was graduated from Clinton Collegiate Institute in 1908, after completing academic, commercial, and elementary scientific courses of study. He acquired electrical and mechanical engineering and business training by private study. Mr. Brown has specialized in mechanical design engineering as related to electrical apparatus with the Crocker-Wheeler Co., Ampere, N. J., and the Westinghouse Company since 1912.

Presented at the Fourth National Machine-Shop Practice Meeting, Chicago, Ill., September 22 to 24, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

three are similar in diameter and length from the center line toward the right; that the two last are similar to each other from the center line toward the left; and that that part of the first from the center line toward the left is similar to that part of all three from the center line toward the right.

Turning to a consideration of the stationary structures, Fig. 3 shows that whereas a frame or stator portion of exactly similar description is suitable for both constant- and variable-speed induction motors, the direct-current motor-frame assembly is greatly dissimilar. The magnetic circuit in the stationary part of induction motors is confined to a stack of sheet-steel laminae carried in a frame structure which furnishes physical strength and means of attachment to the driven apparatus or foundation. The laminated core structure is usually much smaller in diameter than the maximum diameter of the supporting frame, due to the necessity of providing passages for ventilating air. On the other

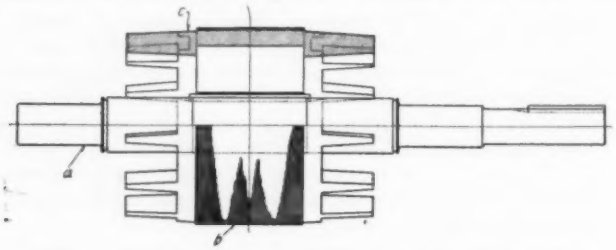

FIG. 1 ROTOR FOR SQUIRREL-CAGE INDUCTION MOTOR

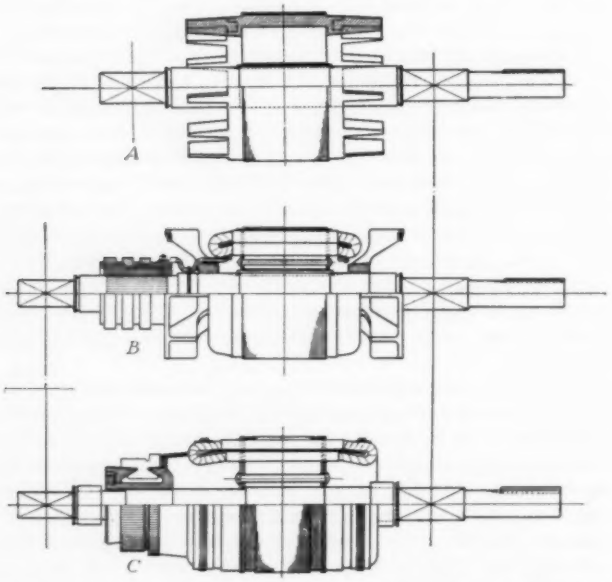

FIG. 2 COMPARISON OF CONSTRUCTIONS OF ROTATING ELEMENTS OF THREE TYPES OF ELECTRIC MOTORS

(*A*, squirrel-cage rotor; *B*, alternating-current wound rotor; *C*, direct-current armature.)

hand, the direct-current motor requires no lamination of the material forming the stationary part of its magnetic circuit due to the fact that in this part the magnetic lines of force are unidirectional rather than alternating, but the diameter of the part carrying the magnetic flux must be relatively larger than in the case of the induction motor due to the salient pole construction required for most efficient design. Instead, then, of a separate laminated core carried in a frame structure as in the case of the induction motor, the frame structure of a direct-current motor must perform the additional functions of composing a large portion of the stationary part of the magnetic circuit and of supporting the pole pieces and the associated stationary windings which are employed in exciting the magnetic circuit of the machine.

The problem is that of suiting these essentially different sets of active elements with accessory mechanical parts necessary to form a motor unit which can be applied to a job. Fig. 4 shows the stationary and rotating parts of the three types being considered in assembled relation. At the right the journal portions of the

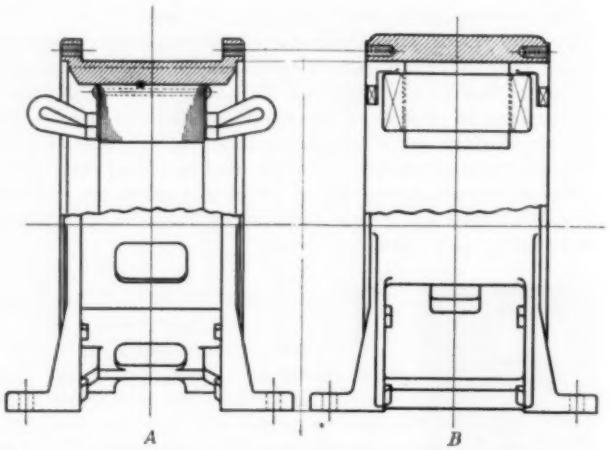

FIG. 3 COMPARISON OF ALTERNATING-CURRENT AND DIRECT-CURRENT FRAME STRUCTURES

(*A*, frame for squirrel-cage and wound-rotor alternating-current motors; *B*, frame for direct-current motors.)

three shafts are in identically the same position from the center line of the machines. Also, the machined ends of both types of frames are identical in position and mounting detail. To support the rotating members from the several frames at this end, it is possible to design an interchangeable bracket structure, fitting and bolted to the frame ends and supporting at its outer end a bearing adapted to fit the journal portion of the shafts.

In a similar way a bracket structure may be designed for the opposite end to serve both the wound-rotor induction motor and the direct-current motor, except that allowance must be made for the different types of brush rigging required for the collector and the commutator. The squirrel-cage induction motor, being symmetrical about the center line, will use the same bracket structure at both ends. Thus, for all motors of a given size, only two distinct bearing brackets are required to serve every electrical type, resulting in maximum activity and minimum cost for this important accessory part.

Electric motors differ not only in electrical type but in mechanical type. Differences in mechanical type are occasioned by requirements of the service. The horizontal, open, ventilated type is the most widely used, but there are many others, differing in the relation of the shaft to the horizontal plane, the measure and method of enclosure, and the method of attachment to the supporting structure. Hence there are both horizontal and vertical motors, open, totally closed, enclosed-ventilated, force-ventilated, self-ventilated, explosion-proof, watertight, floor-mounted, end-mounted, built-in, overhung, etc. In addition, there are variations due to type of bearing and to facilities for mounting accessories such as brakes.

Fig. 5 shows a longitudinal sectional assembly of a horizontal open, sealed-sleeve bearing, squirrel-cage, induction motor. By removing the end brackets (which are shown also in dotted outline in Fig. 6) and replacing them and the shaft with similar parts adapted to ball bearings, as indicated in full lines in Fig. 6, the motor becomes of the ball-bearing type without change in mounting dimensions or overall length.

Referring next to Fig. 7, it will be clear that replacement of the brackets and shaft just shown and the addition of other accessories results in an enclosed-ventilated motor in which the windings are completely protected from destructive elements

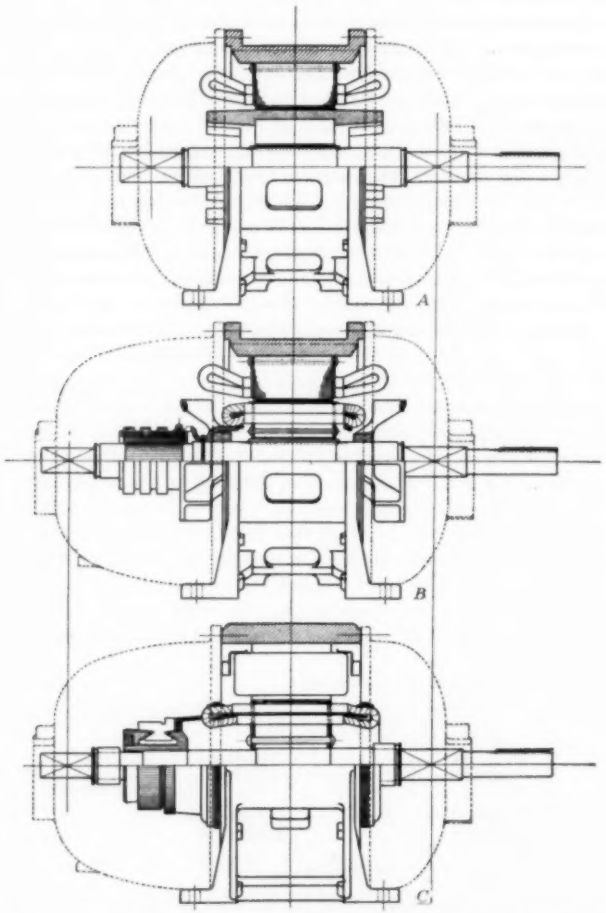

FIG. 4 COMPARISON OF ROTOR AND STATOR ASSEMBLIES OF DIFFERENT TYPES OF MOTORS

(*A*, squirrel-cage induction motor; *B*, wound-rotor induction motor; *C*, direct-current motor.)

permeating the surrounding atmosphere, yet ventilation is effected by blowing air on the exposed portions of the enclosure. Again, the transformation is accomplished without change in mounting or overall dimensions and by using the same frame and electrical parts as in the original, open, horizontal, sleeve-bearing motor.

In a similar way other types can be produced, so that it is possible from a limited number of parts to build any one of many different types or to convert any type into any other type at minimum cost.

Many of the variations in type are accomplished by closure or partial closure of the handhole openings in the end brackets of the open motor, either with or without gaskets. Attention is directed to the end-bracket design in which plane surfaces are invariably employed for engaging the covers and their gaskets. Fig. 8 shows a drip-proof motor. In this, a louvered frame cover is used, while flat steel plates and sheet-cork gaskets effectively close the upper handholes of the end brackets.

In the mechanical variations which must be used, some of which have been described in the foregoing, it is desirable to use identically the same parts as far as possible. If, however, it is not possible to use exactly the same parts, it is still a great advantage in manufacture if parts which must be different from others in some respects can be similar in form and size so that the same tools can be used for casting and machining with as little change in adjustment as possible. These advantages have been secured to a very large extent in the design of the parts forming the combinations described in the preceding paragraphs.

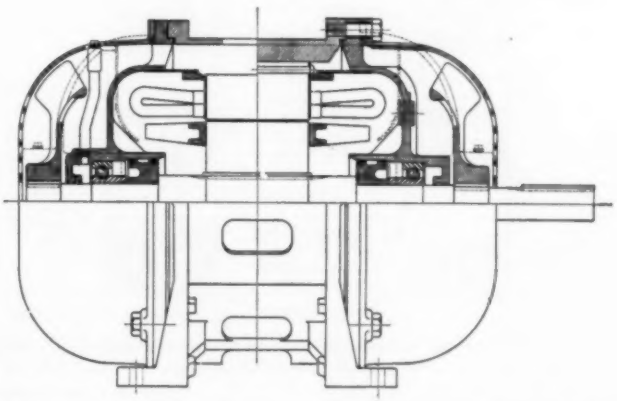

FIG. 7 LONGITUDINAL SECTIONAL ASSEMBLY OF SQUIRREL-CAGE INDUCTION MOTOR SHOWING CONVERSION OF OPEN-BALL-BEARING MOTOR TO THE ENCLOSED VENTILATED TYPE

Of recent years ball and roller bearings have gained favor in

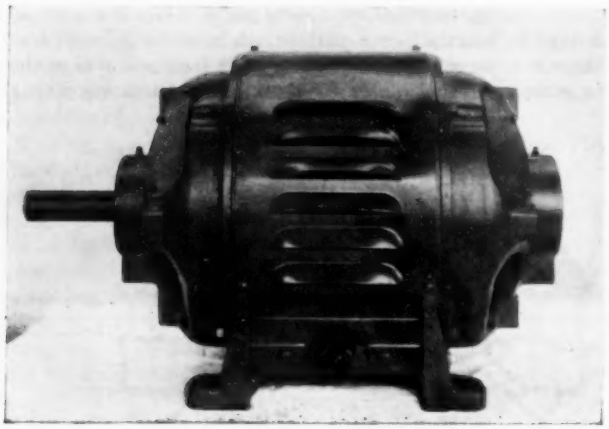

FIG. 8 DRIP-PROOF MOTOR SHOWING SIMPLICITY OF END-BRACKET COVER DESIGN RESULTING FROM PLANE-SURFACE BORDER OF HAND-HOLE OPENINGS

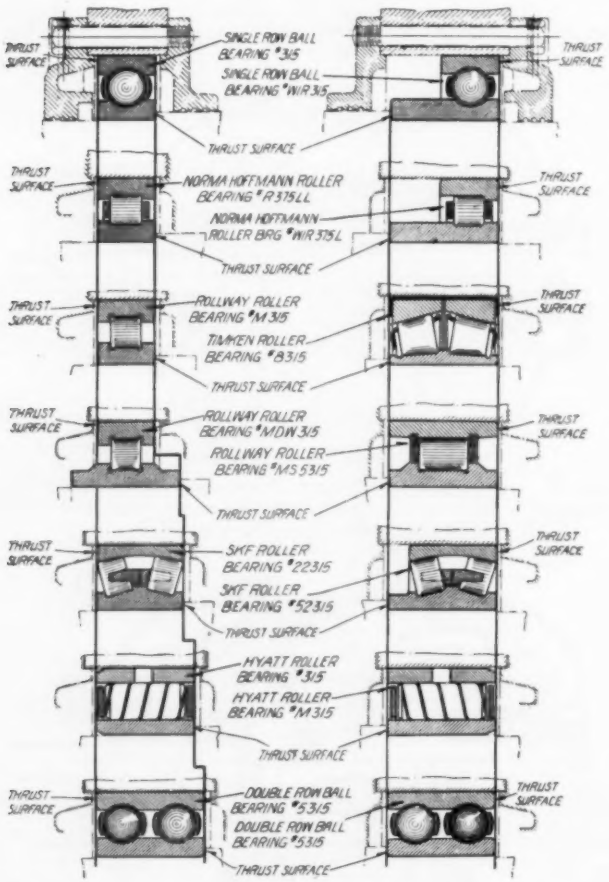

FIG. 9 NON-INTERCHANGEABLE AND INTERCHANGEABLE BALL- AND ROLLER-BEARING DESIGNS

some quarters for motor application. The great variety of types and makes of these bearings, each with its following of proponents among users, has introduced many a problem in their application to motors, and has tended toward diversity of mounting, involving unnecessary expense and delay in delivery of the apparatus to the user. In the design of the line of motors under discussion, the problem of standardization of ball- and roller-bearing housings has been given careful attention.

Ball bearings are made in single and double width by almost all manufacturers. One manufacturer has an intermediate standard. Roller bearings are made to all three standards by various manufacturers, and some differ only a small amount from the standard. Others are made in inch dimensions, whereas most ball and roller bearings have their outside diameters and bores in millimeters. This great diversity in dimensions is one of the factors in making an interchangeable mounting difficult of achievement. A number of bearings of dissimilar width are illustrated in the left-hand column of Fig. 9. The right-hand column shows the various makes of bearings reduced to interchangeability. In this arrangement, the width of the double-row ball bearing is adopted as standard. Single-row bearings are provided with an inner race extended at one side to give a total width equal to that of the double-row bearing. All makes of bearing can be obtained in the double-row width, thus making it relatively easy to serve customers with their preferred brand.

The greatest bearing load occurs at the shaft extension end of the motor, the load at the opposite end being relatively light. To suit this disparity in loading, it has been customary to use a large bearing at the shaft extension end and a small one at the opposite end. This, however, results in two different end brackets for a squirrel-cage induction motor which is otherwise symmetrical. In the new design, this difficulty is overcome and at the same time the bearing capacity is suited to the load by employing the arrangement illustrated in the upper half of Fig. 10. Here a large capacity double-row bearing is used at the pinion end and a relatively lower capacity interchangeable single-row bearing with wide inner race is used where the load is relatively light. The relative simplicity of the new design as compared with

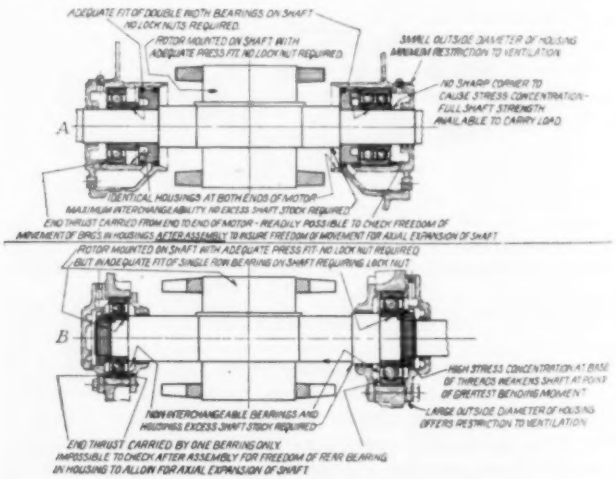

FIG. 10 COMPARISON OF NEW AND OLD DESIGN OF BALL-BEARING MOUNTING IN GENERAL-PURPOSE MOTORS
(*A*, new design, maximum simplicity; *B*, old design, relative complexity.)

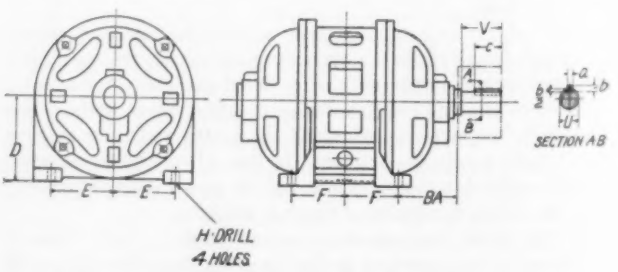

FIG. 11 MOUNTING DIMENSIONS FOR HORIZONTAL MOTORS

the old will be evident by comparison of upper and lower views of Fig. 10.

As ball bearings have increased in capacity due to progress in the art, the contact with the shaft of the inner race of single-row bearings has become insufficient in some of the severe service conditions encountered. Increasing the width of shaft contact by extending the inner race is a means of keeping pace with the advances made in internal design and manufacture of the bearings, without the questionable assistance of locking devices such as appear in the lower view of Fig. 10. It will therefore be seen that the same arrangement which results in the highest degree of uniformity and interchangeability among detail motor parts is ideal in other respects as well.

Important as is the internal design of electric motors, it is no less important that the attachment of the motor to the foundation or driven machine receive careful consideration. Interchangeability from this standpoint has suffered a measure of neglect in the past, and is a feature that recently has been the subject of much profitable discussion.

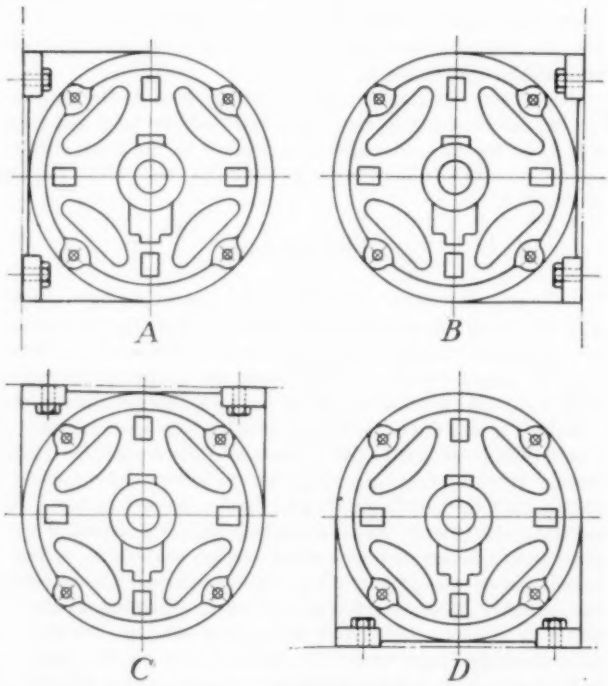

FIG. 12 ILLUSTRATING FLOOR, WALL, AND CEILING MOUNTING FOR ELECTRIC MOTORS

(*A*, left-hand wall mounting; *B*, right-hand wall mounting; *C*, ceiling mounting; *D*, floor mounting.)

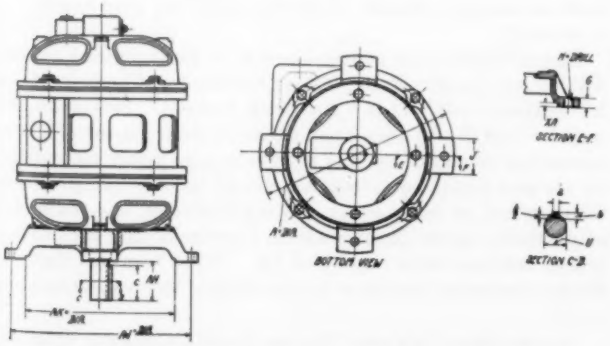

FIG. 13 MOUNTING DIMENSIONS FOR VERTICAL MOTORS

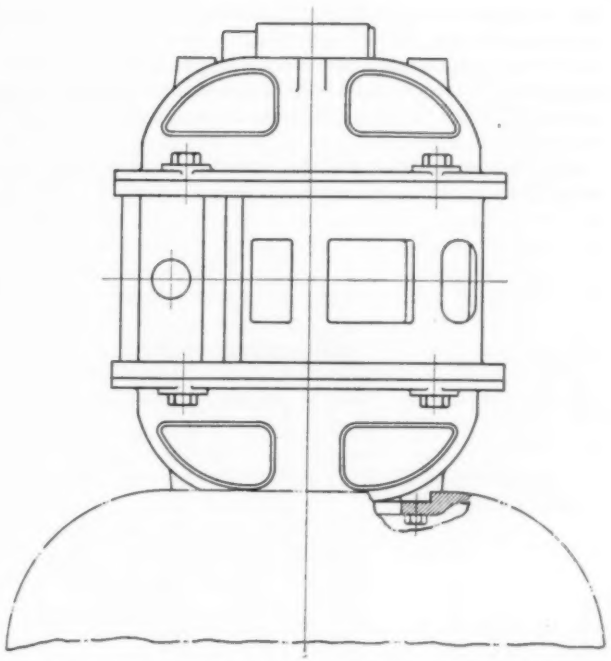

FIG. 14 INTIMATE END MOUNTING FOR HORIZONTAL OR VERTICAL MOTORS

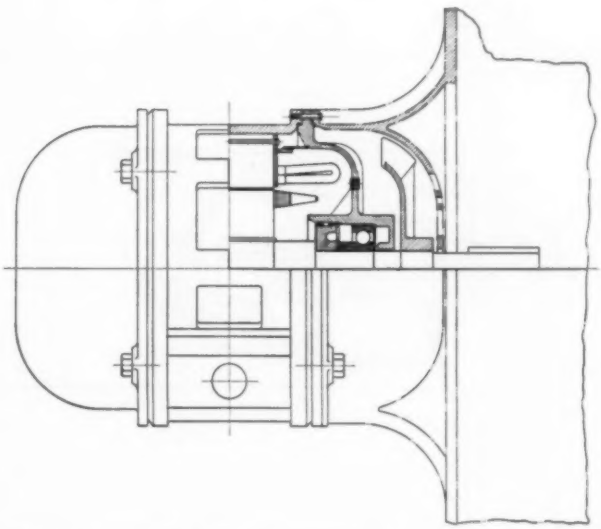

FIG. 15 INTIMATE END MOUNTING OF ENCLOSED VENTILATED MOTOR WHERE DRIVEN MACHINE FORMS REAR BLOWER CASING

The important dimensions affecting interchangeability of standard horizontal motors are the shaft and keyway dimensions, the distance from the face line of the pinion or pulley to the first pair of holding-down bolts, the distance between the first and second pairs of holding-down bolts, the distance between holding-down bolts at right angles to the shaft, the size of holding-down bolts, and the height of the shaft center line above the bottom of the motor feet. These dimensions are illustrated in Fig. 11.

Motors having this mounting arrangement can be attached to a horizontal support below the motor or to the wall or ceiling with the shaft in a horizontal position, and can often be arranged for mounting in intermediate positions as indicated in Fig. 12. Oil-lubricated motors may be tilted so that the shaft makes an angle of 10 or 15 deg. with the horizontal. For greater inclina-

tion up to the vertical position, grease-lubricated motors are the common solution. However, for strictly vertical operation with inclination from the vertical not exceeding 15 deg., it is possible to obtain motors having specially designed oil-lubricated bearing assemblies. Fig. 13 shows the important mounting dimensions for vertical motors.

It often happens that it is desirable to mount motors either horizontally or vertically in more intimate association with the

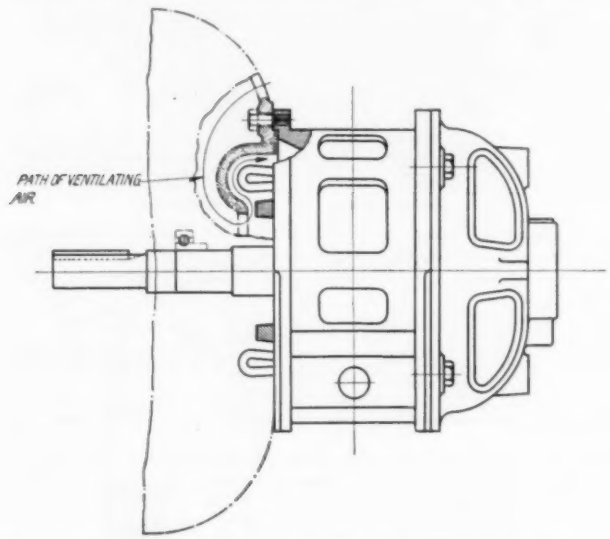

FIG. 16 INTIMATE END MOUNTING OF ELECTRIC MOTOR WHERE MOTOR-DRIVEN MACHINE PROVIDES REAR BEARING AND END GUIDES

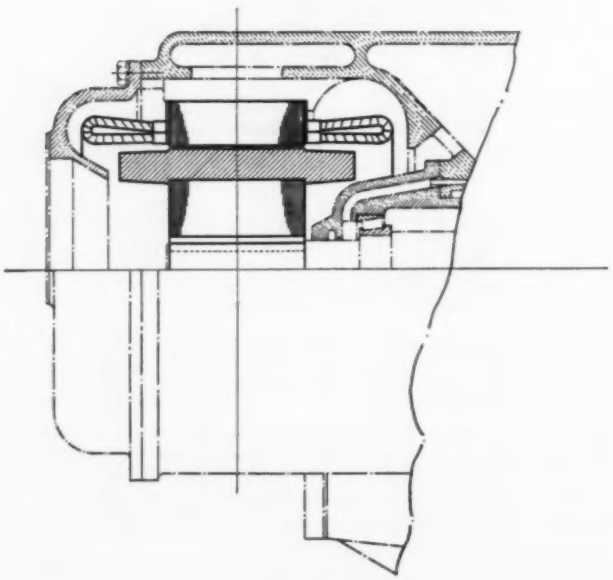

FIG. 17

driven machine than is possible using the more widely used standard mountings. Fig. 14 shows how the driven machine may be substituted for the vertical base so that bosses on the end brackets are employed directly as the means of attachment. It will be readily seen that this provision incorporated in the brackets introduces no interference with machining operations arranged for brackets where this is not required. Indeed, the presence of these bosses in standard foot-mounted horizontal motors is in no way detrimental and may be useful in mounting brakes, gear guards, or other accessories.

Fig. 15 shows an intimate mounting of an enclosed-ventilated motor in which a portion of the driven machine becomes the substitute for the fan or blower casing. The motor is in this case supported through the bracket to the frame ring, and a very neat and compact arrangement is obtained.

In the case of open motors, the driven machine is sometimes formed to take the place of the end bracket, winding clearances and air guides being provided as required. In such cases a so-called "three-quarters" motor is provided, as illustrated in Fig. 16.

In some cases it is expedient, where the shaft of the driven machine is relatively large and rigid, to overhang the motor rotor on an extension of such a shaft without an outboard bearing. The wound stator core may be supported in an extension of the frame of the driven machine, with the net result of great compactness and simplicity. The motor parts furnished in such a case are illustrated in Fig. 17. The wound stator without frame (which is shown in dotted outline), being a unit by itself, can readily be pressed into any frame structure provided, as long as it has the requisite machined fits, clearances for windings, and passages for ventilating air.

Of necessity, in a short paper, a subject such as this must be treated rather sketchily, but it is hoped that this brief discussion will serve to show the efficiency possible in designing electric motors to fulfil in widely varying conditions their simple mission of "service."

Discussion

GEORGE A. BOUVIER.[2] Evidently Mr. Brown has some quarrel with the term "flange-mounted motor." Possibly he is reluctant to identify the types of motors generally designated as flange type for sound reasons; nevertheless, the writer is inclined to believe that the general use of the term justifies its continuance.

Industry, as a whole, is wont to look upon an electric motor as a unit machine in itself, distinct and separate from other equipment. It is true that this is so when the motor is mounted on a ceiling, wall, or floor for driving machinery, lineshafts, etc. The electric motor in such cases is a machine unit used instead of some other power device such as a steam engine, gas engine, or water wheel because of its greater utility or convenience. The machine-tool industry 15 years ago was justified in regarding an electric motor in this way. It is now the general practice, however, in approximately 75 per cent of the cases to drive machine tools by individual motors, but unfortunately the practice of incorporating motors as component parts of the structure is not carried out in as many cases as is practicable. This is also true as to fuse panels, switches, starting equipment, wiring, etc., with the result that a machine, otherwise an engineering achievement to be proud of, looks as though a number of afterthoughts had been hastily incorporated.

Unquestionably the standardization of foot-mounted motors will aid considerably in the further application of built-in drives for machine tools and is a long step forward. Personally the writer would like to see a more intensive development of a corresponding standard covering the flange-type motor mountings. As has been pointed out, these are already used by foreign manufacturers and on many of our own machine tools, and the writer emphatically agrees that it results in a neater looking job and impresses one as a better engineered job. It has been said that the flange-type motor costs more because there is only a small demand

[2] Development Engineer, Western Electric Company, Chicago, Ill.

for them. On the other hand it seems that the demand is influenced by the cost. However, the increased cost, relative to the cost of the general class of machines on which the flange motor is installed, is practically negligible and should not unduly influence any but price buyers. It is the matter of delivery time that is particularly objectionable, and the writer has often been forced, because of the time involved, to use a foot-mounted motor when he would have preferred, for engineering reasons, to use a flange-type motor.

It is remembered, when electrical starters and generators were first used on automobiles, that most of them were equipped with feet, which at that time were most convenient to use because of the tacked-on nature of the first installations. The quickness and skill with which the automobile industry incorporated the starter and generating units as built-in parts of the motor can very well be followed profitably by the machine-tool industry. The adoption of the flange, or what amounts to the equivalent of a flange for these installations, is good evidence of the value of this mounting, particularly for types of machines such as machine tools where the drive should be an integral part of the machine.

The writer would like to see more built-in units—built-in not as attachments or accessories to a machine, but designed to be just as much an integral part of the machine as the clutches or gear boxes. He personally would not have much objection to purchasing such a machine from a competent and reliable builder of machine tools. It would be enough to know that the supplier was as much responsible for this element of the machine as for any other. The writer is of course unfamiliar with the facts on which Mr. Brown based his statement that they had to be prepared to furnish motors with many different types of ball or roller bearings to suit the whims of the customer. It is thought that the majority of users could be satisfied if the maker of the motor would give assurance that he is using a ball or roller bearing as satisfactory for the purpose as any other part of his motor.

The automobile industry is one that many older industries can emulate and are emulating to their advantage. No other industry has done so much in the way of standardization, yet this has not restricted it, either, to hide-bound practices of tradition. So by all means standardize motor dimensions, but do it with the thought that machine-tool engineers will regard this unit as requiring no more special consideration or pampered treatment than any other element of their machine.

MSP-53-8

Flange- Versus Foot-Mounted Motors

By HERBERT CHASE,[1] NEW YORK, N. Y.

Advantages in favor of flange mounting given by the author include: improved appearance, compact arrangement, more rigid mounting, saving in weight, less cost, better alignment, more easy attachment, and better protection against oil, chips, and dirt. Full advantage cannot be taken of the benefits of flange mounting until some effort at standardization is made. Motor manufacturers can easily bring about such a standard to their own benefit and to the benefit of machine manufacturers generally, and the latter, it is believed, will readily accept such a standard.

ENGINEERS who give the subject reasonable consideration hardly can fail to arrive at the conclusion that flange-mounted motors present a number of advantages as compared with the ordinary foot-mounted type. It is far from being the author's contention that the foot-mounted motor has no place in industry, but careful analysis of the conditions involving motor applications to machine tools and to other forms of industrial machines brings out at least eight advantages in favor of the flange-mounted type, whereas the disadvantages, in cases where they are applicable at all, are relatively few. Chief among these is a lack of availability from stock, a drawback which would be overcome quickly, of course, once the flange-mounted type is standardized and when it has found more extensive use.

It is not the contention that the base-mounted or foot-mounted motor should be displaced where it possesses any real advantage over the flange-mounted type, but rather that the subject of flange mounting should be given more consideration than has been accorded to it in the past.

The advantages in favor of flange mounting, as they already have been presented elsewhere[2] by the author, include the following:

1 Improved appearance of the finished machine. The motor looks as if designed as an integral part of the machine, not as if added as an afterthought.

2 Compact arrangement often reduces the floor space required.

3 A more rigid mounting. Overhanging brackets are avoided.

4 A considerable saving in combined weight of machine and motor.

5 Less expense, since a separate bracket is not required.

6 Correct alignment is readily secured, especially if the flange of the motor or the machine flange is recessed to pilot the mating member.

7 Attachment is more easily made, without shimming or other adjustment.

8 Often better protection is afforded against oil, chips, and dirt.

As against these advantages, not all of which, of course, are likely to be realized in any one design, there is the disadvantage of relative unavailability. To date, the mounting flange has not been standardized, and ordinarily flanged motors are not carried in stock. Consequently, replacements, in the event of motor trouble, are somewhat less readily made than they would be with a base-mounted or foot-mounted motor.

In this connection, however, it must be admitted that the foot-mounted motor is not completely standardized. Certain proposed standards for certain types of foot-mounted motors have been adopted, and motors made to these standards are shortly to become available commercially, but this standardization extends so far to include only squirrel-cage induction types.

It is doubtful whether any two makers supply motors for flange mounting with the flange itself and its position in respect to the shaft and other parts of the motor the same. This means, of course, that a different connecting flange must be provided by the machine manufacturer if the machine purchaser is given an option as to make of motors, but a similar diversity exists also in respect to foot-mounted motors, as a variety of brackets is necessary to adapt these motors to the same make of machine. In many cases, also, the same make of motor is not interchangeable as between a.-c. and d.-c. types, but at least one company (Westinghouse) has standardized, so far as its own practice is concerned, a considerable group of sizes of flange-mounted motors in which both a.-c. and d.-c. types are interchangeable within certain limits. It has been found easier, in fact, to effect interchangeability with the flange-mounted type than with the foot-mounted type.

Generally speaking, a smaller and less expensive pattern is necessary to adapt a flange-mounted motor to a machine than is required to adapt a bracket for accommodating a foot-mounted motor.

Today, motors for flange mounting usually cost somewhat more than the foot-mounted type, not because they are inherently more expensive to make, but because they are regarded as special and are made in smaller quantity. Many makers who build machines of various kinds in large quantities have adopted their own standard on flange-mounted types of motors in order to gain one or more of the eight advantages named as applying to this type.

To establish further the case in favor of the flange-mounted motor, the advantages already enumerated will bear some elaboration.

That improved appearance is realized will hardly be questioned by those who compare the accompanying illustrations of flange-mounted motors with motors mounted in other ways, especially on the ordinary pedestal or base. Compactness also is evident from an examination of the designs here illustrated. It is easy to set the flange-mounted motor into the base of many machines and in some cases to house it entirely within the base. While this is true also with other types of mountings, in certain instances, the same degree of compactness is rarely obtained, except perhaps with the barrel-mounted types widely used in woodworking machinery.

Reduction in floor space occupied is obtained in some cases by using a vertically mounted motor placed above the machine. In the opinion of some engineers, a flange is the logical form of con-

---

[1] Associate Editor, *Product Engineering* and *American Machinist*.

[2] "Flange- or Foot-Mounted Motors?" *Product Engineering*, Feb., 1930, p. 84.

Presented at the Fourth National Machine-Shop Practice Meeting, Chicago, Ill., September 22 to 24, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

nection when a vertical motor is to be employed, but to the author it seems as illogical to employ a vertical bracket to mount a foot-type motor as to use a horizontal bracket when the same motor is horizontally mounted. In other words, it is equally logical to use the flange whether the motor is placed vertically or horizontally.

In many installations of foot-mounted motors, overhanging brackets are required, or seem to present the best mounting arrangement for that type. Substitution of a flange-mounted motor under similar circumstances usually will provide a more rigid mounting without the same degree of overhanging. Examination of accompanying illustrations will make this point clear. For similar reasons there is a marked saving in weight with the flange mounting because the heavy casting for the bracket is eliminated.

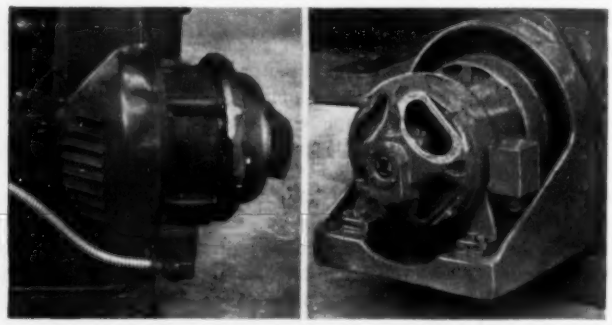

FIG. 1 MOTORS ON GOULD & EBERHARDT SHAPER.
(At the left, the flange-mounted motor; and at the right, a foot-type motor with special mounting bracket. Obviously the former is the neater and less expensive arrangement.)

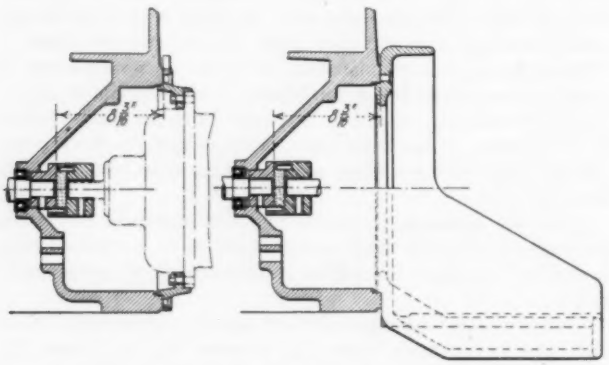

FIG. 2 SECTIONAL VIEWS OF THE TWO MOUNTINGS ILLUSTRATED IN FIG. 1

On the same score, the cost of combined motor and mounting is less in the case of the flange-mounted type, assuming that an extra charge is not added for the flange motor merely because it is classified as a non-standard type. By countersinking the flange into the machine, or by providing on the flange or on the machine a centering boss which is recessed into the mating member, perfect alignment can be assured without any shim, a decided advantage compared to the average arrangement with foot-mounted motors. No shims are required to adjust the shaft height, and the end of the shaft remains in fixed relation to the flange itself.

Better protection against grease, dirt, and chips is likely to be afforded with the flange-type motor, especially when it is placed at the top of the machine, as is done in many installations. It does not follow, of course, that a similar advantage cannot be secured with the foot-mounted type, but in general it is less likely, partly because the foot-mounted motor frequently is mounted on a base extension closer to the floor, where more dirt, oil, and chips fall upon it.

Among machine-tool manufacturers there are already a large number of users of flange-type motors, despite the lack of standardization. Many more certainly would be used if standardization had been effected and the price of the motor was not higher than for the foot-mounted type. Even so, the savings in a flange coupling as compared to a bracket sometimes more than offsets the difference in cost of the motor itself, and brings about a net saving in weight of the combined units.

Ray Millholland, of the Millholland Sales and Engineering Company, is among the designers who have employed large numbers of flange-mounted motors. He mentions the following points as being highly desirable in designs using such motors: Proper protection against dust and chips and provisions for proper cooling. Accurate balance of rotating parts to prevent the transmission of vibration to the frame and tools of the machine. Minimum overhang of the motor. In such machines as the Millholland Company builds it is necessary, of course, to have a motor of ample power, even though the tool used may be dull. Much the same observations might be made concerning foot-mounted motors. It is, for example, just as undesirable to have a bracket with excessive overhang as to have a motor which overhangs more than necessary.

The illustrations (Figs. 1 and 2) of motors mounted on a Gould & Eberhardt shaper afford an excellent opportunity for direct comparison between flange and foot-mounting, as this machine is supplied in either way. W. F. Zimmerman, chief engineer of the company, points out that the flange type of mounting is preferable from the standpoint of attaching, but says that, unfortunately, all motors cannot be mounted in this way because there is no part of the motor housing that can be machined so as to centralize the motor and at the same time secure it to the attaching plate. Presumably this refers to motors with standard frames but without feet. It certainly does not apply to a motor designed for flange mounting.

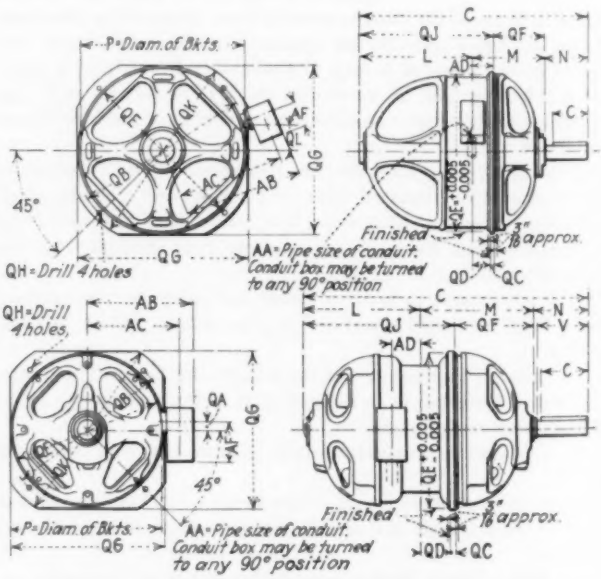

FIG. 3 OUTLINE DRAWINGS OF MOUNTING AND OTHER DIMENSIONS
(These are the interchangeable d.-c. and a.-c. flanged motors standardized by Westinghouse.)

"The flange type is the neater mounting," continues Mr. Zimmerman, "and by centering some portion of the motor frame

there is very little difficulty in attaching as compared with the foot-type mounting."

A flexible coupling is employed to connect the motor shaft and the driven shaft of the shaper. In the same machine, when it is fitted for pulley drive, the driven shaft is continued across the housing to a separate flange where a Timken bearing is employed. This arrangement appears to meet an objection raised by another engineer to the effect that a machine designed for use with a flanged motor is not readily adapted to a pulley drive. This may be true in some cases, but the substitution of a flange containing a bearing in place of the flange of the motor seems to afford a ready solution of this particular problem under certain conditions.

Contrary to some assumptions, the flange-type motor frequently lends itself readily to a belt or chain drive or to the use of gear reduction. It is not a difficult matter to secure almost any reduction desired with either flange type or foot-mounted type of motors. Neither is it difficult to provide for belt or chain adjustment, if this is required, either by turning the flange-mounted motor about one of the flange bolts as a center or by sliding it bodily with its flange mounting in suitable ways. In the case of the gear burnisher made by the Cincinnati Shaper Company, a compact arrangement has been effected by removing one of the standard motor end brackets and substituting a flange with a recess adapted to the particular special bearing required. This works out nicely, but naturally requires a different flange casting for different makes of motors.

According to C. E. L. Dapprich, general engineer of the Westinghouse Electric and Manufacturing Company, interchangeability as between a.-c. and d.-c. types of motors is readily accomplished by the use or flange mounting. This is borne out by the practice of the Westinghouse company, which has standardized a ball-bearing and sleeve-bearing series of flange-mounted motors arranged in four groups covering a wide range of power. Each frame in each a.-c. group of this make is interchangeable in mounting dimensions with every other frame in the same group, and also with the frames of motors in the corresponding d.-c. group. The various dimensions involved in this standardization are shown in an accompanying illustration (Fig. 3).

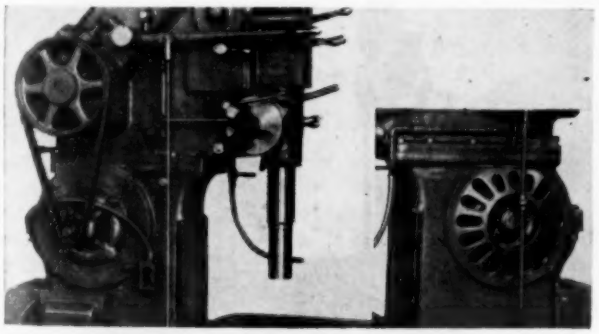

FIG. 4 TWO VIEWS OF A BARNES DRILL WITH FLANGED MOTOR MOUNTED INSIDE THE COLUMN
(Openings for ventilation are shown.)

That it is an easy matter to provide complete enclosure of a flange-mounted motor, as well as proper ventilation, is indicated by the illustration (Fig. 4) of the Barnes drill. In this instance, if the machine is ordered for belt drive instead of for motor drive, a plain column is substituted for that shown. Another illustration of the use of a flange-mounted motor that is built into a machine is that of the Pratt & Whitney jig borer. In this case a vertical motor is employed, the lower end frame being a part of the housing of the head of this machine.

In some respects, European machine-tool manufacturers have gone farther in the use of flange-mounted motors than have American manufacturers. This applies in particular to their use on radial drills, in which considerable overhung weight is added to the arm by placing the motor on the arm and close to the point at which the power is to be applied. An alternative construction used in the Cincinnati-Bickford radial drill is shown in Fig. 5. In this case a flange-mounted motor is employed, but it is placed on the opposite side of the column from the arm, and thus tends to counterbalance rather than to add to the weight of this arm. This same radial drill is furnished, when desired, with a foot-mounted motor, but in that case a heavy and rather expensive bracket is required to hold the motor.

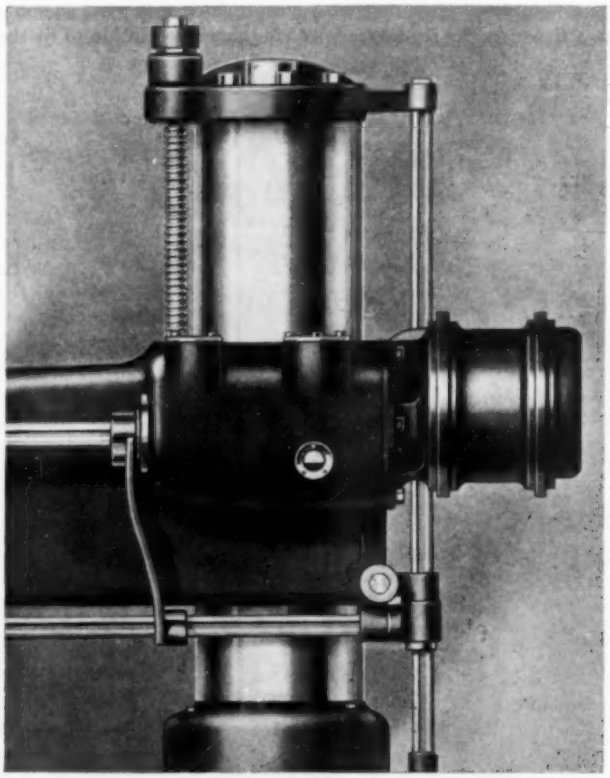

FIG. 5 FLANGED MOTOR ON CINCINNATI-BICKFORD RADIAL DRILL
(Considerable weight is saved and the arm is partly counterbalanced by this location.)

Several manufacturers of machine tools incorporating drilling, milling, and tapping units today are employing flange-mounted motors driving direct to the spindle. In some cases the unit is arranged to be swung through a considerable angle. Among the advantages of the flange-type motor for this type of application is that it gives a compact and self-contained unit. In some such drills built by the Kingsbury Machine Tool Corporation three or more flange-type motors are employed (Fig. 6), and in another arrangement the same motor is used with a belt drive, in which an idler is employed to facilitate speed changes. A small pulley at the lower end of the same motor drives the coolant pump.

Various engineers have pointed out that considerable care is necessary when flange motors are employed to avoid unbalance which produces vibration, not only in the motor itself, but in the machine to which it is attached. Undoubtedly this is true, but it is equally true that many manufacturers require considerable care in balancing motors of any type that are mounted on the

machine, for otherwise the motors are likely to be noisy and to transmit vibration.

A rather unusual form of flange-mounted motor is that employed by the Porter Cable Company in its horizontal disk grinder. In this case the motor is built in as part of the column of the machine, being placed between the grinding wheel and the column.

Another and somewhat similar vertical arrangement of the motor is used in the Gorton milling machine illustrated in Fig. 7. In this case, however, the motor is placed on top of the machine and drives the head through a four-step grooved pulley and belt. The motor itself is not flanged, but is provided with what amounts to a flange in the form of a split ring machined inside to fit the

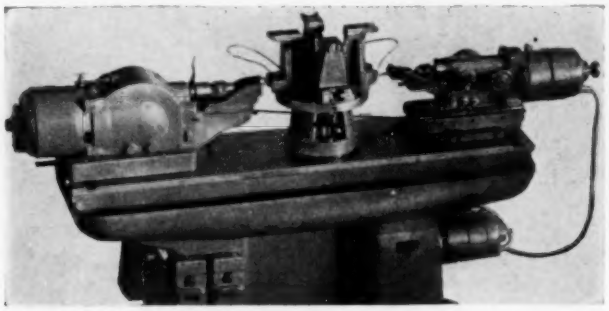

FIG. 6 KINGSBURY DRILL USING THREE FLANGED MOTORS

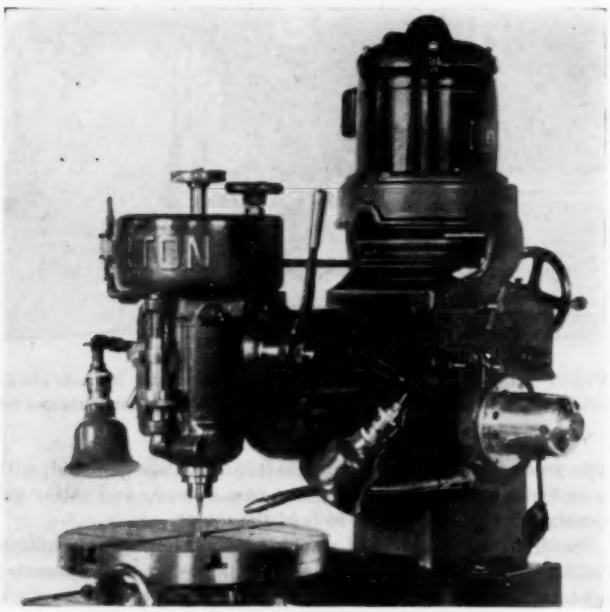

FIG. 7 VERTICAL MOTOR MOUNTING ON GORTON MILLER
(This incorporates two flange-mounted motors.)

motor housing and outside to fit into a recess on the supporting bracket. This bracket forms part of a slide which can be moved back and forth to tighten the belt. The same machine employs a small flanged blower motor driving an impeller which provides a current of air for blowing chips off the work.

A number of manufacturers of tools in England and Germany employ motors with flange mountings for much the same reason that the same type of motor is being used in this country. Some of the illustrations given (Figs. 8 and 9) show slight differences in practice, but basically the designs are similar to those in American tools.

Although most of the illustrations apply to machine tools, it need hardly be said that similar applications of flange motors are easily made to machines of other types. Many are now used extensively on small machines built in large production, such as vacuum cleaners, pumps, and gear reducers. Naturally these

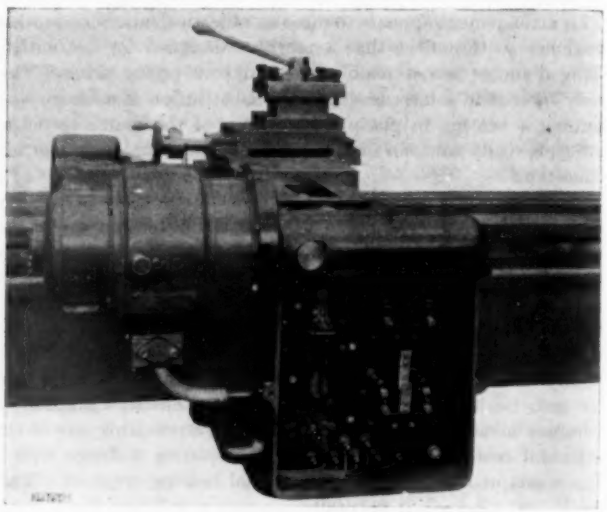

FIG. 8 FLANGED MOTOR ON DEAN, SMITH & GRACE LATHE
(This is used to traverse the carriage on a 25-ft. bed.)

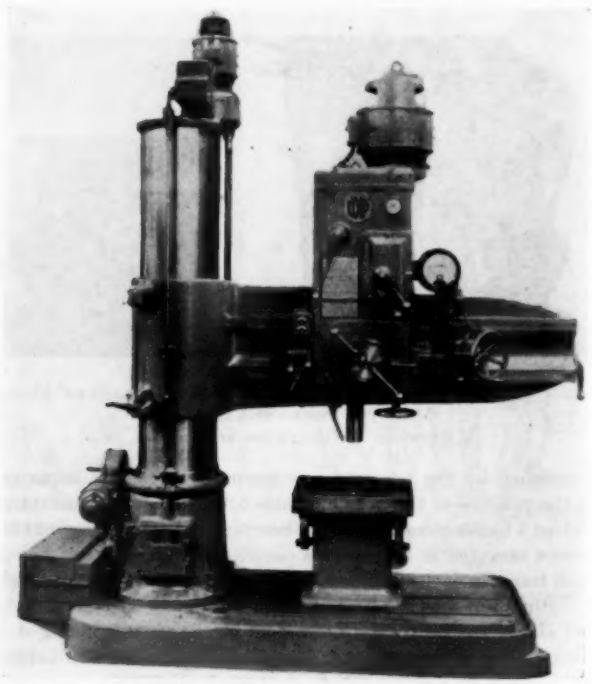

FIG. 9 GERMAN KOLB RADIAL DRILL
(This has three motors of the flanged type.)

applications differ in detail from those described, but they involve similar conditions and advantages.

In cases where the machine manufacturer requires very large numbers of identical motors he can purchase these with flange mounting when desired. However, each purchaser designs his own "standard" flange, except in the case of the Westinghouse

company, already cited, and in this case the standard refers primarily to motors of quite large size.

Naturally, full advantage cannot be taken of the benefits of flange mounting until some effort at standardization is made. Just so long as machine-tool and other machine manufacturers are willing to put up with the unnecessary expense of special mountings, so long will somebody pay the necessary extra expense of special brackets or flanges. If machine manufacturers would get together, however, and cooperate with the motor manufacturers in bringing about motor standardization, including, let it be hoped, a flange-mounted type, both groups would reap considerable advantages, as also would the purchasers of the machines. It is time that this subject of standardized mountings and mounting dimensions for motors be given the attention it evidently demands.

Several motor manufacturers already have their own standards for footless motors. To make such a motor into a flange-mounted type it is necessary only to add a flange to the casting for the drive-end bracket. The dimensions and drilling of such a flange could be standardized easily in such a way as to make it adaptable to any of these motors, without interfering in any way with the design of other portions of the motor than the drive-end bracket. It would remain then only to standardize the drive end of the shaft and the position of the standard flange with reference to the end of this shaft to make all such motors completely interchangeable, at least for all overhung applications.

Motor manufacturers could easily bring about such a standard to their own benefit and to the benefit of machine manufacturers generally. The latter group, it is believed, would readily accept such a standard, thereby relieving themselves and the motor manufacturers of needless delays and expense incident to the production of special flanges.

Discussion

[NOTE: A discussion of this paper jointly with the paper of J. L. Brown by George A. Bouvier will be found with the discussion of the latter paper.]

J. W. HARPER.[3] The question of standardizing a flange-mounted motor, as suggested by the author, already has been given considerable thought by electric-motor manufacturers. At the present time there is before N.E.M.A. a proposal outlining certain dimensions for a flange-mounted motor to be used in connection with the dimensions already standardized for foot-mounted motors.

Five principal dimensions are being considered in this proposed standardization:

(1) Distance from face of flange to shoulder on the shaft (distance from shoulder to end of shaft has already been standardized)
(2) Outside diameter of flange
(3) Diameter of bolt circle in flange
(4) Thickness of flange
(5) Size and number of bolts in flange.

The type of construction proposed would be similar to that shown in Fig. 4 of the paper. By machining both sides of the flange, the motor can be mounted either inside the machine, as shown by Fig. 4, or with the motor outside, and only the pulley end shield inside. Machining the outer periphery of the flange permits it to be used as a rabbet for locating if this should be necessary.

While such a mounting has numerous advantages, there are also several disadvantages. In the first place, if the motor is mounted with the pulley end shield inside the machine, the ventilation on that end is likely to be very much restricted or cut off altogether, unless the machine designer makes provision in his base castings for louvers or the like, as was done in Fig. 1 (left). Another disadvantage is that different flanges are usually required for each different diameter. In order to obtain proper bolt clearances, etc., the bolt circle must be based on the largest diameter frame, so that if the same flange is used for smaller diameters, it becomes abnormally large.

Both these disadvantages can be overcome by still another type of flange where the face of the flange, instead of being located near the end frame of the motor, is located near the nose of the bearing housing. By having the flange thus spaced away from the motor proper, provision can be made by the motor manufacturer for adequate air supply. Furthermore, since the motor diameter does not figure in so prominently, the same flange mounting can be used for more than one diameter of motor.

A disadvantage of type 2 is that the overhang is increased materially over that of type 1. In the latter it is desirable to keep the flange as far from the bearing nose as possible to minimize the overhang. In the former the flange should be spaced away from the bearing nose a distance approximately equal to the thickness of the machine frame. This is to allow mechanical clearance for a chain or belt drive inside the machine if such is used. Type 2 mounting is the one principally used by European manufacturers, as evidenced by the two examples given by the author.

Still another mounting which might be considered of the flange type is where the motor, usually without feet, is furnished less pulley end shield. Under such conditions the end shield is incorporated into the machine design itself, and of course must be furnished by the machine builder to meet his own particular requirement. Usually some special form or feature peculiar to that design is required. An example is where the end shield might be combined with a chain guard or support, or where the end shield would be part of a gear case. Such a construction naturally results in the minimum overhang and most compact arrangement, and for these reasons has found considerable use in this country.

Unquestionably, flange mounting in any of the forms outlined is coming more and more to the front, and its more general use will be hastened by standardization of mountings on the part of the electrical manufacturers.

J. L. BROWN.[4] In commenting on this excellent paper, the writer wishes to offer a few comments which have to do with some of the problems and difficulties encountered in the attempt to make this type of monting practical. These are as follows:

1 Question as to the field for the flange-mounted type of motor.

(*a*) Westinghouse has a line of flange motors available, yet there is no great demand for them, and at the same time there is some demand for other types of end mounting, where an external flange on the motor is not suitable.
(*b*) Machine-tool speeds are usually either higher or lower than available motor speeds requiring some sort of speed reduction drive, rather than direct coupling and rendering end mounting of any kind less advantageous than it otherwise would be.
(*c*) Foot-mounting standardization is in process of development. It may be suggested that after its advantages are fully available and in profitable use, the field for end mounting will be more clearly defined.

2 Type of end mounting to be standardized.

(*a*) If and when end mounting is standardized, the type

[3] General Electric Company, Schenectady, N. Y.

[4] Industrial Motor Engineering Department, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa. Mem. A.S.M.E.

should be such as to be applicable to the standard motor parts with minimum addition of material and machining operations to avoid penalizing this type of mounting with large additional motor cost

(*b*) The design should, as far as possible, dovetail into already existing designs to avoid adding to the number of types of motor, as this tends to reduce the activity of each type, and this, in turn, increases costs

(*c*) It may be suggested that when a real flange mounting makes the most efficient design, a steel ring may be provided and bolted to the motor end bracket and the driven machine, respectively.

R. E. W. Harrison.[5] The author brings up an interesting subject at an opportune moment, having regard to the efforts

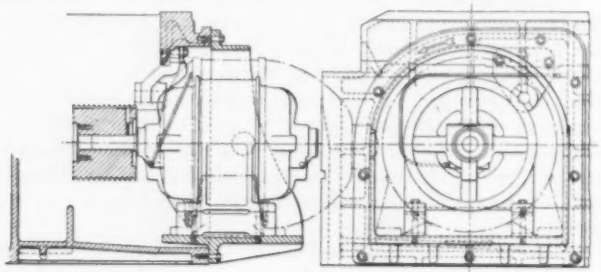

Fig. 10

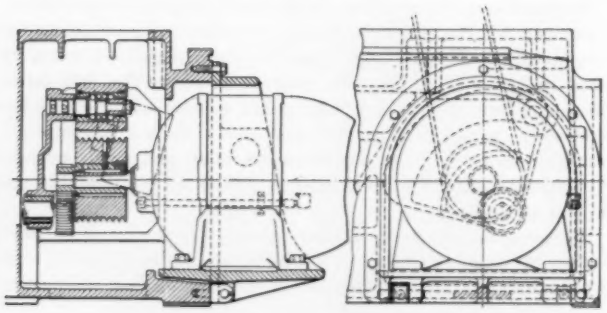

Fig. 11

now being made by the motor manufacturers to accomplish standardization of all those important dimensions of electric motors which affect the type and method of mounting.

In his enthusiasm for the subject, the author, however, has drawn a number of conclusions with which issue can be taken, and based on an experience with close on to one-thousand applications of end- or flange-mounted motors, the following data are offered, taking the list of eight advantages which the author attributes to the flange mounted motor in the order in which they are presented:

1 Improved appearance of the finished machine.

(*a*) It is readily agreed that the flange-mounted motor presents a better appearance than any other type of mounting. However, the disadvantages of lack of flexibility in securing alignment between the driving pulley of the motor and the driven member frequently lead to a condemnation of the flange method of mounting the motor

(*b*) With a flange mounting the inner bearing of a motor is often in a difficult place to reach for inspection, oiling, and eventual replacement

(*c*) The average maintenance foreman and mechanic today frequently expresses the desire for a motor which can be slid into its operating position and then bolted down when the niceties of alignment have been obtained.

2 Compact arrangement often reduces floor space required. While this is true, there is available an alternative method of mounting the motor which gives precisely the same advantages as regards consumption of floor space without many of the inconveniences inseparable from the flange-mounted motor.

3 A more rigid mounting. It is readily granted that a properly designed flange mounting constitutes one of the most rigid forms of mounting which can be devised. However, when this degree of rigidity is secured at the expense of convenience of operation, its merits are likely to take on a diminished importance, having regard to the improvements affected in motor manufacture during the last few years. Such improvements include improved dynamic balance, closer fitted bearings, and improvement in constancy of torque.

4 A considerable saving in combined weight of machine and motor. This saving in weight is apparent only in those cases where a relatively clumsy shovel-type bracket is the alternative method of mounting under consideration.

5 Less expense. Practical experience in both the engineering department and the works and a survey of the final costs indicate that with the facilities for end mounting or flange mounting now available, it is very definitely much more expensive to mount a motor by this method than the alternative foot-mount-method. Numerous patterns have to be kept readily available to accommodate the varying sizes and types of motors of different makes, and these patterns have to be duplicated over and over again to accommodate the peculiarities of the individual motor maker's designs.

6 Correct alignment is readily secured. Agreed, providing that the flange or mounting ring is designed to suit each individual make and size of motor likely to be mounted on any one of a variety of machines.

7 Attachment is more easily made. The consensus of opinion of a number of maintenance departments of the leading manufacturing concerns is to the effect that the job of attaching a barrel-type flange-mounted motor is more costly in time and effort than is the case when the motor is equipped with feet.

8 Often better protection for the motor is obtained. While this in a measure is true, it is possible to obtain all the advantages of adequate protection with a properly designed shelf-type flange mounting of the general proportions shown in Fig. 10. Further development of this type of mounting is shown in Fig. 11, whereon it will be noted that the shelf mounting is provided with a hinge pin so that the motor may be tilted in such a way that the driving belts can be readily removed from the pulley.

The chief difficulty up to date which has been experienced with motors of the flange type is their relative unavailability at short notice, and this has necessitated manufacturers who use them carrying comparatively large stocks of expensive equipment, which is often slow moving on account of the great variety of electrical circuits in general use.

It is therefore the writer's recommendation that, in the present state of the art, extreme caution be used in making a general recommendation in favor of flange-type motors.

There are and there always will be drives on machine tools and other mechanical equipment where the flange-type motor is the only logical way of securing a mechanical drive which is soundly designed in accordance with the best engineering practice. These instances, however, are relatively few, and until the leading motor manufacturers can get together and standardize on flanges with a guaranteed interchangeability, it is suggested that use be continued of the foot-mounted motor with all its shortcomings.

[5] Chief Engineer, Cincinnati Grinders, Inc., Cincinnati, Ohio. Mem. A.S.M.E.

A typical example of where it would be difficult to improve upon the foot-mounted motor is provided by the modern milling machine where a standard foot-type motor is mounted in the base of the column, from which position it can be readily drawn out and serviced whenever the necessity arises. Furthermore, the motor in this position is thoroughly protected against chips, oil, and dirt.

The writer submits the following recommendations as regards procedure:

Suggest that the motor manufacturers carry through and intensify their efforts toward the standardization of foot-mounted motors, but that, concurrent with this, a study be made by all the leading electrical-equipment manufacturers of the possibilities of interchangeable standards of flange mounting, so that no consideration of mounting design will deter the designing engineer from using either the flange-mounted or foot-mounted motor whenever he is convinced that the overall efficiency of his product will be improved by the use of either one of these two types of mountings.

J. D. Riggs.[6] In an intricate machine of course it is the sum total of the various elements that determines its merits, but in an analysis of the same machine we necessarily consider and discuss one element at a time together with some others closely related. In the present case it seems the author might have extended his discussion to include some consideration of the means for connecting the motor shaft with the driven machine.

The direct connection through a flexible coupling certainly has its merits, but does not always give the required speed. Certain forms of roller drive seem to have been used in Sweden on centrifugal machines running at high speed; in England, the Garrard toothless gear has been applied in various ways with apparent success; and in France, it is learned the Société Anonyme has at least got into the patent records with a roller drive of some considerable merit.

If some form of roller transmission can be brought out to serve as a speed increaser in some places and as a reducer in others, and also function as a flexible connection, then it seems the flange mounting for motors might become the common practice. But as one purchaser can see only the merits of toothed gearing, another the reliability of the leather belt, a third wants steel belt, a fourth insists on the short-center silent chain, a fifth wants tex-rope drive, and a sixth intimates that the machine-tool builder should have already established some standard drive, so long as such a variety of demands has to be met it is not easy to standardize on a motor mounting with any hope of having the standard generally accepted.

C. E. L. Dapprich.[7] In order to place flanges on two or more circular or approximately circular motor frames and have the complete motors interchangeable in regard to mounting it is necessary to control only three or four major dimensions. This compares with five major dimensions which must be controlled on foot-mounted motors. The four major dimensions on flange-mounted motors are:

(1) The diameter of the bolt circle for the mounting bolts
(2) Size of mounting bolts
(3) The axial distance from the face of the flange to the nose of the rear bracket on the motor; and also, if accurate centering is required, as is usually the case
(4) A pilot fit on the flange which is to register with a corresponding fit on the mounting surface.

[6] Designer, Indianapolis, Ind. Jun. A.S.M.E.
[7] General Engineer, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

If complete interchangeability is desired instead of only interchangeable mounting, then the shaft extension and its keyway dimensions also must be specified.

When a flange is to be added to the frame or bracket of a motor, it seems quite natural that a circular one, or, more accurately expressed, an annual disk flange, should be used. This is quite in line with old-established practice on flanged pipe. But the conditions surrounding the mounting of a motor on a machine are very different from those which govern the coupling of flanged pipe. The fundamental difference is that the pipe coupling is to make a joint tight against heavy internal fluid pressure, whereas on the motor it only has to resist the motor torque and keep the pilot fits in engagement. This very moderate requirement combined with the fact that in many applications it is desirable or even necessary to place motors close together or immediately adjacent to some obstruction, shows that although the annular disk flange is satisfactory in many cases, the "squared" disk is better. As long as four symmetrically spaced mounting bolts are used, it is advantageous to "square" the disk. The "squared" disk flange furnished at least as good a support as the circular disk, and it allows several motors to be mounted together with the minimum possible center distances. From this viewpoint the extra material in the annular disk flange in every case is not only wasted, but on short-center jobs where this extra material must be machined off it causes an even greater waste in labor.

The German standards on flange-mounted motors are available and have been issued in leaflet form (DIN-VDE 2941), which shows that they use the annular disk flange and on the larger sizes use eight mounting bolts instead of four. Placing the flange on the bracket has the advantage that it can be kept within the frame diameter.

As far as strength is concerned, the writer believes that on small and medium sizes of motor frames which are to be standardized four mounting bolts are quite sufficient and that even where severe vibration is encountered four bolts will still be sufficient if the pilot fit is snug.

A full and detailed discussion of a subject as important as standardized dimensions on flange-mounted motors is very desirable, and following that a careful approach to standardization is also very desirable, since all realize that a standard once set is a rigid and almost immovable thing.

Robert C. Deale.[8] While flange-type motors have undoubted advantages for many applications, particularly for special machinery, it is believed that the foot mounting lends itself better to general use, such as a standard machine tool, which must be adaptable to varying service conditions. It is known that the first machine-tool manufacturer to make extensive use of the flange mounting for motors became very much discouraged because of the difficulties encountered, and the chief engineer expressed the opinion to the writer that the company was just about ready to abandon that type of mounting, after a trial that covered several years.

Most machines, particularly machine tools, must be adaptable for motors of several different horsepower to suit the varying conditions under which the completed machine is to be used. In addition, because of the different frequency conditions found in practice, driving motors of different speeds must be used, while it is usually necessary to hold spindle speeds constant. As a result, changes must be made, either in a pair of gears, or in a belt or chain drive, between motor and spindle, in different machines. For manufacturing reasons this change is usually made in a pair of gears outside the machine proper, or in the motor pulley or sprocket. It is believed that these changes are easier to make

[8] The Norton Company, Worcester, Mass.

with a conventional foot-type motor than with a flange-type, because of the greater accessibility of the motor spindle. Some years ago the writer was interested in a machine that had a motor bracket which covered the spindle end of the motor, and consequently gave an effect similar to that of a flange mounting, although standard foot-type motors were used. It was found that there was considerable difficulty in lining up the first pair of driving gears, of which the pinion was mounted on the spindle, so that they would run smoothly. Unless all gear reductions are built inside the machine and a flexible coupling is used between motor and machine, it is believed that there will be more or less difficulty in lining up the motor and the machine. In the past it has been found that the standards of accuracy to which the average motor builder works are not such as to allow a motor of any type to be mounted without a considerable amount of time being spent in aligning it. It is believed that the foot-type motor lends itself to such alignment much better than the flange-type.

There is some question whether a flange-type motor mounted horizontally is stiff enough for the ordinary machine. When a vertical motor is so mounted, the line of action of the weight falls within the base and helps to hold the motor in place. On the contrary, the weight of a horizontally mounted flange-type motor introduces a bending action that it is believed would be undesirable and would make the machine particularly susceptible to the setting up of vibrations. In the case of most machines this would be very serious particularly for the driving motors of metal-cutting machines.

There would seem to be no inherent difference as far as protection of a motor from oil, chips, etc., between the two types. It is believed that most of the differences found are caused by differences of design. With an equal attention to this detail, it is believed that one type would be as satisfactory as the other.

Where all shafts of a machine are necessarily vertical, as in the jig borer mentioned in the paper, or in a drill, the vertical motor eliminates the use of bevel gears, that are usually less satisfactory than the spur or spiral gears generally used.

In conclusion, it is believed that it is unwise to attempt the general use of flange-type motors, particularly for general purpose machinery, unless such use is clearly called for, as such use will be very likely to cause difficulty.

DR. ING. MAX KRONENBERG.[9] The writer notes that also in the United States the flange motor is receiving more attention than before.

Among the advantages justly attributed by the author to the flange motor, there still is missing a very important viewpoint. Through use of the flange motor not only are extending parts, floor space, etc., saved, but also a great amount of machine parts. In the horizontal flange motor-driven boring machine, in use here, the short driving distance is evident. The flange motor allows for installation close to the working place, and this the writer considers its best characteristic. No more complicated transmission of the developed power is necessary; the source of power is mounted directly on the spindle box. In preceding designs much superfluous intermediate gear was necessary to transmit the power to this point. Hence, the advantages are:

(*a*) Short-distance drive in the machine and consequently improved efficiency, thus increased utilization of the initial power.

(*b*) Omission of shafts, flat circular and conical gears, bearings, etc., and also simplified construction, making for less expensive manufacture and better accessibility. Furthermore, the easy interchangeability of flange-motor and single-pulley drive is of advantage. As a further advantage of the flange-motor standardization, existing already in Germany, one will recognize:

(*c*) The easy interchangeability of the various methods of driving. The drive may be installed after sale according to the desire of the purchaser.

Allow the writer to add a few words to another point in the paper. On the fourth page the author states that the motors for radial boring machines in the United States are installed as a counterweight on the arm, whereas in Europe they are installed on the drill head. The author considers the American method to be more advantageous. However, the writer wishes to state that the motor "as counterweight" would be correct only in case the machine is not working. As soon as the radial boring machine works, an upward-directed force is applied on the axis of the drill which tends to bend the arm upward. Hence, if the motor is installed as a "counterweight," then it assists in this upward bending. However, if the motor is installed on the drilling head, then this bending is counteracted. Hence the additional weight of the motor is no disadvantage, but an advantage.

MSP-53-9

Fundamentals of Machine Polishing

By ROBERT T. KENT,[1] UTICA, N. Y.

The success of machine polishing depends on the proper coordination of the variables present in the work itself, in the polishing wheel, in the abrasive, in the machine, and in the glue used in setting up the polishing wheel. These variables are discussed in detail, and their relation to each other are set forth. Typical polishing machines are described, as well as examples of successful machine polishing.

IN NO INDUSTRY is there so much misunderstanding, due to improper use of terms, as exists in the polishing and metal-finishing industry. In order to avoid confusion in the present paper, therefore, it will be well to establish a few fundamental definitions.

Polishing is the art of producing a smooth uniform surface on metal by means of an abrasive wheel, of greater or less flexibility, the abrasive being glued to the face of the wheel. Polishing begins where grinding leaves off, and should more properly be termed flexible grinding.

Buffing is the art of putting a luster or "color" on a polished surface. It is done by means of an abrasive composition bonded with a wax or grease, smeared on the face of a buffing wheel, made up of a series of cloth disks. The terms *polishing* and *buffing* are frequently interchanged by misinformed persons, and this interchange is often the cause of confusion and expense.

A polishing wheel is a flexible wheel with abrasive grain glued to its cutting surface. It may be of many different forms and materials, as described in detail later in this paper.

A polishing or buffing machine is a machine for presenting the work to be polished or buffed to the polishing or buffing wheel. The machine may be a separate piece of apparatus from that driving the wheel or the wheel may be integral with the machine. Polishing machines are frequently called automatic machines. This is incorrect, as the present machines are not automatic in their action, but require manual control and loading. Usually they also require manual unloading, although sometimes automatic unloading is possible. The full-automatic machine is possible but is still in the future.

The success of machine polishing depends on the consideration and coordination of all the variables that may affect the condition of the final surface. These variables may be enumerated as follows:

1 *Variables of the Work*
- *a* Material, as iron, steel, brass, copper, aluminum, etc.
- *b* Condition of original surface, as hot rolled, cold rolled, ground, machine finished, i.e., showing tool marks, pitted, scaled, etc.
- *c* Condition of final surface, i.e., degree of luster desired, whether edges must be held sharp, whether or not holes must be free from dragging or rounding over, whether or not the finished surface must be held within close tolerances
- *d* Contour of work.

2 *Variables of the Polishing Wheel*
- *a* Type of wheel, as disk, clothflex, compress, etc.
- *b* Material of the wheel, as canvas, muslin, leather, walrus felt, sheepskin, paper, etc.
- *c* Density, as soft, medium, hard, superhard, etc.
- *d* Cushion of the wheel, i.e., the depth of the flexible portion of the wheel.

3 *Variables of the Abrasive*
- *a* The kind of abrasive, as natural abrasive, such as Turkish emery, or manufactured abrasive, as Alundum, Crystolon, Carborundum, Aloxite, etc.
- *b* The grain size of abrasive.

4 *Variables of the Machine*
- *a* The peripheral speed of the polishing wheels
- *b* The speed at which the work is fed past the wheels
- *c* The pressure of the wheels on the work
- *d* The provision, or lack of provision of oscillation, in either the work or the polishing wheels, in order to avoid straight-line polishing marks in the surface
- *e* The cushion under the work as it passes beneath the polishing wheels
- *f* The tendency of the machine to set up vibration in either the work or the polishing wheels
- *g* The type of fixture used for holding work in the machine.

To these variables, there may be added another set, namely, the variables affecting the glue with which the abrasive is bonded to the wheel. These variables are as important as, if not more important than, any of the others. They are, however, completely covered in B. H. Divine's paper, "Prerequisites of Successful Polishing,"[2] and further reference will not be made here to them.

These variables are all more or less interrelated. For instance, the character of the material will determine the character of abrasive. A sharp, hard, abrasive that fractures along definite planes as it wears, such as Alundum, is the proper abrasive to use for steel. Such an abrasive is unsuitable for cast iron that requires a mirror finish. This material calls for an abrasive such as Crystolon that will crush rather than fracture. Then, too, the condition of the original surface influences the size of the abrasive grain that is to be employed. The initial abrasive should be large enough to cut down to the bottom of the deepest pit, and to reduce the metal surrounding that pit to the same level. This is followed by abrasives that are successively finer, until the final one produces the desired surface. On the other hand, it will be a mistake to use an abrasive coarser than necessary on the initial wheels, as its effect will be to put scratches in the work that the

[1] Director of Engineering, Divine Brothers Company. Mem. A.S.M.E. Mr. Kent was graduated from Stevens Institute of Technology in 1902 and for a time was associated with the Link Belt Co. of Philadelphia. For four years he was engineering editor of *Iron Trade Review*, and for many years was engaged in consulting work in the shop-practice and management fields. During the war he served as chief engineer of Meyer, Morrison & Co. and in this capacity supervised the organization of several large metal-working plants. Robert T. Kent is the son of William Kent, the author of Kent's "Mechanical Engineers' Handbook," and is himself the editor-in-chief of the 10th edition.

Presented at the Fourth National Machine Shop Practice Meeting, Chicago, Ill., Sept. 22 to 24, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] A.S.M.E. Trans., 1927–1928, vol. 49–50, MSP-50-6.

following wheels and finer abrasives must remove. Much money may be wasted in initial investment and in operating costs, by unwise selection of the sequence of abrasives.

The contour of the work will influence the selection of the type of wheel. Work with a plane surface calls for a hard, somewhat rigid wheel. Work that has a curved contour calls for a softer, flexible wheel that will fit itself to the surface to be polished. The degree of finish to be obtained also influences the speed of the work past the polishing wheel, as the slower the speed of the work past the wheel the better will be the finish.

One factor in machine polishing that is frequently overlooked is the fact that in a machine, once the work has passed the wheel, that wheel is finished with it. In hand polishing, if the surface formed is not satisfactory, the work can be applied again and again to the wheel as often as may be necessary. Hence, machine polishing usually calls for a larger number of wheels than hand polishing. For example, if a hand polisher obtains a satisfactory finish by passing work four times over a wheel set up with No. 90 abrasive, and finishes it with two passes over a wheel set up with No. 120 abrasive, the indications are that a six-wheel machine will be required to simulate the hand operation. This, however, may be modified by the differences inherent between machine and hand work. It is at this point that experience fails to be a guide, and the laboratory should take charge.

With the interrelation of the several variables in mind, and also the limitations of machine polishing as outlined, a detailed discussion of the variables affecting the application of the machine to polishing may be undertaken.

Variables of the Work

a Material. The material of which the work is composed determines the character of abrasive that must be used. Alundum or any manufactured abrasive of similar characteristics is suitable for steel and brass. These materials require sharp cutting edges to be continuously presented to the work. The abrasive, therefore, should fracture in such a manner, and along such fracture planes, as to form cutting edges that are always of the same character. An abrasive that fractures in such a manner as to cause splinters and slivers will prove unsuitable, as these splinters will put scratches in the work that will later have to be removed.

Soft cast iron presents an entirely different problem, due to the difference in metallurgy between it and steel. The sharp-cutting grains tend to dig the iron particles out of the softer carbon matrix and to roll them along the work under the wheel. This produces deep scratches in the finished surface, and attempts to remove them with following wheels set up with the same abrasive only tend to aggravate the difficulty. A solution is found in the use of an abrasive that will crush instead of fracturing. An example of this type is Crystolon. The importance of the selection of the proper abrasive for the material is indicated by the fact that much time and money were spent in attempting to machine polish the cast-iron parts of a certain article that is in wide household use. The attempts were a consistent failure until the laboratory discovered the unsuitability of the sharp cutting abrasives for this material and substituted Crystolon.

Space will not permit a detailed discussion of the selection of abrasives suitable, not only for the different metals, but also for the alloys and grades of those metals. The following is an abbreviated list of abrasives that have proved suitable for the metals indicated, and under the conditions under which the work was done:

Steel.....	Alundum	Cast iron....	Crystolon
Aluminum..	Turkish emery	Duralumin..	Turkish emery
Brass.....	Alundum	Copper	Turkish emery

Another factor that depends on the character of the material is the horsepower required. Brass requires several times the horsepower that steel does. Other materials require still different amounts of power. Research has not yet progressed to the point where it can be stated definitely what power is required over a certain range of conditions to polish the different materials. One fact, however, can be stated with certainty: *The size of motor in a hand lathe that will produce a desired finish is absolutely no criterion of the size of motor that should be installed in a polishing machine.* There are a number of reasons for this fact, but they may all be summed up in the statement that there are inherent differences in the action of the wheel on the work in the two methods.

The practice of the company with which the author is connected is to simulate in the laboratory the actual conditions under which the work will be done in the machine, and then to take wattmeter readings of the power required. It is believed that this is the only safe method to use in powering polishing machines.

b Condition of the Original Surface. The condition of the surface of the work as it comes to the polishing machine falls under several heads. The work may come directly from the forge shop or rolling mill, as in the case of automobile bumpers or steel shapes. It then will be coated with mill scale, and perhaps be deeply pitted. The mill scale will be hard and difficult for the polishing wheel to break. Furthermore, it will clog the wheel and render it ineffective in a short time. Deep pits require that the polishing wheels remove all the surface metal down to the bottom of the deepest pit and may impose a wholly unnecessary burden on the wheels. Tumbling or pickling may improve both of these adverse conditions, but if not carefully done may enhance the difficulty.

The surface may be ground or it may be machine finished. In either event, the polishing wheels must first remove the metal down to the bottom of the deepest grinding scratch or deepest tool mark. The surface may be uniformly coated with a hard scale or oxide through which the polishing wheel must break before it can actually begin its true work of polishing. This scale may dull or clog the wheel, greatly reducing its efficiency, or even putting it out of business in a very short time.

The condition of the original surface is an item of major importance in machine polishing. It is axiomatic that the polishing wheel will work best on a clean, uniform surface. If that surface is not provided for it in the beginning, the polishing wheel must make it. It follows then that the better the original surface, the lower will be the investment in machinery, in polishing wheels, and the lower will be the labor cost of the polishing operation.

A case in point is the experience of a large company making automobile bumpers. A machine was installed for polishing these, the number of wheels being determined by tests on production quantities of the regular run of steel used by the bumper manufacturer. After the machine had been in operation for some time, complaint was made that it was not cleaning up the bars, and that they required a second and third pass through the machine. An examination of the steel as it came to the machine showed that it was much inferior, so far as surface was concerned, to the steel in the reference sample from the test run. Inquiry revealed that the bumper manufacturer had changed his source of supply. An insistence on adherence to steel specifications, rigid inspection, and liberal rejections of poor steel, shortly thereafter caused the polishing operation to resume its original efficiency.

c Condition of Final Surface. The condition of the final surface of the work dictates both the number and character of polishing wheels that must be used in a machine. Several considerations enter into the final surface, one being its appearance or "color," and the other the dimensional characteristics of the work itself. By the latter is meant the closeness to which the work

must be held to dimensions, and also whether corners and edges must be held sharp and square. Quite frequently work that is susceptible to machine polishing in all other respects presents considerable difficulty, for the reason that its contour is such that the polishing wheel will round edges as it passes over them, or drag the edges of drilled holes until the holes are elliptical. When such difficulties are encountered, they may be overcome in several ways. A proper selection of the wheel may obviate some of them. A change in the design of fixture may eliminate others. A change in the direction or rotation of a wheel quite frequently offers a solution. A soft polishing wheel striking against a sharp edge or corner will invariably round it over. If each wheel be made to trail over the edges with which it comes in contact, it is possible to hold the edges square and sharp.

Frequently polished work must be held within tolerances sometimes as fine as plus or minus 0.001 in. Such close tolerances call for micrometer adjustments in the machine and a careful selection of the wheel. They also call for extreme care in setting up the wheel and making it truly cylindrical at operating speeds. The wheel should be of hard density, as a soft wheel will flex on the work, and thereby cause lack of uniformity in the contour of the surface polished.

Too much stress cannot be laid upon making the wheel truly cylindrical at operating speeds, particularly where the surface to be polished is relatively wide. It is a comparatively easy matter to make a wheel truly cylindrical when truing it up in the lathe preparatory to applying the abrasive head. However, it should be borne in mind that in the ordinary wheel-dressing machine or engine lathe, which is sometimes used for the purpose of truing wheels, the speed of rotation is relatively low. When in operation, the polishing wheel rotates at from 1800 to 2500 r.p.m., depending upon the diameter. The wheel will become distorted at these high speeds, and the surface that comes in contact with the work is no longer cylindrical. After considerable difficulty, due to the failure to produce a uniform finish upon wide areas, it was discovered that the cause of the trouble was the distortion of the polishing wheel at operating speeds. To correct this condition, a machine was developed to true the wheels at the same speed at which they were to be used. The wheel, when at rest, would not be truly cylindrical, but would take this form when brought up to working speed. Thereafter there was no difficulty obtaining truly plane surfaces over wide areas.

If the work is to be held within close tolerances the material entering into the construction of the wheels must be considered. As indicated, a soft wheel will flex on the work and produce uneven surfaces. This immediately rules out a large number of materials, and limits the choice of the wheel to practically two types, the compress-leather or the compress-canvas wheels. Since both of these wheels can be made to extremely hard densities, it is a comparatively simple matter to maintain tolerances with them.

Variables of the Polishing Wheel

a Type of Wheel. Probably the oldest type of polishing wheel is a wooden disk made in one piece, or built up of laminated sections with a strap of leather glued and pegged to the face. Such a wheel produces a high-class finish upon almost every type of metal, but it is rapidly passing out of use for a number of reasons which need not be enumerated here. In general, it may be stated that this wheel is poorly or not at all adapted to use in a polishing machine.

The type of polishing wheel that has been in most general use up to a few years ago is what is technically known as the clothflex wheel, consisting of sections of ordinary cotton buffs glued or sewed together to form a wheel of the requisite width of face. These wheels were frequently home-made, in that the polisher bought the buff sections, and glued them together to fit his needs. Wheels made in this manner possess many defects, as they usually are out of balance, lack uniform flexibility and cushion, and possess other defects that render them unsuitable for use in the polishing machine. As polishing has gradually gained recognition in the industry as a precision operation with considerable engineering behind it, the fact has become recognized that good work could not be obtained with crude tools. The clothflex wheel, as today manufactured for precision work, as in the polishing machine, is made from carefully selected buff sections properly balanced, and with the sewing of the buff sections themselves, and the sewing and gluing of one section to another, so designed as to give a wheel exactly suited for the work that it is to do.

Many manufacturers even today have the idea that a buff is a buff, and a polishing wheel is simply a collection of buffs glued together. To illustrate the fallacy of this idea, it is only necessary to state that eight different grades of cloth are used in the manufacture of buffs which enter into polishing wheels. Every one of these grades is selected because it is particularly adapted to one class or another class of work. Furthermore, the buffs made from these different grades of cloth may be sewed in several different ways. They may be spirally sewed over the entire surface, at wide or narrow intervals, or they may have two or many rows of concentric sewing from the center hole out to the periphery. Each class of sewing is dictated by the character of work that the wheel is to do, and a wheel that is eminently fitted for one job will prove a hopeless failure on another. Furthermore, the various buff sections of which the clothflex wheel is composed may be glued together from the center hole clear out to the circumference of the wheel, or the gluing may stop at 3 in., 2 in., or any other distance from the circumference, depending upon the hardness and the cushion desired in the wheel. If a very soft wheel is required, the gluing may be omitted altogether, and the various buff sections hand sewed together with two or more rows of concentric sewing.

The foregoing are but a few of the variables entering into the clothflex wheel. The fact that there are so many variables, each one of which has its influence upon the character of work done by the wheel and on the efficiency of the wheel, is sufficient indication that the selection of the proper wheel for the work is a most important item in machine polishing.

Another type of wheel which is largely used in machine polishing is the compress wheel. This wheel is constructed of blocks of material set on edge, clamped between two steel flanges, and compressed radially, circumferentially, and longitudinally. It is essentially different in its action from the clothflex wheel, in that the cutting edges of the fabric in the clothflex and other disk wheels run parallel to the movement of the work across the wheel. In the compress wheel, the cutting edges are transverse to the movement of the work, and the effect of this change in direction is most important. One advantage of the compress wheel that is possessed by no other type of wheel is that the cushion and density of it can be exactly controlled. By cushion is understood the depth of flexible material projecting out from the rigid part of the wheel, in this case from the steel flanges.

By density is meant the degree of hardness of the wheel. Various jobs require different depths of cushion and different densities, in order to produce satisfactory work. The compress wheel can be made in all depths of cushion up to 3 in., and in certain cases, up to 4 in. Within certain limits of diameter and cushion, the density can be varied from super-soft to super-hard. A super-soft wheel is so soft that a person can push his thumb into the surface of the wheel, while a super-hard wheel is so dense that it is difficult to drive a nail into it with a hammer. The compress wheel can be made of many different materials. The most common are heavy canvas and bullneck leather, although other ma-

terials sometimes used are walrus, sheepskin, paper, and felt. The characteristics of each of these materials vary from the characteristics of each other in a given density and cushion. The proper selection of the material, of the cushion, and of the density in a compress wheel will determine whether or not a machine-polished job will be a success or a failure.

Another type of wheel that is commonly used is the disk type, built up of disks of canvas or bullneck leather, wool felt, walrus hide, and other materials that are homogeneous in structure and can be cut into disks and glued or clamped together. Each of these wheels has its own special field on the polishing machine. For instance, for roughing out work, such as automobile bumper bars, the disk canvas wheel, headed with the coarser abrasives, is superior to any other type of wheel. It is highly unsuited, however, for finishing, and for this purpose the compress-canvas wheel of medium density and 2-in. cushion has shown itself superior to any other.

It is impossible in the space available to give a complete list of the uses to which the several types, grades, and densities of wheels available are adapted. The following notes are merely indicative of some of the fields in which these wheels may be successfully used:

The disk canvas wheel is especially adapted to roughing work, with the coarser grains, say up to No. 60. It is flexible and can be used on work with curved contours such as agricultural machinery parts, plowshares, oval or straight-faced automobile bumpers, etc.

The clothflex wheel is used for contour work, similar in character to the disk canvas wheel, but with the finer grains. It may be made highly flexible and will adapt itself to curved surfaces such as shovels, automobile bumpers, and more or less irregular shapes.

The compress wheel is a precision polishing tool of the highest order. It is an all-around wheel that can be used for practically every purpose that any other wheel can be used. Its face can be formed to fit contour surfaces, and by the possibility of regulating its cushion and density it can be made exactly to fit the job it is to do. Due to its high first cost, it is in some cases not the most economical wheel for roughing with the coarser grains, but for all other work up to the finest finishing it is believed to have no equal. Its high first cost is counterbalanced by its extremely long life. Wheels that have remained in service for upward of 20 years are not uncommon, and one instance is known of a wheel that was taken off the polishing lathe after 31 years of continuous use.

The compress-canvas wheel is extensively used in the polishing of cutlery, flatirons, shears, skates, golf-club heads, bicycle and automobile parts, machine parts, and similar work.

The compress-leather wheel has its field in the initial operation on flatirons, the polishing of carpenter's chisels, plane blades, axes, etc. It is used where edges have to be held sharp, and holes kept free from dragging.

The compress-felt wheel is employed on work where a high color is required, such as surgical instruments.

The compress-sheepskin wheel is comparatively little used, except in those cases where a flexible wheel that will give a very fine super finish is needed.

The compress-paper wheel is adapted to rough work. It has little flexibility, and approximates in its action the solid grinding wheel.

The solid felt wheel is used for polishing glass, and for greasing and coloring operations where a high color is required. It has a distinct field in the polishing of formed surfaces of stainless steel.

Variables of the Abrasive

The variables of the abrasive as they affect the operation of the polishing machine have been discussed in general in the preceding paragraphs. They will not be further discussed here.

Variables of the Machine

a The Peripheral Speed of the Polishing Wheel. The polishing machine should be designed, wherever possible, to maintain a constant peripheral speed of the polishing wheel as close as possible to 7500 lin. ft. per min. In general, the higher the peripheral speed, the more efficient is the action of the abrasive. The figure 7500 ft. is chosen because this speed is about the maximum at which the glue holding the abrasive to the surface of the wheel will maintain its strength under the action of the heat generated by the operation of the wheel upon the work. An increase in the speed of the wheel would increase the efficiency of the cutting momentarily. It would, however, generate sufficient heat to soften the glue, and thereby permit the abrasive to be torn from the wheel before it had rendered its full service as a cutting medium. The overall efficiency, therefore, would be less than it would be were the wheel operated at a lower speed.

If the peripheral speed of the wheel is decreased below 7500 ft. per min. the cutting action of the abrasive is less efficient and a longer time is required for the removal of a given amount of metal. The general rule, therefore, for wheel operation is to drive the wheel at the maximum speed that is possible without softening the glue. With the best grades of glue, this has been demonstrated to be in the neighborhood of 7500 lin. ft. per min.

Another factor, however, enters into the question of speed in its relation to heat generated. This is the work itself. Speeds that may be entirely safe from the standpoint of the wheel may be ruinous to the work, for the reason that the heat generated will have adverse effects upon the metal of which the work is composed. For instance, in die castings or other alloys of zinc, if the wheel speed is so high as to generate sufficient heat to distort or melt the metal, the speed must be decreased even though it means lowering the speed below the ideal speed for maximum efficiency of the wheel. Other metals may suffer changes in temper, hardness, etc., as a result of the heat generated by excessive wheel speed. All of these things must be taken into consideration in fixing the speed at which the wheel spindles of a polishing machine shall operate. Here again the laboratory is the safest guide in determining the proper wheels and wheel speeds, and also the speed at which the work passes under the wheel.

The polishing wheel, when correctly built and properly maintained, should not decrease appreciably in diameter with use. The wheel should never be operated after the abrasive head has worn through to the fabric of which the wheel is composed. Otherwise, it will burn and require trimming, which means a reduction in diameter, with a consequent reduction in peripheral speed. In setting up the wheel, a protective head of glue should be placed on it before the glue that holds the abrasive is applied. As soon as the wheel wears down to this protective head, it should be removed from service, the old abrasive removed, and a new head applied. Given this treatment, the diameter of the wheel should be maintained fairly constant for a period of years, and no provision, therefore, need be made for a change in spindle speed due to wheel wear. On the other hand, if the polishing machine is to be used for a variety of work requiring different sizes of wheels, and therefore, different spindle speeds, provision should be made for changing the spindle speed with change in wheel diameters. This has proved a more or less difficult matter until recently, but the advent of flexible endless-belt drives has made it a comparatively easy matter to change spindle speeds by a change in the pulley diameters in the drive. In the design or selection of a polishing machine, attention should be given to the ability to change the spindle speed if the character of work is

such that there will be a change in the wheel diameter from time to time.

b Speed of the Work. The speed of the work past the wheel is an important consideration in machine polishing. The speed depends upon the material of which the work is composed and the degree of finish that is required. It varies between wide limits. For instance, strip zinc can be fed past the wheels at the rate of 200 lin. ft. per min., whereas 15 ft. per min. is a high rate of speed for stainless steel. Another item entering into the speed at which work can be done in machine polishing is the speed at which separate pieces can be loaded on the machine. Usually this is a limiting factor in the capacity of polishing machines. It frequently happens that a polishing machine has a capacity of from 200 to 300 pieces of a given size and shape per minute, but it is manifestly beyond the ability of an operator to feed work at this rate, particularly where the work must be more or less accurately placed in work-holding fixtures. It sometimes is possible to arrange a machine so that two or three operators can load it, the unloading being taken care of by an equal number of operators, or automatically. Sometimes the shape of the work permits the provision of mechanical feed, but such cases are the exception, rather than the rule.

Another factor governing work speed is the degree of finish required. A polishing wheel requires a definite interval of time in which to do its work. The work must remain under the wheel long enough to permit the wheel to get a bite upon the metal and to remove it. While it is entirely possible to design machines that will feed the work past the polishing wheel at rates of 200 ft. per min., or even higher, it is hardly feasible to operate at this speed. The polishing wheels would merely ride over the work without removing metal. Then, too, the slower the work speed the higher the luster that will be obtained with any given size of abrasive grain. The overall finishing time for a given piece of work may actually be reduced by the adoption of a lower work speed, in that this lower work speed will give the desired finish which otherwise might require an additional operation to obtain. Again, the choice of work speed is, as a rule, best determined in the laboratory, rather than in the shop.

c Pressure of the Wheels on the Work. Ability to regulate the pressure with which the polishing wheels bear on the work is highly important from two standpoints: first, the effect on the wheels, and second, the effect on the work. Excessive pressure causes rapid destruction of the abrasive head, excessive heat, and eventual burning of the wheels. As regards the work, the heat engendered by the high pressure in some classes of work may change the character of the metal and render it useless for its purpose. In any event, excessive pressure greatly increases the operating cost, as it wastes grain, glue, and labor for the setting up of wheels, and it also requires more operations on the work due to the inefficiency of highly heated wheels. In the design or selection of polishing machines, attention should be given to the possibility of adjusting the pressure, either manually or automatically. A machine that has no provision for this regulation should be rejected forthwith, since it will be nothing but a constant source of trouble and expense.

d Provision for Oscillation. In hand polishing the workman handles his work in such a manner as to "cross the scratches." That is, he presents the work to the wheels at varying angles, so that wheel marks intersect, and thus tend to obliterate each other. In most cases of machine polishing, and particularly in straight-line work, it is desirable to approximate this effect by moving either the wheel or the work transversely to the line of travel of the work past the wheel. This is done by means of an oscillator on the wheel spindle or a mechanism that oscillates the table. The resulting wheel marks then take the form of a sine curve, which is a much more desirable surface than one with straight-line marks, parallel to the direction of motion of the work. The reason for this is that, without oscillators, each wheel tends to follow in the wheel marks left by the preceding wheel and to deepen them instead of cutting them out. If the final surface of the work requires the appearance of parallel lines, oscillation may be omitted on the last one or two wheels. As a general rule, however, oscillation is a desirable feature in nearly all classes of machines.

e The Cushion Under the Work. In some classes of work it may be desirable to divide the cushion required for flexible grinding between the wheel and the work. The wheel is made of the proper density and cushion to give the desired finish, and a cushion surface is provided under the work to enable it to give sufficiently to take care of slight variations in contour that would cause the wheel to cut deeper were the work not able to recede somewhat from the wheel. The cushion can be provided by means of a resilient material, such as a canvas or leather belt, or springs. The greater the cushion the less accurate will be the surface so far as dimensional properties are concerned. Hence it follows that on highly accurate work, where the dimensions must be held within close limits, or corners and edges held up sharply, little or no cushion should be provided under the work. On the other hand, where the work does not have to be held to close limits, and where the shape may be slightly irregular, production is facilitated by some cushion under the work. For instance, in polishing cylindrical work, which may be slightly out of round, cushion under the work will permit it to recede slightly when the longer diameter comes under the wheel. Were this not possible, a flat spot might be ground on the work, the work might be burned, or the abrasive stripped from the wheel. Cushion under the work is not so important a factor as some of the others enumerated, but, nevertheless, lack of proper cushion may be the cause of failure in adapting a certain class of work to machine polishing.

f Vibration in Machine or Work. Vibration in a polishing machine produces the same evil effects that it does in any other kind of machine, except that these effects are magnified due to the very nature of the work that the machine is called upon to do. The object of polishing is to provide a smooth uniform surface on the work. Vibration causes the polishing wheel to put chatter marks in the work and thus destroys the very object aimed at. Due to the high speed of the polishing wheel, vibration is more easily set up than in machinery operated at lower speeds, and consequently must be guarded against more carefully.

The more common causes of vibration are: Inadequate machine foundations, improperly or lightly constructed buildings, light floors, machines improperly located on upper floors, insufficient weight in machine bases, shafts too light, or with bearings too far apart, giving them a tendency to whip at high speeds; insufficient bearing surfaces; improperly braced machine members, or members whose vibration period corresponds to some recurrent motion in some moving part of the machine; and unbalanced polishing wheels. One of the mistakes made in the design of earlier polishing machines was the provision of light frames. Some were made of structural sections riveted or bolted together. Most of these machines have failed in one respect or another. The present-day polishing machine is a rugged structure, with heavy box-type frames, ball or roller bearings in the moving parts, massive spindles, and automatic lubrication.

Vibration can also be caused by the work being improperly seated in the fixtures, although such vibration usually is local, and confined to the work itself. A good machine should be sufficiently heavy to absorb such local vibration, although its effect on the polishing operation may be just as serious as vibration in the machine itself.

Too much cushion also may tend to set up vibration in the polishing wheel. An extreme example of this is the polishing of automobile bumpers. The springiness of the bumpers themselves furnishes a particularly resilient cushion, and at times the vibration period of the bumpers is such as to amplify the movement and actually to cause the wheels to bounce off the bumpers as they pass over them. In this case, the cushion is lessened by providing supports at two or three points under the bumper, and attaching dash pots to each wheel spindle to damp the vibration.

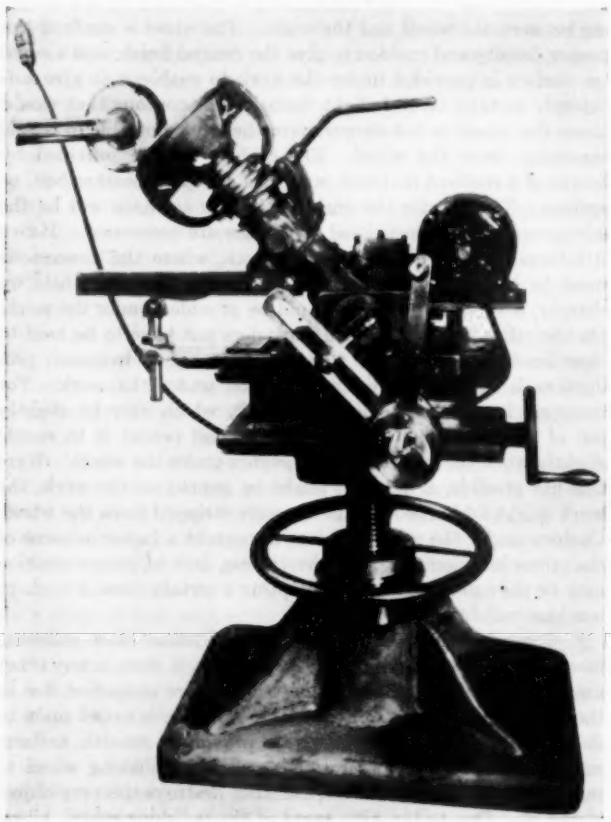

FIG. 1 MACHINE FOR FINISHING THE INTERIOR SURFACE OF HEADLIGHT REFLECTORS

g Types of Fixtures. Properly designed fixtures are a prime essential in machine polishing. Their function is to hold the work firmly, to present it in the correct position to the polishing wheels, and, in such cases as may be necessary, to provide a certain amount of resiliency and automatic adjustment of the work to the wheel. Fixtures must have certain characteristics embodied in their design and construction. First, and most important, they must hold the work so that it cannot be dislodged when it comes in contact with the wheels. It is just about as safe to stand in the path of a rifle bullet as to stand in the path of a piece of work thrown out of a fixture by a polishing wheel. Many jobs that are otherwise ideal for the polishing machine are impossible because of the impossibility of safely holding them in any practical type of fixture.

Another important point is ease of loading and unloading the fixture. A polishing machine that is capable of passing 60 pieces of work per minute under the wheels is badly handicapped if the fixture is designed so as to require two or three seconds for loading. In many cases the fixture is attached to the machine, and must be loaded and unloaded "on the run" as it were. It therefore must be easy to load and unload, and free from complicated locking devices. In other cases, the fixture is detachable, is loaded at the bench, and transferred loaded to the machine. Such fixtures should be light, yet rigid. All fixtures should have provision for compensation for wear, and in those cases where the fixture masks a portion of the work for one reason or another, the masking part must be capable of easy replacement. The fixtures should be made so that they can be placed on the machine in one position only. Otherwise the work may be ruined or thrown from the machine, or the fixture itself may be thrown. Several serious accidents have occurred through neglect of this precaution.

Where the shape of the work precludes the use of mechanical fixtures, substitutes may sometimes be employed. For very flat work such as ornamental plates or spherical or similarly shaped work that is to be polished on the inside, and which is impossible of gripping in any type of mechanical chuck, a vacuum chuck frequently will prove to be feasible. For articles made of steel or iron the magnetic chuck is sometimes employed, although for polishing operations it possesses certain disadvantages. For flat strips or sheets, pressure rolls on either side of the polishing wheel frequently may be substituted for fixtures.

The success or failure of many machine-polishing jobs more often than not depends on the ability to design a fixture that will properly hold the work. There is a wide field for ingenuity and real engineering in this one phase of polishing alone.

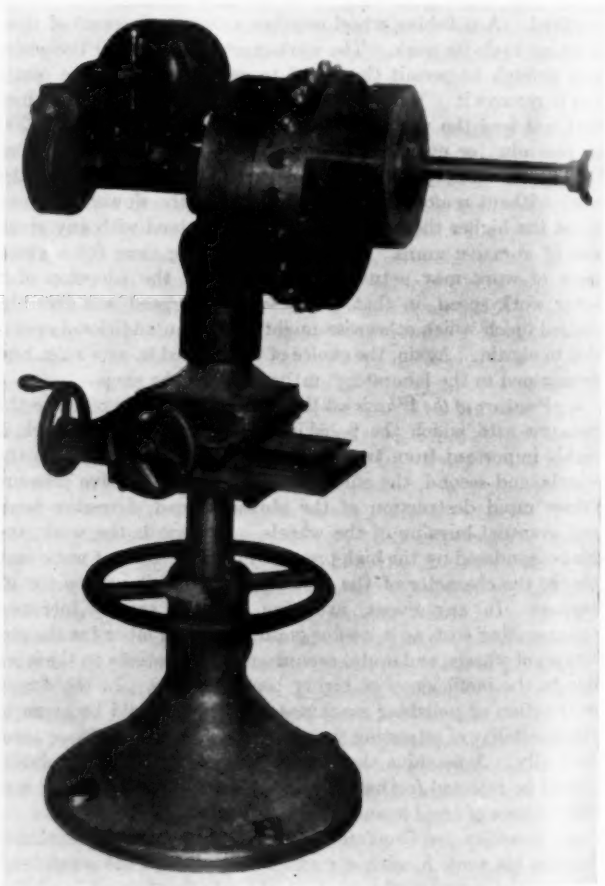

FIG. 2 POLISHING MACHINE FOR FINISHING HEADS OF BOLTS, ETC.

TYPICAL POLISHING MACHINES

Polishing machines may be divided roughly into two classes:

those which rotate the work in contact with the polishing wheel, and those which pass it in a straight line past the wheels. Examples of the former class are shown in Figs. 1 to 5 inclusive.

Fig. 1 is a machine for finishing the inside of headlight reflectors and similarly shaped articles. The reflector is placed in the chuck, which is set at an angle from the vertical. The chuck is mounted on a slide which is moved forward to bring the work in contact with the wheel, being actuated by the handle in the foreground. When in contact with the wheel, the work is rotated by means of the small motor shown above the slide, working through a bevel-gear train.

Fig. 2 shows a machine for finishing the heads of bolts and other objects which have a long stem. It consists essentially of a drum containing a number of chucks which rotate about their own axes while the drum itself is rotated about an axis parallel with the axis of the polishing wheel. The operator of the machine drops the work to be finished into the holes in the chuck, which lock on the work as it approaches the polishing wheel. After the work

FIG. 3 FOUR-SPINDLE MACHINE FOR POLISHING CIRCULAR WORK

has passed the polishing wheel, the chuck opens and the work drops out when it comes to the lowest position on the drum.

Fig. 3 is a four-spindle polishing machine for finishing small circular objects, such as hub caps, etc. The work is carried on chucks mounted on spindles projecting from the face plate. Each spindle is rotated about its axis as it comes in contact with the polishing wheel. The machine is so arranged that the face place indexes at definite predetermined intervals, thus allowing the work to remain in contact with the polishing wheel for a sufficient length of time to obtain the finish desired. Machines of this type are frequently provided with chucks which automatically unload the work when the spindle is in the lowest position.

Fig. 4 illustrates a machine for polishing long circular work. The work is mounted upon a chuck, supported at the outer end by the overhanging arm, and rotated against the wheel. At the same time, the spindle is reciprocated back and forth so that the polishing wheels cover the entire cylindrical surface.

Many variations of the foregoing machines are made to adapt them to different classes of work. The illustrations are merely typical of the varieties of work that are possible in this type of machine.

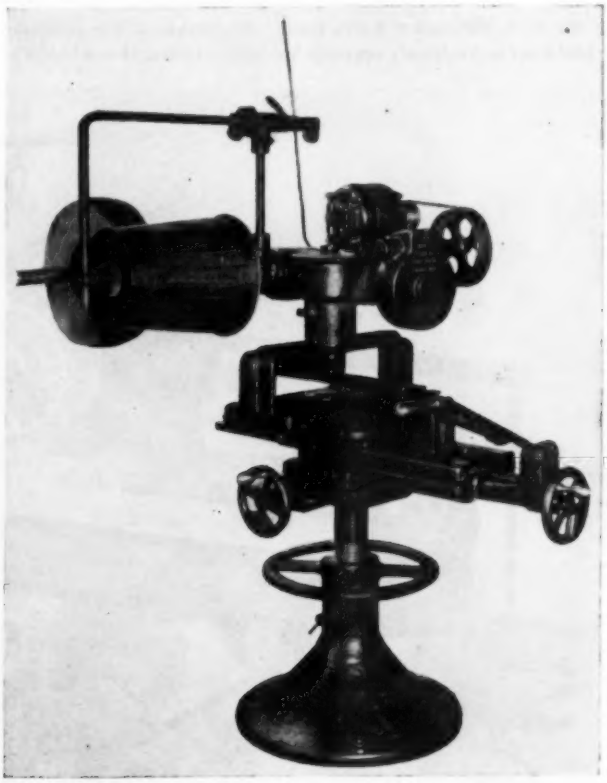

FIG. 4 RECIPROCATING TYPE OF MACHINE FOR CIRCULAR WORK

FIG. 5 ROD AND TUBE POLISHING MACHINE

Fig. 5 shows a machine for finishing tubes or other long cylindrical objects. The work is carried upon the two longitudinal

rollers in the foreground, and is moved past the wheels by the belts shown immediately behind the rollers, these belts being set at an angle to correspond with the speed of longitudinal movement desired. The belts are driven from the motor shown at the rear of the slide, through a worm gear. In operation, the polishing wheel is set immediately opposite the belt, which acts as a brake to prevent the work rotating at the same speed as the polishing wheel, and also causes it to move past the wheel. In the illustration, the relative position of the polishing wheel and the belt is shown on the second machine. The polishing wheel opposite the first belt has been omitted in order to show the details of the machine.

Fig. 6 shows one of the earlier types of continuous straight-line polishing machines. Originally designed for polishing long flat bars or strips, it has been found adaptable to the finishing of a great variety of work of many shapes and sizes, some of which are illustrated elsewhere in this paper. The principal feature of this machine is the carrying of the polishing wheels upon a swinging arm, which has a movement about the spindle A, permitting the wheel to rise and fall with change in contour of the work. Each wheel is driven by a motor directly connected to the wheel spindle. Wheels and motors are balanced by means of counterbalance weights shown at the left of the illustration. The work to be polished is placed upon the conveyor belt, and

carried underneath the wheels which are set up with such different abrasives as may be necessary to secure the desired finish. The machine is built on the unit system, and as many wheel spindles are provided as are necessary to give the desired finish on one pass of the work through the machine. The feed belt is driven through a variable-speed drive, permitting the speed to be changed to suit the conditions of the work. The pressure of the wheel on the work can be varied by shifting the counterweights, and micrometer adjustment is provided for the wheels in order to permit of precision work.

This machine is in extensive use for the polishing of work ranging in size and contour from as large as automobile bumpers to as small as the smallest link in use in the construction of adding

FIG. 15 IRONING MACHINE, POLISHED WITH FORMED-FACE WHEELS

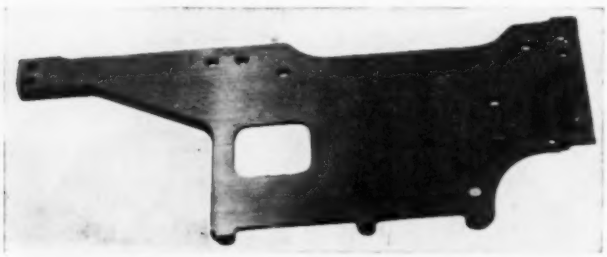

FIG. 16 TYPEWRITER SIDE FRAME—THE DESIGN OF FIXTURE WAS THE MAJOR FACTOR IN POLISHING THIS PIECE

machines. Fig. 7 shows the evolution of the continuous straight-line machine to its present form. The direct-connected motor has been replaced by a motor mounted upon the opposite side of the swinging arm from the polishing wheel, the wheel being driven from the motor by means of a Texrope drive. The base of each unit of the machine forms an oil tank, in which is a large float almost completely filling the tank. A heavy rod on the float, projecting through the base terminates in a ball-and-socket joint underneath the center line of the wheel spindle. The float is adjusted so that it bears the entire weight of the wheel and swinging arm, thus bringing zero pressure upon the work. Any desired pressure then can be secured by a simple shifting of the weights on the arm. The float also acts as a dashpot to damp any tendency to vibration on the part of the polishing wheels. The wheels can be set at an angle to the work, if so desired, the entire head swiveling around the supporting rod on the float.

Fig. 8 illustrates a machine for polishing sheet metal. The machine in question was built for sheets up to 50 in. wide. The sheets are carried by the conveyor belt *A*, underneath the polishing wheel *B*. Pressure rolls *C*, on either side of the polishing wheel, provide the necessary pressure of the work on the conveyor belt to furnish traction, and also hold the work in position to pass under the polishing wheel without lifting.

Fig. 9 illustrates a vertical double-header polishing machine for finishing putty knives, spatulas, and similar flat work, where the polishing marks should run in a direction parallel to the length of the work. The work to be finished is suspended from a holder at *A*, and is lowered by a crank motion between the polishing wheels. As the lower edge of the work approaches the line joining the centers of the wheels, a cam motion closes the two wheels upon the work. It passes down between them and is then withdrawn, being in contact with the wheels during the entire time of passage. As the work leaves the wheels the cam motion moves them apart ready for the entrance of the next piece. Usually these machines are operated in pairs, the first machine carrying the roughing wheels, and the second the finishing wheels. The machine can be arranged to stop at the end of the upward stroke, or it can be set to run continuously. With a skilled operator, continuous operation is the rule, as he can detach finished work from, and insert new work in, the holder without stopping the machine.

Fig. 10 is a machine for the finishing of axe heads, which operates somewhat on the same principle as the double-header machine just described. It is manual in its operation, instead of automatic as in the case of the double header.

Fig. 11 shows a machine for finishing strip brass. The polishing wheels are mounted on the spindles whose ends project through the large drum-shaped structure at the top of the machine. Each wheel is driven by a 50-hp. motor through a Texrope drive, and oscillation is provided on each wheel spindle. The oscillator is driven from the Texrope drive shown projecting above the top of the machine. The brass strip is fed from a coil, passes over pressure rolls underneath each polishing wheel, and is coiled by means of a friction winder at the opposite end of the machine. These coiling devices are not shown. The two handles projecting upward operate a quick release for the pressure rolls, to

FIG. 17 TIRE-VALVE PARTS POLISHED IN ROTARY TYPE OF MACHINE

permit dropping the work out of contact with the polishing wheels, if for any reason it is necessary to do so without stopping the machine. The two hand wheels at the front of the machine are for the purpose of raising or lowering the pressure rolls, to provide variations in pressure of the wheel on the work, and also to compensate for wear of the wheels.

TYPICAL MACHINE-POLISHING JOBS

A few typical machine-polishing jobs are illustrated in Figs. 12 to 17 inclusive. Fig. 12 illustrates parts of Stillson wrenches which have been finished in the continuous straight-line machine. These are typical examples of small jobs that can be handled in large quantities by the machine, and form a splendid example of

work for which the capacity of the machine exceeds the ability of the operator to load. In the case of these wrench parts, this difficulty was overcome by providing an extension end table, and putting two operators to work loading the conveyor belt. The parts were unloaded automatically as the conveyor passed over the tail pulley.

Fig. 13 is an automobile fender guard also polished in the continuous straight-line machine. The polishing wheel followed the curve of the fender guard from end to end, with the exception of a short space near the eye. The same machine also polishes automobile-bumper rails, from 16 to 18 units being employed for this purpose.

Fig. 14 represents an extreme case of straight-line machine polishing. This is a bicycle rim which was required to be polished on the inner surface. This feat was accomplished by fitting the conveyor belt of the continuous straight-line machine with a track, and mounting the rim in a fixture which held it in the proper relation to the polishing wheel while resting on the track. The movement of the conveyor belt and its track caused the rim to rotate in the fixture while in contact with the polishing wheel, and thus completely polished it around the entire circumference. Two operations were necessary, formed face wheels being used.

Figs. 15 and 16 are other examples of work that is adaptable to a straight-line machine. Fig. 15 shows the shoe for an ironing machine which required polishing on the inner concave face. This was accomplished by means of formed wheels. Fig. 16 is the side frame of a typewriter, which was polished with hard compress-leather wheels. This piece is a first-class example of a job wherein the proper design of the fixture was essential to the final solution of the problem. The piece is a difficult one to hold under the polishing wheel, and at the same time obtain the precision that is required in the finishing of this particular part.

Fig. 17 shows a job that was done in the four-spindle machine illustrated in Fig. 3. The upper piece is an automobile-tire-gage casing, while the two lower ones are automobile-tire valve caps.

Economics of Machine Polishing

Little has been said heretofore about the economics of machine polishing. It is difficult to lay down any general rule covering this phase for the reason that many different factors enter into it. Where the machine is adapted to the work and can eliminate hand operations, and where there is sufficient production to keep the machine busy a fair proportion of the working day, machine polishing usually will prove economical. Where, however, the time required to load and unload a piece for machine polishing is equal to the time in which a polisher could finish the work by hand, machine polishing would prove uneconomical. Where conditions are right, however, the substitution of machine polishing for hand work represents a tremendous saving in the cost of manufacture. Each case should be investigated on its merits, and the possible economies worked out before the decision is made either for or against machine polishing.

As an example of the saving possible by machine polishing, in one installation a single polishing machine displaced 30 hand polishers. The machine required four men to operate it, three of these men being used for loading it. In the case of the ironer shoe, Fig. 15, with hand polishing the number produced per man was three shoes per day of eight hours. The polishing machine, operated by two men, produces a completely finished shoe every three minutes.

Up to within a few years ago, the polishing department in nearly every industry was regarded, as has been very aptly expressed, as the "Cinderella of the works." Within the past few years, however, it has been recognized that there is no department of the manufacturing plant in which greater savings can be effected per dollar of investment than in the polishing department. There is a vast amount of engineering and research work to be done before polishing is on the same technical plane as other departments of the metal-working industry. It is, however, a field which merits the study and best efforts of the engineering profession.

Discussion

Floyd T. Taylor.[3] The paper makes a notable contribution to the literature on polishing, at a time when such contributions ought to be very welcome. A number of points naturally arise in the minds of those who have had contact with hand or machine polishing.

Polishing, at the present time at least, can be described as an art guided by a science. The line of demarcation between the art of polishing and the scientific guide now being applied to it is somewhat indefinite.

From the mechanical engineer's standpoint, polishing may be considered as the transfer of a portion of the energy in a revolving polishing wheel into luster on the work, and it should be noted that this transfer takes place across a coating of adhesive and abrasive. Heat losses, inherent with a transfer of energy, must be dissipated from the face of the polishing wheel and from the work. The polishing wheel itself is a poor conductor of heat, and consequently there can be little relief through the conduction of heat away from the face by the polishing wheel. Means of cooling the face of the wheel are therefore of paramount importance, and yet up to the moment, except as on such types of polishing machines as employ a "coolant" on all the wheels, little attention has been paid to this point.

It is also obvious that an improvement in the efficiency of polishing, through the use of abrasives which cut and do not drag, will reduce the heat losses at the face of the polishing wheel.

There are two distinct actions in polishing—one a cutting action which tears off metal and the other a burnishing action which flows the metal. The cutting action is a high-speed operation at light pressure. The burnishing action is a slow-speed operation at considerably heavier pressure.

The author has used the word "color" without defining color as applied to polishing. Color may be defined as a condition of the surface where the average depth of the defects has been reduced to a point which causes almost all of the light striking the surface to be totally reflected. Through the use of a photoelectric cell, definite measurements of color can now be made, and therefore the degree of color need no longer be a matter of individual opinion, based on eyesight alone.

The author states that the power required to drive a hand-operated polishing lathe is no criterion for the size of motor which should be installed on a polishing machine. This statement leads to the observation that machine polishing is very much more of a continuous load than hand polishing can possibly be. In addition to a difference in power requirements, there is a very considerable difference in the use and behavior of wheels and abrasives. A further point in connection with power supply is that the polishing wheel, whatever its linear speed may be, should be run at a constant linear speed, and therefore polishing machines will be much improved when synchronous motors are applied to them. Where it is necessary to use induction motors, the low-resistance end-ring type should be used, since these motors give a considerable closer speed regulation than the so-called high-torque types.

The author has aptly stated that the condition of the material when it comes to the polishing room has a vital and important

[3] The Bullard Company, Bullard-Dunn Process Division, Bridgeport, Conn.

bearing on the polishing operation. When iron or steel is covered with black magnetic heat scale, the first polishing operations are not polishing operations at all. They are very costly and inefficient grinding operations done with polishing wheels. Polishing wheels should never be required to do grinding. Moreover, grinding, sand-blasting, or pickling, plain or electrified, will not remove this black heat scale thoroughly and successfully. Electrolytic treatments have been devised, however, which remove this black scale completely and cheaply.

The author cites the case of polishing bumper bars, and in this connection it should be pointed out that in one of the large bumper-bar plants, where originally an effort was made to polish bumper bars before the black heat scale had been completely removed, wheels coated with these abrasive grain sizes were used, in succession, Nos. 30, 60, 90, 120, 150, 180, and grease. When, however, the bumper bars were completely free from scale, they were satisfactorily polished, beginning with the No. 90 wheel.

The elimination of polishing wheels set up with the coarser grain sizes makes another saving, namely, that of frequent wheel changing, because coarse grains are much more readily ripped from the face of the wheel than the fine grains.

In discussing the condition of the finished surface, the author states that the finish desired determines the number of wheels required. This statement should be qualified, because actually the number of grain sizes required is determined by a double consideration; namely, the condition of the surface at the beginning of the polishing operation and the final finish desired.

In speaking of the density of polishing wheels it should be pointed out that no measure of density has been standardized; therefore, what one might think is a hard wheel another might think is a soft wheel. A standard of wheel density should be sought and established. Furthermore, the density may vary considerably with the reduction of diameter as the wheel wears down and also with the aging of the adhesive used to hold laminated wheels together.

Under "Variables of the Abrasive," the author states that these variables are discussed generally in the fore part of the paper, but variables of the abrasive are so important that it would seem well to have a discussion of them and their effect on polishing in a section of the paper set aside for this purpose alone. The first question that arises is, Are the present standard grain sizings correct for polishing and are the tolerances within these sizings close enough?

Since it would be a great advantage if wheels could be run under water instead of oil as a coolant, the availability of the so-called water-dispersed rubber cements for facing polishing wheels should be checked. A final point in connection with the variables of abrasives on machines is this: Not nearly enough care has been taken on automatic machines thus far produced to see to it that the coarse grains detached in operation are completely removed from the work before it passes under a wheel of finer grain set-up.

Under "Peripheral Speed of the Polishing Wheel," the author states that, where it is possible, polishing wheels should be run at a surface speed of 7500 ft. per min. He gives as a reason that this speed is about the maximum which can be used on account of the holding power of glue. He further states than an increase of speed would increase the efficiency of cutting momentarily, but that this cutting efficiency would promptly become lower due to overheating. No mention is made at this point of the fact that pressure is also a factor. Furthermore, it seems worth while to point out that the polishing wheels generally used are 12, 14, 16, or 18 in. in diameter. At 7500 ft. of surface speed these diameters correspond to the following revolutions per minute:

12 in.	2385
14 in.	2045
16 in.	1790
18 in.	1590

The interesting point about these rotating speeds is that a great percentage of the modern polishing machines are run from 60-cycle circuits, and therefore the 16-in. wheel is the only one that can be run direct-connected if this linear speed of 7500 ft. per min. is to be maintained.

Under the heading of "Pressure of the Wheels on the Work," a statement should be made that the pressure should remain constant, and furthermore that it should be light to give the abrasive a real opportunity to cut. When a wheel is used for burnishing, however, the pressure must be heavy to flow the metal.

In the section on "Provision for Oscillation" the statement is made that unless the wheels oscillate they are likely to track, and when they track, the tendency is to deepen the scratches instead of cutting them out. It is doubtful if the scratches will be deepened on account of the reduction in grain size of the wheel facings as the work passes from one to another.

Under "Vibration of Machine or Work," it should be pointed out that soft wheels are freer from vibration than hard wheels, and this is particularly true of the cloth and canvas types.

Under "Machine Design," it should be noted that up to the present time little or no attention has been paid to designs which make the changing of wheels a quick and easy job. Too little attention has been paid to the protection of the machinery from the damage caused by its own abrasive, and too little attention has been paid to the cooling of the surface of the wheels.

Author's Closure

The author finds himself in agreement with practically all of the statements made by Mr. Taylor. All of the points raised are fruitful suggestions for further experiment and development. It is well recognized that means of dissipating heat from the polishing wheel would greatly prolong its life and increase its cutting efficiency. The engineering difficulties of accomplishing this, however, have put it some distance in the future as a practical addition to polishing machines.

So far as the use of the photoelectric cell for the determination of finish is concerned, this device has not proved as useful as may have been anticipated. It has failed to detect the difference between surfaces of widely different finish. After numerous experiments, this method of measuring finish or "color" reluctantly has been abandoned. The method developed by R. E. W. Harrison and described at the Annual Meeting of the Society in December, 1930, gives more promise of success, and experiments are still being carried out along these lines.

The author is in complete agreement with Mr. Taylor's statements concerning the removal of scale, the standardization of grain sizes and wheel densities, protection of machines and work from abrasive dust, and the regulation of pressure of wheels on the work. These and other matters are all highly desirable developments for the future. It should be remembered, however, that commercial considerations also must be taken into account. The polishing industry has not, as a whole, been educated to the point where it realizes that refinements are a profitable investment, and where it is willing to pay for these refinements.

MSP-53-10

Transmission of Torque by Means of Press and Shrink Fits

By J. W. BAUGHER, JR.,[1] PITTSBURGH, PA.

The most important formulas for calculating the stresses existing in press and shrink fits are presented, together with charts for readily obtaining numerical results when steel shafts and cast-iron or steel outer members are used. Equations and charts also are given for determining the pressure existing between fitted parts. From the records of a number of fits observed by the author and others, values of coefficients of friction are suggested for use with the pressure in computing the probable tonnage required in making a fit and the torque capacity of a fit when no key is used. Equations are given for the tonnage and torque capacity.

WITH the increasing use of press and shrink fits without keys for the transmission of power and the more general realization that high localized stresses are produced at the corners of keyways and keyseats, such fits have become of considerable importance. In some cases keys are necessary to locate parts in particular positions on their shafts, but there are many instances in which keys may be dispensed with, and press or shrink fits, perhaps slightly heavier than would be used with keys, will be adequate to transmit the torque. The elimination of keys, keyways, and keyseats reduces manufacturing costs, removes the danger of failure from concentration of stress, and permits the use of smaller shafts than would be possible if they were keyseated.

For street-railway gears, which are subjected to reversing loads, it has been found that keys become pounded over on the corners and eventually work loose, and the majority of these gears are pressed on the axles without keys.

It is certain that keys quite often serve no useful purpose and are a constant source of trouble.

A great deal has been written about press and shrink fits; yet unfortunately the material presented is not in too good agreement and is not always in such a form that it can be readily used. In this paper the more important formulas and other data will be given in a manner that the author has found convenient to use.

[1] Engineering Department, Westinghouse Elec. & Mfg. Co. Mr. Baugher was graduated in 1924 from the Virginia Polytechnic Institute with the degree of B.S. in mechanical engineering and a year later received the degree of M.E. He then entered the graduate student course of the Westinghouse Electric and Manufacturing Company and attended the mechanical design school. Following this training he was connected with the mechanical section of the company's Railway Equipment Engineering Department at East Pittsburgh. Since 1929 he has been a member of the Engineering Department of the Nuttall Works of the Westinghouse Elec. & Mfg. Co.

Contributed by the Machine Shop Practice Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Stresses

A number of formulas based on the theory of thick cylinders subjected to internal pressure are in use for the determination of the stresses in the outer ring of a press or shrink fit. Among these formulas are those of Lamé, Clavarino, and Birnie. According to several authorities Lamé's theory takes no account of lateral contraction as expressed by Poisson's ratio. The equations of Clavarino are derived for a cylinder with closed ends, and while they have been used considerably in the design of hooped guns, they are not applicable to the usual case of a machine fit. Birnie's formulas are for cylinders with open ends, and also are employed for the design of large guns. Another formula used to some extent is Barlow's. This expression, however, applies only to thin cylinders. The subsequent equations likewise are attributed to Lamé and are probably the best for the determination of these stresses.

When a hub or ring of appreciable thickness relative to its diameter is forced or shrunk on a solid shaft of larger diameter than the bore of the ring, two principal stresses are produced in the ring: a tangential tensile stress S_t and a radial

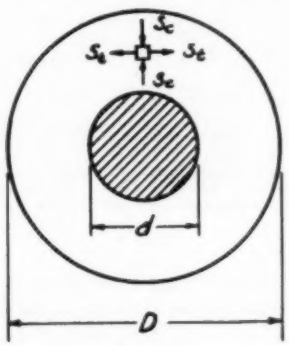

Fig. 1

compressive stress S_c. (See Fig. 1.) If the shaft and ring are of the same material, the maximum value of the tangential or hoop stress, which occurs at the bore, is

$$S_t = \frac{Ee}{2}\left[1 + \left(\frac{d}{D}\right)^2\right] \quad \text{[1]}$$

where E is the modulus of elasticity of the material, e is the fit allowance per inch of shaft diameter, d is the shaft diameter, and D is the outside diameter of the hub. If the shaft and ring are of different materials, the maximum tangential stress at the bore is

$$S_t = \frac{e}{\frac{1}{E_1} + \left[\frac{V_1}{E_1} + \frac{1-V}{E}\right]\left[\frac{1-\left(\frac{d}{D}\right)^2}{1+\left(\frac{d}{D}\right)^2}\right]} \quad \text{[2]}$$

where E and E_1 are the moduli of elasticity of shaft and ring, respectively, V and V_1 are Poisson's ratio for shaft and ring,

and e, d, and D are the same as in Equation [1]. The maximum radial stress, also at the bore, when the material in the shaft and ring are the same is

$$S_e = \frac{Ee}{2}\left[1 - \left(\frac{d}{D}\right)^2\right] \quad \ldots\ldots [3]$$

When the material in the shaft and ring are different, the maximum radial stress is

$$S_e = \frac{e}{\frac{1}{E_1}\left[\frac{1 + \left(\frac{d}{D}\right)^2}{1 - \left(\frac{d}{D}\right)^2} + V_1\right] + \frac{1 - V}{E}} \quad \ldots\ldots [4]$$

where the symbols have the same meaning as in the preceding equations.

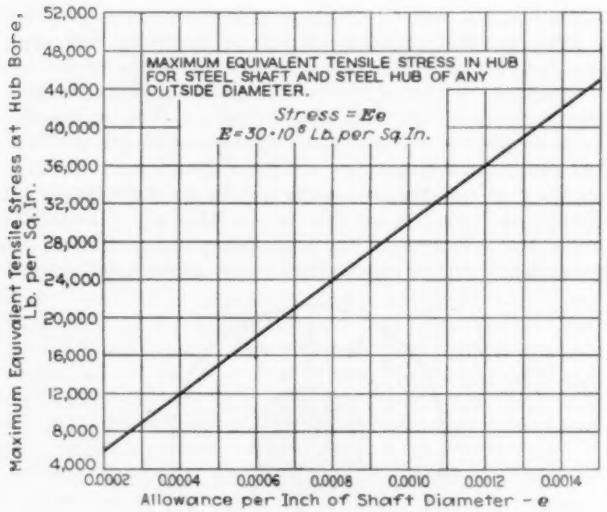

FIG. 2

The statement will be found quite often that the tangential stress, which is always greater than the radial stress, is the stress upon which the safety of the fit depends. In any case where more than one principal stress exists, however, these stresses must be combined according to one of the "theories of strength," and the equivalent stress thus found will be the criterion of strength of the part.

For steel and other ductile materials the maximum shear theory is commonly accepted at this time as being most nearly correct. According to this theory the maximum equivalent tensile stress in the ring due to the combined effect of S_i and S_e is

$$S = Ee \quad \ldots\ldots [5]$$

This stress, which is at the bore, is also the maximum stress in the fit; therefore, this equation determines the fit allowance that can be used when the same ductile material is used in both ring and shaft. It will be noted that when the frequently specified allowance of 0.001 in. per inch of shaft diameter is used the maximum equivalent tensile stress for steel is 30,000 lb. per sq. in., which approaches the yield point of annealed medium carbon steel. If the yield point is exceeded, a permanent set will be produced and a light fit will result. Stresses much above the yield point will cause the outer ring to fracture.

For brittle materials, such as cast iron, it is generally agreed that the maximum stress theory is the correct theory of strength. The critical stress according to this theory is the maximum principal stress, which, as has been seen, is the tangential stress at the bore of the ring as given by Equation [2]. If the shaft is steel and the ring is cast iron and it is assumed that Poisson's ratio is the same for steel and cast iron and that the modulus of elasticity of cast iron is half that of steel, this equation reduces to the simpler form of

$$S = \frac{Ee\left[1 + \left(\frac{d}{D}\right)^2\right]}{3 + V + (1 - V)\left(\frac{d}{D}\right)^2} \quad \ldots\ldots [6]$$

This stress is the greatest stress in the fit. For an allowance of 0.001 in. per inch of shaft diameter, this maximum stress is between 9000 and 15,000 lb. per sq. in., depending upon the ratio d/D. For ordinary cast iron this stress is near the breaking strength, but for the high-strength cast irons now being produced it is well within the limits of safety.

For a complete analysis the stress due to the fit must be combined with the stress at the bore due to the transmission of power, which stress is difficult to determine and is usually quite low, and for very high speeds with the stress due to centrifugal

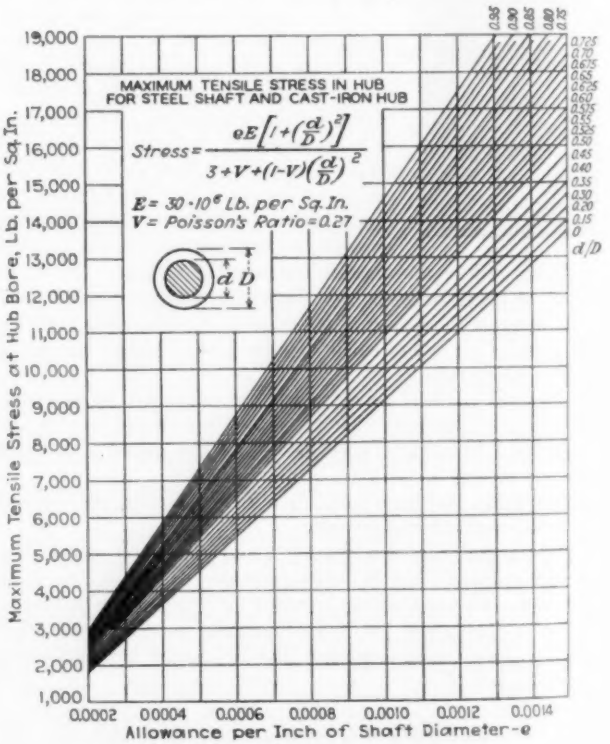

FIG. 3

force, which tends to relieve the pressure between the fitted parts and destroy the effectiveness of the fit. The stress due to centrifugal force[2] will usually be of no consequence, however.

In most instances it will be found that an allowance greater than 0.001 in. per inch of shaft diameter is unnecessary to provide capacity for transmitting the torque.

If a thin ring, such as a bushing, is shrunk or pressed on a shaft or into a thicker ring, the equations given heretofore,

[2] S. Timoshenko and J. M. Lessells, "Applied Elasticity," first edition, p. 303.

which are derived from the theory of thick cylinders, need not be employed. In this case the theory of thin cylinders will be used. This theory assumes that all the deformation occurs in the thin ring and that the tangential stress is uniform over its cross-section. This tangential stress determines the safety of the ring and is $S = Ee$ whether the ring is on a shaft or inside another ring. In the first case S will be a tensile stress and in the second case a compressive stress. This formula is the same as Equation [5].

Figs. 2 and 3, which are charts plotted from Equations [5] and [6], respectively, are useful for quickly determining the critical stresses. If the ring is a gear, a flywheel, or any part in which there is metal outside the actual hub, such as arms and a rim, an equivalent value of D larger than the hub diameter must be used in Equation [6] and the chart. The error that results from estimating this equivalent outside diameter will be usually only a few per cent.

Torque Capacity

The torque that a press fit or a shrink fit can transmit is obviously the product of the unit pressure existing between the shaft and the ring, or hub, the coefficient of friction between the two surfaces, and the area of the surfaces in contact.

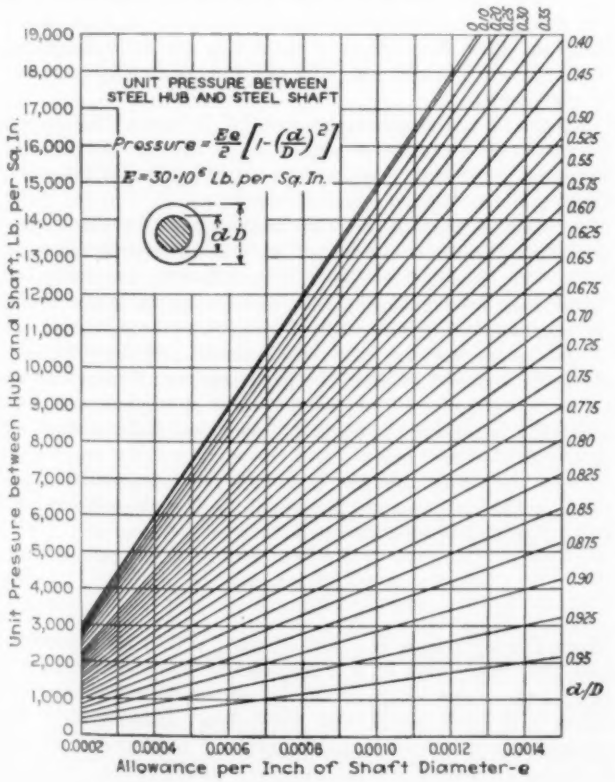

Fig. 4

The pressure has the same value as the radial stress at the bore and may be determined from Equation [3] or Equation [4]. If the shaft and ring are of steel, Equation [3] must be used. The unit pressure is therefore

$$P = \frac{Ee}{2}\left[1 - \left(\frac{d}{D}\right)^2\right] \quad \ldots\ldots\ldots\ldots\ldots [7]$$

If the shaft is steel and the ring cast iron, Equation [4] becomes

$$P = \frac{Ee\left[1 - \left(\frac{d}{D}\right)^2\right]}{3 + V + (1 - V)\left(\frac{d}{D}\right)^2} \quad \ldots\ldots\ldots\ldots [8]$$

if the same assumptions are made as in deducing Equation [6]. The charts, Figs. 4 and 5, plotted from these two equations will be found convenient in determining pressures. As with Fig. 2, an equivalent hub diameter must be used for D when the diameter of the actual hub is not the outside diameter of the outer member.

If the shaft is hollow, Equations [7] and [8], and also Equations [5] and [6], are not exact. If the diameter of the hole is less than 25 per cent of the shaft diameter, however, the

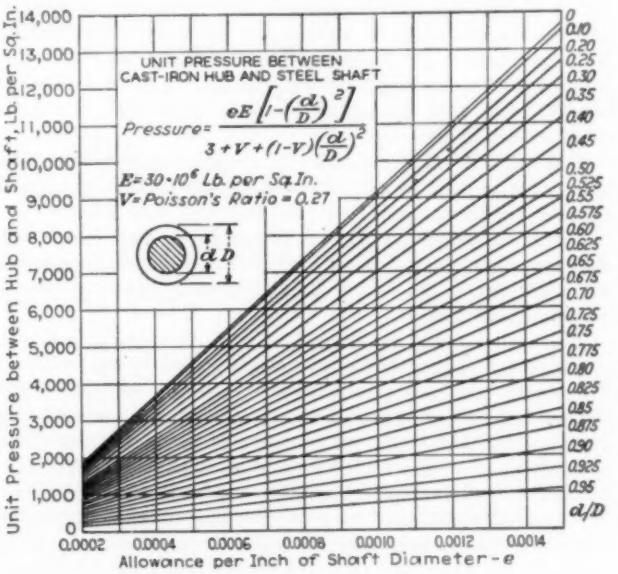

Fig. 5

shaft can be considered solid and these formulas be used with a maximum error (when d/D is zero) of about 7 per cent. The error decreases as d/D increases.

A number of factors affect the coefficient of friction between the fit surfaces, and among these the most important are the finish of the surfaces, the roundness of bore and shaft, the straightness or taper of bore and shaft, and, in the case of a press fit, the lubricant.

Views held on the effect of the finish of the fit surfaces are in direct contradiction. One contention is that the better the finish the lower the coefficient of friction. The opposite view borne out by the experiments of N. N. Sawin[3] is that the coefficient is larger with finer finish because the minute ridges on the metal are smaller and the actual contact area more nearly equals the theoretical area of the surfaces in contact. Values that the author calculated from the results of more than a hundred press fits in which one of the members was finished by grinding and the other either by grinding, finish-turning, or rough-turning show practically no effect of this difference in finish. It is to be expected, however, that there is a limit beyond which the ridges on rough-finished parts will shear off during assembly and a low tonnage will result. It is probable, also, that the force required to press the members apart will be less if the finish is poor than if it were good, even though the

[3] N. N. Sawin, *American Machinist*, May 31, 1928, p. 889.

force required to press them together were the same in both cases. For this reason and because grinding allows closer tolerances and more accurate measurement and seems to produce greater uniformity of results, ground surfaces are preferable.

After a shaft is pressed into a hub, the lubricant in time tends to squeeze out and the metal surfaces to freeze together, and a greater force will be required to press the shaft out if the fitted parts are allowed to stand for several days. A greater force will be required also to press a shaft out of a ring that has been shrunk on than if a press fit has been made with the same allowance. This fact is due, probably, to some lubricant remaining between the surfaces of a press fit and to the wearing of a path in the metal when the shaft is forced into the hub.

One of the laws of friction for partially lubricated surfaces is that the coefficient of friction increases with increase of pressure per unit area. The pressures between fitted surfaces in practice range from about 2000 lb. per sq. in. for very light fits to more than 15,000 lb. per sq. in. for heavy fits. For this range variations in pressure seem to exert no effect on the coefficient of friction between the surfaces—probably because the pressures are so high.

The hardness of the metal, its chemical composition, and whether it is cast, forged, or rolled appear to have much less effect on the friction coefficient than the other variables.

Actual coefficients of friction in pressing a shaft into a hub may vary from about 0.040 to 0.340. The coefficient in pressing the shaft out of the hub is usually greater with a minimum value of about 0.10.

The author found coefficients of 0.10, 0.11, 0.11, and 0.14 in pressing $5^1/_4$-in. diameter oil-quenched steel shafts of about 175 Brinell hardness into hardened cast-steel spiders of 160 to 260 Brinell hardness. When the shafts were pressed out after the fits had stood for 24 hours or more, the respective coefficients of friction were 0.14, 0.14, 0.12, and 0.15. Coefficients in pressing apart shrink fits were 0.16 and 0.17, about 25 per cent greater than the corresponding values for press fits made with the same shafts and hubs. In another series of 15 press fits for which the author recorded data, the coefficients of friction in pressing in the shafts ranged from 0.075 to 0.25, with an average value of 0.15. In these cases the shaft was $6^1/_{16}$ in. in diameter and of medium carbon steel quenched in oil. The ring was a pinion of the same material treated in like manner. The hardness of both shaft and pinion was about 170 Brinell. As in the cases cited heretofore the lubricant used in making the press fits was a mixture of white lead and light machine oil and the fit surfaces were ground. In all cases, also, great care was taken to obtain correct measurements of shaft and bore, readings being taken on a number of diameters in several planes and the micrometer calipers being checked against each other and against a standard gage.

In tests[4] with a tapered, ground, hardened steel shaft of $6^1/_2$ in. mean diameter and a hardened steel pinion with a ground bore the coefficients of friction in forcing out the shaft were 0.15, 0.17, and 0.21. The coefficients in forcing out the shaft after shrink fits had been made with the same allowances were 0.21, 0.22, and 0.23, respectively. The average shrink fit coefficient is about 25 per cent above the average press fit value.

In extensive researches on force fits N. N. Sawin[5] pressed long, tapered steel shafts through thick steel and cast-iron rings, thus gradually increasing the fit as the shaft was forced through the ring. The shafts and ring bores were ground, and when the fits were made, rape oil was used as a lubricant. While few numerical values were published, certain test data sent to the author yielded coefficients of friction for hardened steel shafts and rings of 0.054 to 0.22, with an average of 0.11. The diameters of the shafts used were 0.315 to 8.2 in. In some cases the coefficient of friction decreased as the shaft progressed through the ring; in other cases it remained practically the same.

Records of over two-hundred press fits published by C. F. MacGill[6] gave coefficients of friction for steel shafts and steel hubs ranging from 0.077 to 0.33 and for steel shafts and cast-iron hubs from 0.053 to 0.30, the average of all values being 0.17. The finish of the surfaces was not mentioned.

Coefficients of friction were computed by the author from data on 123 press fits, about half of which were made with both bore and shaft ground and the remainder with either the shaft turned and the bore ground or the shaft ground and the bore rough or finish-bored. Shafts were of heat-treated medium carbon or alloy steel, and outer members, which were gears or pinions, were of heat-treated medium carbon cast, rolled, or forged steel. The values of the friction coefficient varied from 0.03 to 0.25, the lower values being undoubtedly due to yielding of the soft steel around the bore because of too large fit allowances. The average coefficient where either bore or shaft was not ground was 0.091, while for ground shafts and bores the average was 0.086, about 6 per cent lower. It would seem, therefore, that the method of machining the fit surfaces has little effect on the coefficient of friction and the tonnage necessary to make the fit.

Except for the classic experiments of Wilmore,[7] the author knows of only one series of tests of fits in torsion. Four shrink fits were made[8] with shafts $2^1/_2$ in. in diameter, and the coefficients of friction ranged from 0.25 to 0.33.

A general average of the coefficients of friction realized when pressing in shafts would be probably in the neighborhood of 0.15. For pressing out shafts the coefficients are somewhat higher than for pressing in, and for twisting the shafts in the fits the values are greater still. Therefore, in the determination of the torque that a press fit will transmit and the force that should be required to press the parts together, it is reasonable to use a value of 0.10 for the coefficient of friction in torsion and 0.075 in making the fit, and these values have been found to give satisfactory results.

Since the torque that the fit is capable of transmitting depends on the coefficient and the area of the fit surfaces in contact, this torque may be expressed as

$$T = \frac{\pi}{2} f P L d^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots [9]$$

where T is the torque in pound-inches, f is 0.10 for a press fit and 0.125 for a shrink fit, P is the pressure obtained from Figs. 4 or 5, L the actual length of the fit, and d the shaft diameter. While it is fairly certain that the values suggested for f are conservative, they are based largely on coefficients realized in pressing shafts and hubs together; consequently, it is advisable to allow a safety factor in Equation [9]. However, for the common fit allowances and the usual proportions of bore, hub length, and hub thickness it will be found that there is ordinarily a generous factor of safety; in fact, in medium and large-size machinery it is surprising how seldom a key is necessary to transmit the power.

[8] These experiments were made by S. Timoshenko and L. S. Jacobsen, then of the Engineering Department, Westinghouse Elec. & Mfg. Co.

In a similar manner the average force in tons required to force the parts together may be stated as

$$F = \frac{\pi}{2000} f_1 PLd \ldots\ldots\ldots\ldots\ldots [10]$$

In this equation 0.075 may be used as an average value of f_1. Values of f_1, however, may vary from a minimum of about 0.05 to a maximum of about 0.30, so that the tonnages also will vary within wide limits. P, L, and d are the same as for Equation [9], and it will be observed that the force of pressing is in direct proportion to L, the length of the fit. In case a key has been used, the area πLd must be reduced by the area of the keyway.

With the equations presented every important question concerning a fit can be determined in advance. Furthermore, if the force required to make a press fit be recorded, an excellent estimate can be had of the torque that the fit will transmit. It is to be hoped also that more experimental data will soon be available on coefficients of friction for fits subjected to torque; and if so, perhaps designers will be inspired with more confidence in press fits and shrink fits and the use of keys will be confined to the few cases of necessity.

Discussion

D. V. Waters.[9] This paper is one that we can use in our every-day life. However, where mating parts are made in quantities not sufficient to justify the use of gages, it would seem that the safest plan would be to use keys, as we cannot always depend upon the man in the shop giving us the fit we should have. It is true that the stress concentration due to keyways is undesirable, but it may be somewhat minimized if they are cut with a disk-type cutter instead of an end mill, and if care is taken that the keyways do not extend clear to any shoulder that may be turned upon the shaft.

This is not intended in any way as a criticism, as for parts made with gages to interchangeable limits a good shrink or press fit is no doubt entirely adequate to transmit the torque required.

E. O. Waters.[10] Designers have grown used to employing the press fit and shrink fit as a means of securing rigidity in an assemblage of parts, without regard to the possibility of transmitting torque. It is fortunate that the author of this paper has seen fit to call attention to this possibility, and there can be no doubt that his straightforward analysis of the stresses and pressures involved, leading up to a simple method for calculating the torque capacity of one of these tight fits, will prove very useful in future design and construction.

However, it appears that the author, in his enthusiasm for press and shrink fits, has treated the keyed fastening with somewhat less than justice. Is it generally true that the elimination of keys and keyways reduces manufacturing costs? It would seem self-evident that, if the fit is relied upon to transmit the torque, the manufacturing tolerances must be held within much closer limits, and special equipment will be needed to make the assembly. Moreover, the process of disassembly becomes more difficult.

In the second place, what may be called the "space efficiency" of a keyed joint is much greater than that of a press fit. Assume for example, that a steel hub of diameter $2d$ is keyed to a steel shaft of diameter d with a steel key of width $^1/_4 d$. Then, if S_s represents the shear stress in the key, the torque transmitted per inch of length is

$$^1/_4 d \times {}^1/_2 d \times S_s = \frac{d^2 S_s}{8}$$

Compare with this a friction fit in which the shear stress at the bore of the hub also equals S_s. Then, in the author's notation,

$$S_s = {}^1/_2 Ee \text{ and } S_s = S_s[1 - (d/D)^2] = {}^3/_4 S_s$$

With a coefficient of friction of 0.10 and a factor of safety of 2 against slippage (roughly equivalent to the factor of safety against overstress that would probably be used in the case of the key), the torque per inch of length is

$$^1/_2 \pi \times \frac{0.10}{2} \times {}^3/_4 S_s \times d^2 = \frac{d^2 S_s}{17}$$

If the hub is made of cast iron with an assumed maximum tensile stress of $^1/_2 S_s$, then

$$S_s = \frac{1 - (d/D)^2}{1 + (d/D)^2} \times {}^1/_2 S_s = 0.3 S_s$$

and the torque per inch of length is

$$^1/_2 \pi \times \frac{0.10}{2} \times 0.3 S_s \times d^2 = \frac{d^2 S_s}{42.5}$$

In one case, the friction fit would have to be over twice as long, and in the other, over five times as long as the keyed fit, to transmit the same torque. This would indicate that the force or shrink fit is best suited to transmitting torque when the hub takes only a small portion of the maximum torque capacity of the shaft—a condition excellently exemplified in the street-railway application cited by the author.

A. M. Wahl.[11] The author deserves credit for presenting a fairly simple means for evaluating shrink and press-fit allowances, together with convenient graphs for the use of the practical designer. In looking over the paper, the writer noted the statement on the second page to the effect that, if the yield point of the material were exceeded, a light fit would result. Assuming that we have a ductile material, so that yielding occurs under practically constant stress, it is not quite clear to the writer just why this loss of fit would occur. Possibly an explanation of this phenomenon would involve plastic after-effects or the shape of the stress-strain diagram on removal of load. The writer was also wondering whether this loss of fit due to yielding had actually been observed in practice, although it appears to be the general opinion among engineers that this will occur. Of course, where brittle materials, such as cast iron, are involved, it is clear that too high a stress will result in fracture, with consequent loss in fit. If this loss of fit actually occurs for steel shrink or press fits, when the allowance is such that the yield point is exceeded, the writer would be interested in obtaining a rational explanation.

Sanford A. Moss.[12] The formulas for stress which the author uses are all correct, regardless of any comparison with Lamé, Clavarino, and Birnie. However, as an actual fact, the formulas pro-

posed by those three gentlemen are also all correct and in agreement with Mr. Baugher's formulas. All of the formulas take proper account of the lateral contraction expressed by Poisson's ratio. Lamé's formulas only go as far as giving internal stresses. The Birnie final form uses the stresses as given by Lamé or Mr. Baugher, but adds them together so as to obtain a criterion for failure according to the maximum strain theory. The Clavarino final form is for a cylinder with internal pressure with heads, and also on the basis of the maximum strain theory. Mr. Baugher gives reasons which seem to be correct for using the maximum shear theory instead of the maximum strain theory. So far as is known, this was applied to force fits for the first time in the *General Electric Review* paper which Mr. Baugher mentions. A rational derivation of all of these formulas is given in a paper, "Increase of Bore of High-Speed Wheels by Centrifugal Stresses," Trans. A.S.M.E., 1912. This paper gives an explicit and easily followed demonstration of two fundamental principles applying to any sort of stresses in thick cylinders, called Lamé's laws. These are:

(1) The sum of the values of radial and tangential stresses at any radius has a constant value.

It follows that the longitudinal strain (which is the sum of the lateral contractions due to radial and tangential stresses) is the same at all radii.

(2) The difference between the values of the radial and tangential stresses at any radius varies inversely as the square of the radius.

This statement of Lamé's laws is based on the convention that tensile stresses are positive and compressive stresses negative. On this basis, all of the author's compressive stresses should have a minus sign, which seems to me to be the most consistent way of handling the matter. The writer has not seen Lamé's original paper, but has understood that he does not give a thorough derivation of his laws. The laws are correct, however, based on the use of Poisson's ratio, and, as stated, are rationally deduced in the 1912 A.S.M.E. paper.

Mr. Baugher is of course aware that the transmission of torque by means of a shrink fit, as he proposes, is standard practice in many cases, and the advantages he claims for it have been found to be true. However, Mr. Baugher introduces a number of numerical values which have not been before brought together. It would be desirable if he would give a value of f for his Equation [9], which has a proper factor of safety for a specified case, so that Equation [9] will give a value of torque which will be transmitted with a factor of safety proper in Mr. Baugher's judgment.

JOHN MANSA.[13] The author presents formulas and graphs for determining the maximum tensile stress in a hub and the radial pressure per unit surface of a fit. The formulas are clearly explained and the graphs are very convenient to use. The paper is therefore a help for the designing engineer.

However, when one reviews his friction data, it will be seen that there is a rather discouraging variation in the observed friction coefficients. The writer is of the opinion that this might be because the calculation of the friction coefficients have been based on assumptions which do not represent true conditions.

An example will show more clearly what is meant than an abstract treatment.

In Fig. 6, S is a shaft fitted in a hub H. The fit is transmitting a torque T. Mr. Baugher assumes that each unit of the fit surface is transmitting an equal part of the torque T. As the internal torque in the shaft is T at the beginning of the fit (section A-A) and zero at the end of the fit (section B-B), then the average torque in the part of the shaft within the fit is $^1/_2\ T$. The angular distortion of section A-A relatively to section B-B will be

$$\frac{^1/_2\ T \times L}{G \times \pi/_{32} \times d^4} \text{ (radians)}$$

where T is the total torque transmitted through the fit, L the length of the fit, d the diameter of the fit, and G the shearing modulus of elasticity for the shaft material.

This proves that for the assumed torque distribution there is a definite angular deformation of the shaft between the sections A-A and B-B. If now, and that will practically always be the case, the elasticity of the hub is different from that of the shaft, then a relative movement between the shaft and the hub must take place somewhere in the fit. But a sliding in some parts of the fit will destroy the joint, and therefore the assumption of uniform torque transmission cannot be correct.

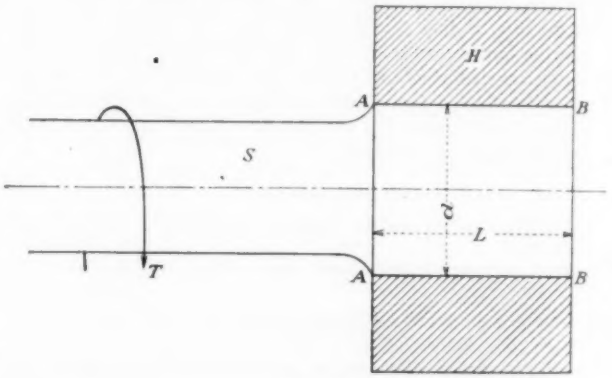

FIG. 6

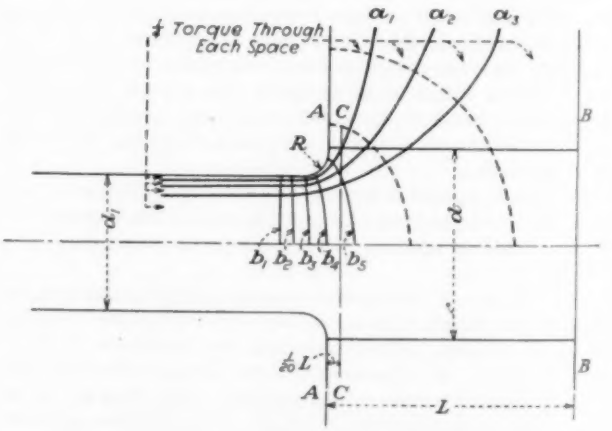

FIG. 7

The correct torque distribution must be determined by assuming no relative movement between shaft and hub in any part of the fit. This problem is practically the same as to find the stress distribution in a torque-transmitting shaft of varying diameter. A solution of that problem is given by F. A. Willers.[14]

Fig. 7 gives the approximate picture of the "torque flow" through a fit from a shaft to a hub. The lines a are equimomental lines; one-quarter of the torque is flowing between the surface and the line a_1, another quarter of the torque is flowing between the lines a_1 and a_2, and so on. The lines b are called equiangular lines; they are connecting points with the same an-

[13] Oil-Engine Designer, Ingersoll-Rand Company, Phillipsburg, N. J. Mem. A.S.M.E.

[14] *Zeitschrift für Mathematik und Physik*, vol. 55, 1907, pp. 225–263. Porter has used the same method for determining the stiffness of a shaft with varying diameter. Trans. A.S.M.E., paper APM-50-8.

gular distortion. It will be seen that for this special fit one-quarter of the torque is transmitted through one-twentieth of the surface (located between section *A-A* and *C-C*). If a joint like this is twisted to the point of sliding, then the friction coefficient calculated by Mr. Baugher's Equation [9] (in the following referred to as the "apparent friction coefficient") will be five times smaller than the true friction coefficient, existing between section *A-A* and *C-C*.

If the true friction coefficient always was five times the apparent, then the error would be of no importance. However, the relative values of the fillet radius R, the diameters d and d_1, the length L, and the outside diameter of the hub D have an overwhelming influence on the ratio between the apparent friction coefficient and the true one. The ratio varies from 1 to 10, or even more for fits of commonly used design.

From this it is obvious that for the calculation of a fit the knowledge of the torque distribution over the surface of the fit is as important as the knowledge of the friction coefficient. The large variation of the friction coefficients determined by the author might more or less be due to the disregarding of the torque distribution in the different fits tested by him.

The writer has referred only to torque-transmitting fits. Of course, similar conditions take place when a fit is subject to a force in axial direction.

CHARLES JABLOW.[15] The paper is a concise and useful treatise for any engineer in making or using press or shrink fits. Some of the suggested methods of calculation have been given the acid test over a period of years and this has resulted in entire satisfaction.

In reading the paper there are several points that suggest themselves. One thing is that it is not only important to know the torque that a fit will transmit, but of greater import is it to arrive at the true value of torque that the fit will be called upon to withstand. Many loose fits, of course, can be traced to the various factors enumerated. The writer wishes merely to point out that the normal duty of the fit will be only a fraction of the occasional duty, and therefore it is desirable to predetermine the maximum possible rates of acceleration or retardation and the inertia of the connected masses. The writer has in mind a pinion fit of a car or locomotive motor during an emergency brake application or perhaps a flashover in the motor. Under such conditions, the normal duty of the fit falls far short of requirements.

It is hardly conceivable to imagine a key working in parallel or as an aid to a fit. The writer's experience includes sheared keys that failed at about six times the maximum torque for which they were designed. Had a fit alone been used in this application, it is probable that the shrink fit would have been adequate. In spite of the admission that keyways are not always cut accurately in the plane of the axis of the shaft, many designers are prone to insist upon their use, and in the case of an electric motor, where a loss of a fit without a key might result in excessive overspeed, causing failure of the motor, these keys may be justified.

The lubrication of a press fit has been referred to, but few consider the lubrication in a shrink fit. It has been our experience with a ground shaft and ground bores that where extreme care was taken with the ring gage to check the shaft and a plug gage to check the pinion, the resulting lubricant remaining in the bore due to the prussian blue check resulted in just a sufficient film of lubricant to seriously affect the holding power. With the method of heating formerly used in the particular case referred to, this lubricating film was not removed. Subsequent heating with a gas torch in the bore, to the same temperature as previously used, resulted in very much higher tonnages. It is therefore important to notice that the character of the machine fit is not the all-important thing it seems.

It is the practice among certain manufacturers to specify tonnage instead of fit allowance. If, as the author indicates, the lubricant is squeezed out in the fit, this would seem to be a great fallacy, and it is more important to make sure that the fit allowance is had. It is no secret among men operating a press that they will obtain the tonnage required almost in spite of the fit allowance.

The author is to be commended for clarifying the points involved in making press and shrink fits.

[15] Railway Equipment Engineer, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa. Mem. A.S.M.E.

AUTHOR'S CLOSURE

The point raised by Mr. D. V. Waters regarding the use of keys where mating parts are made without gages is well taken. The author's experience, however, has been largely with miscellaneous gears, quite often fitted without keys and for which gages usually were not used, and there have been practically no cases of trouble resulting from insufficient fit allowances.

What Professor Waters says of the increased cost brought about by closer tolerances and special equipment necessary in employing press and shrink fits is probably true in many instances; yet it is the author's belief that, in the majority of cases where keys are used, a press fit or a shrink fit also is used, as Professor Waters brings out, to secure rigidity.

The second point raised by Professor Waters is very interesting, although the author cannot agree with the conclusions. Several errors seem to have been made in deducing the equations, so that a true comparison cannot be made with the equations as presented.

First, in the expression $d^3S_s/8$ in his first equation, S_s is the shearing stress in a steel key (see Fig. 8); whereas in the third

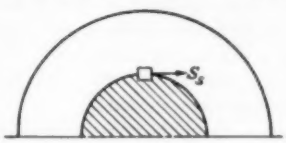

FIG. 8

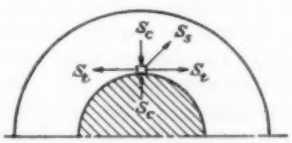

FIG. 9

equation S_s is the maximum shearing stress in a steel hub (see Fig. 9). A comparison of the two equations becomes, therefore, a comparison of the allowable shearing stress in key steel with the allowable shearing stress in the steel of which the hub is made. Obviously, the two allowable values are seldom the same; and as key stock is usually low-carbon steel, the advantage will most often be decidedly in favor of the material in the hub, especially if it is heat-treated. Therefore it cannot be said that for a steel shaft and hub the "space efficiency" of a press fit is only half that of a keyed joint, since for many cases it may be equal or greater, depending upon the materials used. Second, a safety factor of two is used in the third equation, but none is used in the first equation. This factor alone accounts for the difference in torque capacity represented by the two equations.

These discrepancies apply also to the comparison of the first and fifth equations. In addition, the assumption made in deducing the fourth equation—i.e., "cast iron with an assumed maximum tensile stress of $^1/_2$ S_s"—is open to question, since the failure of cast iron in torsion is actually a tensile failure. Most published data give the maximum tensile strength of cast iron as 0.83 to 0.90 of the maximum strength in shear. If the lower value were used, the fourth equation would become $S_s = 0.5\ S_s$, and the right-hand side of the fifth equation would become $d^3S_s/25$. If the safety factor were then omitted, as in

the first equation, the right-hand side of the fifth equation would become $d^2S_s/12.5$. A fair comparison may then be made between the first and fifth equations. It must be remembered, however, as before, that the values of S_s in the two equations are not the same.

The author is convinced, also, that when more comprehensive results are available on the behavior of fits in torsion, the safe value of f will be found to be several times the figure of 0.10, which is recommended in this paper and used in Professor Waters' third and fifth equations. If this proves to be true, the third equation will become at least equal to and perhaps greater than the first equation, even though the other points are neglected.

Therefore it seems to the author that Professor Waters' equations really show that the "space efficiency" of a press fit is greater than that of a keyed joint when the hub is steel and is nearly equal to that of a keyed joint when the hub is cast iron. There is considerable proof in practice that this is true for a steel hub.

The author was fortunate in being able to consult Dr. A. Nádai,[16] an authority on the plastic state of metals, with regard to the question raised by Mr. Wahl. The answer to this question is, as Mr. Wahl suggests, the plastic flow which occurs when the material in the hub is stressed beyond the yield point. If a straight bar is stressed above the yield point and the load is then held constant, the bar will continue to stretch a small amount. The same action takes place in a plastically overstressed hub of a press fit. Therefore what the author has called a decrease in the coefficient of friction is really a decrease in the pressure between the two parts. If, in such a case, Equation [10] be reversed in order to determine the friction coefficient f_1 from actual data observed in making a fit, the theoretical value of P obtained from the pressure chart will be greater than the pressure which actually existed between the fitted parts, and the error will show in a decreased value of f_1. The author has observed such a result a number of times when the fit allowance was so high that there was little doubt that the yield point of the metal in the hub had been exceeded.

The comments of Dr. Moss are a valuable contribution in clarifying the questions which the author was unable to explain, regarding the formulas given by the various authorities. In a number of texts on machine design and mechanics of materials, however, there does seem to be a lack of agreement concerning the form of the equations attributed to the different authorities.

Regarding the value of f which has a proper safety factor for use in Equation [9], the author believes that 0.05 represents the minimum value that need be used on the basis of present knowledge of press fits. The use of this value, of course, is equivalent to incorporating a factor of safety of 2 in the equation, the other values remaining as recommended on the fourth page. With what may be termed standard proportions of machine parts in use at present, the factor of safety above the torque to be transmitted usually will be considerably greater than 2 for a value of f equal to 0.10 and a value of e equal to 0.001 in. per in. of shaft diameter. As stated before, the author believes that when more data are available on the behavior of fits in torsion, the safe value of f will be found to be much greater than 0.10.

Every one who has compiled results of a large number of press fits has observed a great variation in the coefficient of friction. The author does not feel, however, that Mr. Mansa's explanation offers a complete solution, because he does not believe that the case of axial force in making or disassembling a fit—from which practically all the data given in this paper are taken—is similar to the case of twisting. The former is a case of constantly increasing area of contact—in pressing two parts together—accompanied by a proportionately increasing force, while the latter is a case of non-uniform distribution of torque.

Mr. Mansa's discussion of the correct torque distribution is of great importance. The author is familiar with Willers' method of determining the stress distribution in a shaft of varying cross-section. In fact, Timoshenko and Jacobsen applied this theory in 1924 to the case of press and shrink fits in the unpublished report to which the author referred on the fourth page. This report brings out several interesting facts. One is that slippage starts at one end of the fit—at A-A in Fig. 6, for example—and progresses with increase of torque until the entire fit slips. This result, of course, is to be expected. The torque required to produce the initial slip does not increase as the length of the fit is increased beyond a length of about half the shaft diameter. The torque required to produce complete slip does increase, however, directly in proportion to the length of the fit. The coefficients of friction at the instant of complete slip, as computed from an equation similar to [9], were found to be in the neighborhood of 0.30, as noted on the fourth page. According to Willers' theory, the torque required to produce initial slip will decrease, as Mr. Mansa suggests, as the fillet radius—R in Fig. 7—is decreased. Since in the majority of fits in practice the hub is pressed directly on a straight shaft so that there is no fillet, it is to be expected that initial slip of such fits takes place at very low values of torque. There seem to be no serious results of such conditions, however, and hundreds of cases can be cited where the fits are performing satisfactorily.

As the analysis given by Mr. Mansa assumes that there is no slip between hub and shaft, it would seem that a solution by this method would yield only the torque necessary to produce first slip, which in most cases is probably quite low in comparison with the ultimate torque capacity of the fit. Practical experience proves that it is not necessary to limit the torque to be transmitted to the initial slip value. Therefore, in view of these facts, it seems to the author that there is considerable justification for a simple statement of the ultimate torque capacity of a fit, as expressed by Equation [9], in which the value f_1 is admittedly an average coefficient of friction.

It is unnecessary for the author to emphasize the importance of Mr. Jablow's statement with regard to the correct determination of the maximum torque that a fit will be called upon to transmit. In many applications the maximum torque can be easily computed, but in others it cannot. Unless it is known quite exactly, however, similar safety factors must be used for the fits as are used in determining the design of the other parts of a machine.

Haynes Stellite Cutting Tools

By W. A. BECKER[1] and E. E. GORDON,[2] KOKOMO, IND., and W. A. WISSLER,[3] LONG ISLAND CITY, N. Y.

This paper describes briefly the physical properties of Haynes Stellite and gives the more important details of several types of machining operations on which it is being successfully used. Its most important property is red hardness. Measurements of hardness were made by an improved method up to 1100 deg. cent. The resulting data show that the cobalt-chromium-tungsten alloy is harder than high-speed steel at temperatures above 500 deg. cent. This is believed to account for its superior cutting quality.

When used for milling, three typical jobs on cast iron show 87, 100, and 27 per cent increased production, respectively, on high-speed steel. On boring cylinder blocks the increase was 64 per cent. Turning operations in cast iron show 33, 35, and 60 per cent increase in production, and on steel, 123 and 93 per cent.

In general, Stellite bits and blades can be used economically on all operations on cast iron, semi-steel, malleable iron, bronze or similar metals, and on mild steel if the section is heavy and the tools are rigidly supported. It has not been successful on automatic or semi-automatic machines for cutting steel.

W. A. Becker

E. E. Gordon

W. A. Wissler

HAYNES STELLITE is a non-ferrous alloy consisting essentially of cobalt, chromium, and tungsten, invented and patented by Elwood Haynes, who is also credited with having built one of the first successful automobiles. The early experiments were directed toward the development of a non-tarnishing alloy for use in the manufacture of cutlery, but it was soon found that the addition of tungsten conferred a high degree of hardness; the resulting alloys were tested and found satisfactory as cutting tools in the Haynes automobile plant. The superiority of the alloy over cutting tools then in use was very striking, and its introduction into the machining industry progressed more or less rapidly until the war, at which time the alloy took its place as an important factor in the rapid production of war supplies. Its widespread use in subsequent years needs no description.

It is obvious that the properties of these alloys will vary considerably, depending upon their relative compositions. Some of them are soft enough to be forged and rolled to a very limited degree; these grades are used for knives and similar purposes. As more tungsten is added the hardness increases, reaching its maximum in grade No. 3, which is used largely for machine tools. Grade No. 1, furnished as welding rod, is almost equal to No. 3 in hardness, but has been especially adapted for welding on machine parts subject to abrasive wear. This paper will be confined to No. 3, and all data and figures given refer to this grade of metal, which must be cast to shape and finished by grinding.

Aside from the cutting quality of the tool, which at the present time must be determined by an actual cutting test, there are a few physical properties that are of sufficient interest to the subject at hand to be tabulated herein. Comparative strength figures, determined by a cantilever method duplicating rather closely the conditions under which a lathe tool operates, show that Stellite is admittedly weaker than high-speed steel; this is, however, compensated for in the design of tool holders and tools, and causes but little trouble in operation.

TABLE 1 PHYSICAL PROPERTIES

Hardness cold:	Stellite No. 3	High-speed steel, hardened and drawn
Rockwell	C-61	C-63
Brinell	600	627
Tensile strength, lb. per sq. in.	38,000	.....
Compressive strength, lb. per sq. in.	311,000	382,000
Cantilever strength (1/2 in. sq., 1 in. overhang), lb.	2500	5000

Haynes Stellite is usually thought of as being an extremely hard alloy, but its hardness when measured cold is not unusually great, as will be seen in Table 1. This fact makes it difficult to account for the superiority of the alloy as a cutting tool until it is realized that the cutting edges of tools in operation are heated to surprisingly high temperatures. It is very seldom that a visual examination of a lathe tool in operation gives any indication of a red heat, but Mr. E. G. Herbert, who has carried out extensive researches in England on the mechanism of cutting, has given definite determinations of cutting-tool temperatures.[4] By using a set-up in which the tool and the billet are made the

[1] Sales Engineer, Haynes Stellite Company. Mr. Becker spent five years in the employ of several of the large machine-tool and motor builders, actively engaged in research on the fundamentals of milling, boring, turning, etc., studying from both the practical and theoretical angles. Immediately following this work, in 1920 he became a sales engineer for the Haynes Stellite Company, connected first with the Detroit office and then in the Chicago territory.

[2] Sales Engineer, Haynes Stellite Company. Mr. Gordon has been a sales engineer for the Haynes Stellite Company since 1922, working in both the Cleveland and Detroit offices. Immediately prior to this he was engaged for six years in production work, time study and research on problems relating to the most efficient use of steel and alloy tools in one of the large automobile shops. The practical experience gained by this work was supplemented by technical training along the lines indicated.

[3] Metallurgist, Union Carbide and Carbon Research Laboratories, Inc. Mr. Wissler became metallurgist for the Haynes Stellite Company in 1917 and was closely associated with Elwood Haynes during the development period of the company. In 1923 he was transferred to the Union Carbide and Carbon Research Laboratories in charge of research and experimental work on alloy cutting tools. Prior to the connection with the Haynes Stellite Company he had secured degrees in chemistry and electrometallurgy and had held several positions more or less closely connected with the non-ferrous alloy industry.

Contributed by the Special Research Committee on Cutting of Metals and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[4] *American Machinist*, Feb. 18, 1926, p. 281.

elements of a thermocouple, and using very sensitive instruments for recording by photographic methods, Mr. Herbert determined that cutting-edge temperatures vary from 250 to 700 deg. cent. while cutting dry and from 100 to 525 deg. cent. when using a coolant, the temperatures being higher with greater cutting speeds. Obviously, if the tool does its work at such high temperatures, the effective hardness is the hardness of the tool within that range of temperatures. Mr. Herbert carried on experiments correlating the cutting quality and red hardness of different high-speed steels heat-treated by different

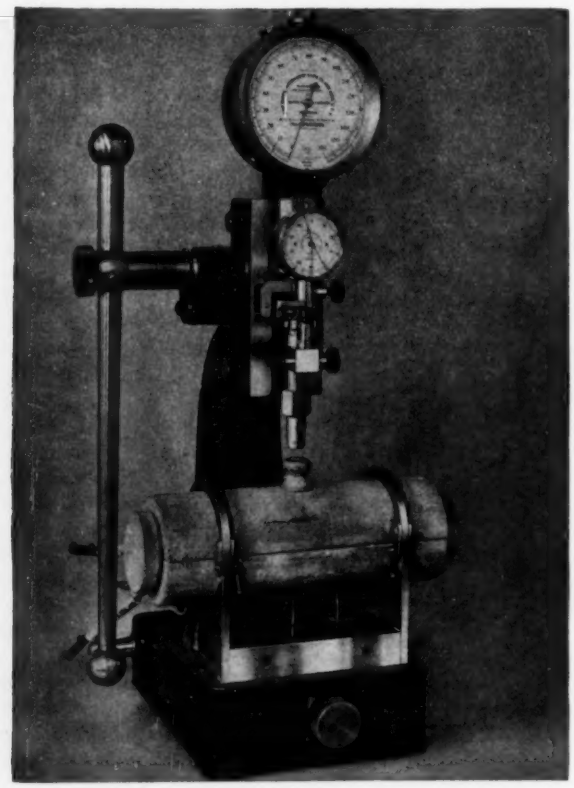

FIG. 1 MONOTRON HARDNESS-TESTING MACHINE

methods, and concluded that high-speed steel tools could be evaluated by a "figure of merit" consisting of a certain hardness at a certain temperature, the temperatures being somewhere in the neighborhood of 600 deg. cent.[5] For these experiments the pendulum hardness tester was used.

In view of the importance of the red hardness property in cutting tools, the Union Carbide and Carbon Research Laboratories has investigated hardness from ordinary temperatures to as high as 1100 deg. cent. After quite a number of experiments it was decided that the Monotron hardness-testing machine (Fig. 1) would be most readily adaptable for the purpose. This machine can be equipped with a furnace so designed that the hardness of a bar may be determined without removing it from the furnace, thus eliminating heat losses with the exception of those occurring by conduction through the penetrator, and by making the determination as quickly as possible these losses can be reduced to a minimum. Using this apparatus, data have been secured from which curves (Fig. 2) have been drawn showing the average hardness of Haynes Stellite and several makes of high-speed steel from room temperatures to 1100 deg. cent. At temperatures of 500 deg. cent. and higher, Haynes Stellite is harder than any steel tool or ferrous alloy as yet examined. This property is believed to be the dominating factor in the values of Haynes Stellite—supporting evidence being offered in that the successive development of plain carbon steel, Mushet steel, chromium-tungsten and chromium-tungsten-cobalt high-speed steel has resulted in every case in the production of a tool having greater hardness at higher temperatures.

The large majority of Haynes Stellite cutting tools are furnished in the form of bits and blades of solid Haynes Stellite, but for certain purposes it is advisable to use a welded tool consisting of a tough steel shank and a Haynes Stellite tip. It is recommended that solid tools be used in every case where it is possible and economical and that welded tools be used only on jobs where there is considerable overhang and when the size of the tool would result in extremely high costs if it were made solid. On practically all production jobs today tools of cross-section 1 in. sq. and under are made solid. Solid tools possess maximum cutting quality. They are cast in a special manner with chilled cutting surfaces. The excessive heat of the welding operation incident to the manufacture of welded tools destroys some of the outer chill and slightly impairs the cutting quality. Extensive tests in large production shops have proved conclusively that solid tools of Haynes Stellite are 10 to 15 per cent more efficient than welded tools.

Speeds: 3000 to 4000 ft. per min.

All cutting tools must be properly ground, and it is natural to expect that the proper practice for alloy tools would differ

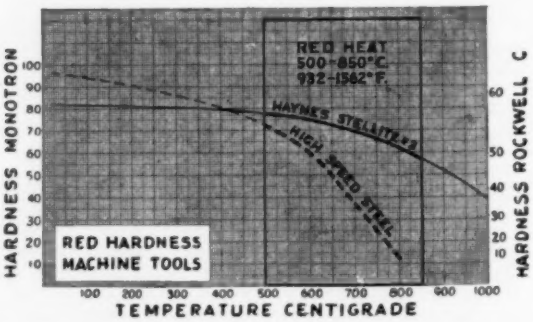

FIG. 2 AVERAGE HARDNESS OF HAYNES STELLITE AND SEVERAL MAKES OF HIGH-SPEED STEEL

from that for high-speed steel. Experience gained over a period of years in our own and customers' shops enables us to make the recommendations listed herewith. In addition to using the proper wheels, care should be exercised that the tools are not overheated and checked in the grinding operation. The generation of sudden heat should be avoided and the tool be heated gradually. If heat is suddenly applied, the alloy has a tendency to check and crack.

No one tool alloy has as yet been found to be the most economical on all types of operations. General rules are always of some value, although they always have exceptions, and it is

[5] Cutting Tools Research Committee, Institution of Mechanical Engineers, London, Dec. 2, 1927.

believed the following should be borne in mind in regard to Haynes Stellite tools. Machining may be divided into four general divisions. One of these consists of the machining of cast iron, semi-steel and malleable iron. The second division consists of the machining of mild steel when the operation is done under conditions having a considerable degree of rigidity, by which is meant that the steel casting or forging is of a rigid section, the number of tools used is small, and the machine is heavy and in good condition. The third type may be said to include the machining of light steel parts on automatic or semi-automatic machines and the machining of alloy-steel parts. The fourth class would consist of a miscellaneous heading, covering such materials as chilled iron, brass, bronze, aluminum alloys, hard rubber, fiber, mica, and similar materials. These materials are grouped not because of similarity, but because of their minor importance. It may be said that Haynes Stellite cutting tools are nearly always successful on the first and second classes, that they have met with but little success in the third class, and that they have come into wide use on some of the materials in the fourth class.

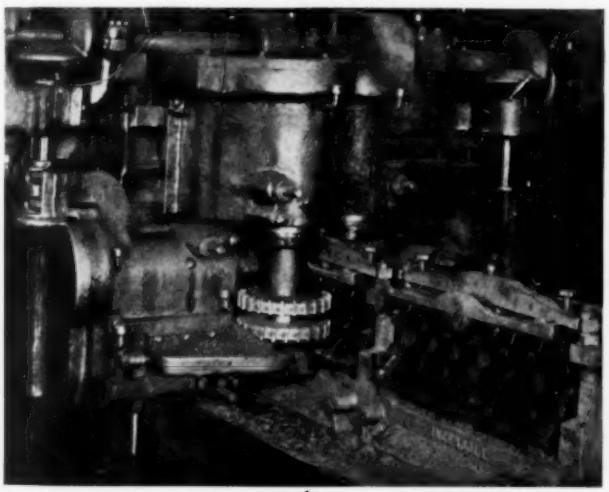

FIG. 3 MILLING CYLINDER BLOCK

Specific applications will be discussed under three general headings—milling, boring, and turning. Many of these jobs are being done exclusively with Haynes Stellite, and it was found necessary to go back a number of years and present the data obtained when the alloy was introduced on the job. In some instances these records are eight years old. In such cases there has been shown the comparison between Haynes Stellite and high-speed steel at the years indicated and there has been tabulated also the performance of the former at the present time. The percentage increase of production is shown based on the original figures, inasmuch as it is not possible to estimate the exact superiority under present conditions. It will be noted that a marked increase in the rate of production has taken place during the periods shown. This is due partly to the extensive experimental and development program carried out jointly by the Haynes Stellite Company and the Union Carbide and Carbon Research Laboratories, and to a lesser degree to improved machinery, better material to work upon, and to increased knowledge and skill as to how to secure the best results. Inasmuch as the authors cannot with accuracy estimate the increased production given by high-speed steel tools in the same period of time, it has been preferred to base the increase in production on the original figures and to show what Haynes Stellite is doing on these jobs at present.

The authors also have refrained from going into tool cost, and in some instances pieces per grind. Tool cost is figured in different ways in different shops, and a quotation of such figures might be misleading. If tool costs were to be determined with a high degree of accuracy, it would be necessary to consider the following items: first cost; scrap value, if any; number of times reground and total cost of regrinding; cost and loss of production due to changing tools. These items divided by the total number of pieces produced per tool will give an accurate figure on tool cost per unit of production. It is also difficult to give in all cases the number of pieces per grind. Some users will continue to operate tools that other men would change, and in other cases the material being machined varies so greatly that figures from day to day are not consistent. It is believed that the data given in this paper will enable production men and engineers to estimate reasonably closely the savings they may expect to make in their own shops.

MILLING OPERATIONS

Haynes Stellite used for milling has been most successful on cast iron, including all grades from grey to semi-steel, and production figures will be confined to examples on this material. In the last few years, however, owing to improvement in strength and cutting quality, a few milling operations on steel have been, and are being, successfully done with Stellite. Although at the present time the extent to which steel is milled with Stellite is very limited, there is reason to believe that applications of this kind will increase greatly in the near future.

Milling has been divided into three classes—heavy, medium, and light; the first two classes being done on jobs such as cylinder blocks, cylinder heads, and crankcases and the latter on chain-case covers, manifolds, bearing cups, and other small parts. A typical example of each of these classes of operations is given.

Table 3 contains data on the rough milling of cylinder blocks. It will be noted that the tools were introduced on a showing of an 87 per cent increase in production. Since that time a secondary increase of 27 per cent has been made, which would give an increase of 138 per cent for Haynes Stellite in 1930 over high-speed steel in 1922.

block. It will be noted that the speed was increased from 60 to 120 ft. per min. and the feed from 9 in. to 18 in. per min., resulting in a 100 per cent increase in production.

Table 5 represents comparative time-study data on a light milling operation on a cast-iron manifold. In this case the cutting speed was increased from 119 ft. to 148 ft. and the feed was increased from 8¼ to 15¼ in., representing a reduction of 46 per cent in machining time and 27 per cent increased production.

Table 6 is a tabulation of miscellaneous milling operations, covering practically every phase of milling on which Haynes Stellite tools are used. These figures represent operating conditions when Haynes Stellite was demonstrated and adopted as standard cutting tools on these jobs. Cutting speeds, feeds, and production vary according to the kind of material machined, size and shape of the casting, type of machine, cutter set-up and other operating conditions. A comparison with other tools indicates average increases of 63 per cent in cutting speed, 59 per cent in feed per minute, 139 per cent in pieces per grind and 55 per cent increased production.

Table 7 is introduced to show speeds and feeds at which similar milling jobs are being run today. It is impossible to summarize these data, but the individual figures will indicate what may be expected on jobs of these types.

The successful application of Haynes Stellite tools on milling operations, and in fact all machining operations, depends upon the proper ratio of speeds and feeds and methods of application. Hardness of material machined, kinds of fixtures used, condition and strength of machine, nature of castings, proper selection of cutters, and proper cutting and clearance angles all have an important bearing on the final results. As a rule 3 deg. on the face and 5 deg. on the diameter are used.

Boring Operations

The rough-boring of cylinder blocks is no doubt the largest single item of boring operations on which Haynes Stellite tools are used. There has therefore been selected a typical example of boring cast-iron cylinder blocks of a popular make of automobile. Table 8 lists comparative data showing that the cutting speed was increased from 45 ft. to 66 ft. per min. and the feed was increased from 2½ in. to 4½ in. per min., representing an increase in production of 64 per cent. More recent figures, as given, show an increase in production of 143 per cent over high-speed steel tools in 1922.

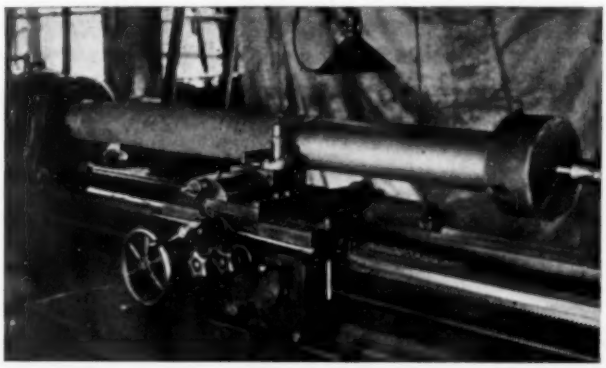

Fig. 4 Turning Ink Roll

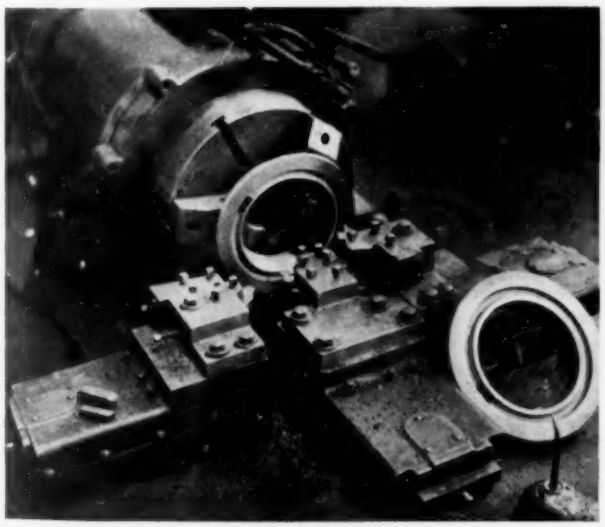

Fig. 5 Turning Bearing Retainer

Table 9 gives the operating data on eight cylinder-boring jobs as they are being run at the present time. As a general rule

TABLE 9 ROUGH BORING, CYLINDER BLOCKS

4	65	55	3.3
4	100	74	6¾
4	85	75	7¾

cutting angles of 6 deg. without any back slope are recommended for this kind of work. Cutting speeds range from 41 ft. to 104 ft. per min. and feeds from 2.9 to 8.5 in. per min.

Turning Operations

Turning operations with Haynes Stellite tools cover a larger range of work than either milling or boring. Milling and boring are generally done on machines designed especially for that purpose. Turning operations are done on various types of screw machines, lathes, and semi-automatics. As is true on milling operations, speeds and feeds for turning with Haynes Stellite tools largely depend upon the hardness of the metal machined, condition of the machine, shape of the casting, class of work, number of tools in the set-up, nature of the cut, and other operating conditions.

In regard to the materials being machined, it is of course well known that Stellite is successful on cast iron under almost any conditions, assuming only that the machines used are in a reasonably good condition. It should, however, not be forgotten that the first use of Haynes Stellite cutting tools on a

Fig. 6 Flywheel Milling

large scale was in turning steel shells during the war. Many steel jobs can be successfully and economically machined with these tools, especially if the work consists of roughing cuts with round-nosed tools when the work is rigidly supported and it is not necessary to machine sharp corners. The specific applications shown will include cast iron, steel, and bronze.

Table 10 gives comparative results on turning a cast-iron ink roll. On this job the speed was increased from 55 ft. to 87

ft., with a resultant saving in machining time of approximately 34 per cent. The cutting angles used on this tool were 5 deg. top side slope, 6 deg. side clearance, and 6 deg. front clearance.

Table 11 is a rough turning, boring, and facing operation on cast-iron bearing retainers on an automatic lathe. With Haynes Stellite tools it was possible to increase the speed of the job from 80 ft. to 115 ft., using the same feed as previously used with other tools. This increase in cutting speed resulted in an increase in production of approximately 35 per cent. The cutting angles used on this job were 10 deg. side clearance and 6 deg. front clearance, with no top side slope.

This job is representative of the type of operation referred to in the second of the four general subdivisions of Haynes Stellite machining operations. It consisted of machining a steel part rigidly supported, of heavy section, where the number of tools was small and the machine was heavy and in good condition. The cutting speed in this case was increased 100 per cent and the feed was increased approximately 22 per cent, resulting in an increase in production of 120 per cent. The cutting angles used on this job were 22 deg. front clearance and 20 deg. side clearance. The tool was hollow-ground on top parallel to the cutting side with a 1/32-in. land.

Table 14 gives the comparative results on turning and chamfering an S.A.E. 1020 rear-axle shaft. On this job the cutting speed was increased from 66 ft. to 110 ft. and the feed was increased from 0.015 in. to 0.021 in. per revolution. This increased speed and feed resulted in an increased production of 93 per cent. The cutting angles used on the turning tool were 10 deg. top-side slope and 7 deg. side and end clearance.

TABLE 14 TURNING, S.A.E. 1020 STEEL

Straight-End and Chamber Rear-Axle Shaft 1 15/64 In. Diameter by 6 7/16 In. Long; Machine, Special Lathe

	High-speed steel	Haynes Stellite
Depth of cut, in.	1/8	1/8
Surface speed, ft. per min.	66	110
R.p.m.	16	280
Feed per revolution, in.	0.015	0.021
Pieces per grind	15	35
Machining time	2 min., 36 sec.	1 min., 6 sec.
Floor to floor time	3 min., 6 sec.	1 min., 36 sec.
Pieces per hour	19 1/2	37 1/2
Increased production, per cent	..	93

Table 15 shows the comparative results on a rough turning operation on a bronze bushing. Cutting speed was increased from 78 ft. to 131 ft., and in this case the same feed was employed. On this job production was increased 50 per cent by the use of Haynes Stellite tools. The cutting angles used on this tool were 10 deg. top-side slope, 10 deg. front and side clearance, and 5 deg. drop grind or negative back slope.

Floor to floor time	1 min., 30 sec.	1 min.
Pieces per hour	40	60
Increased production, per cent	..	50

Summary

It would be difficult and perhaps of little value to attempt to make a mathematical summary of the data presented in this paper. Figures of this type but covering a much larger number of jobs indicate that the use of Haynes Stellite on operations now being done with steel tools will result in increased production and increased life per grind within minimum and maximum figures as follows:

	Increase in production, per cent	Increase in number of pieces per grind, times
Cast Iron:		
Milling	25 to 100	2 to 5
Boring	25 to 110	2 to 6
Turning	20 to 140	2 to 5
Mild Steel:		
Milling	25 to 35	2 to 3
Boring	30 to 120	1 1/2 to 5
Turning	15 to 125	1 1/2 to 6

Discussion

A. K. Dean.[6] The papers on cutting tools by d'Arcambal and by Becker, Gordon, and Wissler are each so comprehensive and authoritative that the writer does not propose to attempt to refute any statement, but can only heartily agree with each.

This paper will be confined to a discussion of some practical methods of procedure in the selection and adaption of the proper cutting tool for the job, and will try to emphasize one or two points in the light of experience.

All will agree that there are four distinct steps in cutting material: (1) Carbon steel, (2) high-speed steel, (3) Stellite, (4) cemented tungsten carbide. While each class may be termed an advancing step as to hardness over the preceding class, yet no one of the groups has replaced any of the others. There is still a place for each.

[6] American Laundry Machinery Company, Rochester, N. Y.

The initial cost and the ultimate life must be considered in this selection. There is no justification for using a material which costs $450 per lb. if a carbon steel will do the work nearly as fast

The writer's first introduction to high-speed steel was in a railroad shop about the year 1904, and the excitement caused recently by the advent of cemented tungsten carbide was mild as compared to the rush then to change from carbon to high-speed steel; and the results obtained on tire turning, cylinder boring, driving-box bronze turning and boring, etc., led to a sweeping change for all classes of work.

In our brass shop where we had 15 brass finishers making injector nozzles, blowoff cocks, drain cocks, gage cocks, lubricator parts, and other red and yellow brass parts, we soon discovered that carbon steel was far superior to high-speed steel and has not yet been replaced.

About a year ago the writer asked a man whose duty it was to select machine tools and cutting steels for a large manufacturing concern, with shops located in several cities, what he was doing with cemented tungsten carbide. His reply was that they had spent about $8000 for Carboloy, Widia, and other makes, but that he had found as he visited the different shops that generally it was on the shelf and the better understood high-speed steels were in use.

That is a good demonstration of how not to begin the change from one cutting material to another, which differs so radically in character. Trying to gorge a shop with a large quantity generally spells failure so decisively that it is hard to get a good start again.

In 1914 the writer has his first introduction to Haynes Stellite, and noting its remarkable performance turning steel high-explosive shell bodies in munition plants, he tried to adapt it to general work, principally turning cast-iron gear blanks, pulleys, and general lathe work, most of which had intermittent cuts. The results were so poor that not until 10 years later, in 1924, was he induced to again try Stellite. This time the results were highly satisfactory, no doubt largely due to the improvement in Stellite, but also in large measure due to a much more intelligent approach to the job.

This time our procedure was as follows: The selection of a department manned by a foreman who was interested in getting the highest possible production, as a laboratory or proving ground; and then by taking one job at a time and carefully selecting the proper size and shape of tool coupled with correct speeds and feeds, we learned how to adapt it to other jobs, so that now this material has earned a permanent place in our shop, but has by no means replaced high-speed steel, which is still supreme on many jobs.

We are using this material in two forms: (1) Square cast bars, principally for turning 65 per cent carbon spindle steel, a step-up from 80 f.p.m. to 140 f.p.m. (2) Machine steel shanks with Stellite tips. These tipped tools are splendid in design for general cast-iron turning, and in cost figure lower than high-speed steel when labor of forging and heat treating is considered.

The writer first saw a demonstration of cemented tungsten carbide about three years ago, and it was a really remarkable performance. Among other things, he saw it turning glass, porcelain, hard rubber, manganese bronze, etc. He also saw the operator chuck a sash weight (and any one who is familiar with the foundry practice in vogue in making sash weights knows that they are not meant to be machined and that there is no cutting material that will successfully machine one except cemented tungsten carbide), so that it ran eccentric $^3/_8$ in., and take a cut $^1/_4$ in. deep, so that at each revolution the cutting tool had to cut into the scale and sand inclusion at a cutting speed of 350 f.p.m., and after taking a cut 14 in. long, the tool showed no abrasion or dulling. This was the most impressive test because best understood.

We have now spent two years fitting cemented tungsten carbide to some 12 or 15 jobs. During that time we have abandoned 12 or 15 other jobs as not suited for cemented tungsten carbide and have gone back to high-speed steel.

All of this cutting and trying has been done in this same departmental laboratory or proving ground, and we now feel as though we have learned the fundamentals of this latest addition to cutting tools, and are ready to make many further applications as soon as normal production will permit.

While our experience as to cutting tool design, machine tools, and care of tools in operation and grinding checks generally with that of Mr. St. Clair, we wish to emphasize one or two points.

1 Design of a cemented tungsten-carbide tool.
   (*a*) Tools of ample size should be used. Owing to the relatively high initial cost compared to high-speed steel, there is a temptation to attempt too small a tool for the job. This is false economy and generally spells defeat.
   (*b*) Do not be afraid to do a little experimenting on your own account. While sales engineers for cemented tungsten carbide generally recommended a tool that is flat on top and with a large radius at cutting edge, we have obtained better results in some cases with top and back slope and a radius of as little as $^1/_{32}$ in. This top slope gives better shearing action and cuts down the power required, and is thus easier on the machine tool. Any cutting tool should be set slightly above the center in a turning operation, but this is especially important with cemented tungsten carbide. If tool is below center, the chip pressure tends to pull the cutting edge rather than push it, and fails to take advantage of its compressive strength. Care should be taken, however, so that work will not rub the tool, with 4 to 6 deg. clearance.
2 The machine tool.
   (*a*) It is not necessary to await the purchase of new rigid superspeed tools to cash in on cemented tungsten carbide. Much can be done with our present tools. We have made successful applications of cemented tungsten carbide to jobs on lathes that have been in constant heavy duty use for eight years, and we are showing a 30 to 50 per cent saving over any previous performance. However, any one purchasing new tools should do so with a view to getting cutting speeds, rigidity, and power that will stand up under heavy cuts with cutting speeds of 250 to 300 f.p.m. on cast-iron turning and not less than 125 f.p.m. on planing.

Early in November the writer saw a planer on the test floor of a prominent manufacturer of planers, which was the largest tool ever turned out by that manufacturer, with a table 10 ft. wide and 30 ft. long, arranged for cutting speeds of 20 to 120 f.p.m., and in the same shop he saw a planer at work on regular production work, cutting cast iron at 120 f.p.m.

The manufacturers of cemented tungsten carbide have said that they were not ready for planer application, but from what we can see around the corner, they are about ready now, and any planer with a cutting speed of less than 125 f.p.m. may soon be in the obsolete class.

With regard to the power requirements on machine tools, when using cemented tungsten carbide, that is, the high-speed in-put required, this does not seem to be in direct ratio to the results, as the cemented tungsten carbide will hold a much keener cutting edge, and thus the removal of the metal is a clean cutting oper-

ation requiring less power than if a tool with a more blunt edge were used.

Owing to its ability to resist sand inclusion and hard spots in cast iron, cemented tungsten carbide is an ideal material for the new semi-automatic machine tools with complicated set-ups where tool grinding is an expensive operation, due to disturbing an expensive set-up. In cases of this kind, the high initial cost is justified even if there is not much gain in speeds and feeds.

As to the care of tool in operation, our practice when starting a new job on cemented tungsten carbide is to double the feed and speed as standard for Stellite, and then make gradual changes from that point until we get best results. Experience shows this to be about the correct speed and feed for new rigid tools, but on old machine tools, higher speeds with lighter feeds seem to work better.

As to grinding, we have found hand grinding to give best results owing to the more sensitive control. Any attempt to force the grinding operation beyond the cutting capacity of the wheel only results in rapid wheel wear.

On the 12 per cent cobalt material we are using a 60-grain I-grade wheel for roughing, and finishing on a 120-grain I-grade wheel. On the 50 per cent cobalt material, we are using much harder wheels.

Honing the cutting edge between grinds has increased time between grinds by as much as 300 per cent.

We believe 5000 f.p.m. surface speed to be the maximum, and better results are generally obtained below this speed.

All our applications of cemented tungsten carbide so far have been turning operations, but we are planning on some boring jobs, not so much to increase quantity as to improve accuracy. Boring with our present method generates so much heat in the part that it is hard to handle in the unloading operation, and thus varies in size when cool.

If we duplicate our turning experience on boring operations, we will find the heat in the chip rather than in the work. On our heaviest cuts, such as $^3/_{16}$ in. depth of cut and $^1/_{10}$ in. feed at 200 f.p.m., on cast iron, the work was not over 110 deg. fahr., while the chips were red.

In closing the writer wishes to say that every job is a law unto itself, but these laws are constantly changing with new developments in cutting steels. One of our largest production jobs is planing gray-iron with about 20 per cent steel. For this job nothing works as well as 18 per cent tungsten high-speed steel. Another job is turning steel pipe, and here again high-speed steel is still on top, although both Stellite and cemented tungsten carbide have been tried.

Authors' Closure

By W. A. Wissler. Mr. Dean's discussion outlined a very rational method of undertaking the introduction of a new cutting material into one's own shop; such a plan is particularly applicable and desirable if the tool in question is a new and as yet unproved product. Usually it is most satisfactory and economical to proceed slowly until the new material has definitely proved its value. The final answer may, however, be obtained more quickly if the experience and knowledge of the maker's service department are fully utilized.

As Mr. Dean states, no new tool metal produced since the beginning of the steel age has displaced entirely any tool already in use. The introduction of a new tool either has permitted old operations to be done more economically or has made possible the working of materials theretofore considered unmachinable. There is a decided possibility that tungsten-carbide tools will permit the use of steels much harder than at present.

The difference in results obtained from Haynes Stellite tools in 1914 and 1924 can be explained partly by the improved machine tools available to the latter date, but largely by the fact that intensive and continued research will improve any product. During the period mentioned, the major improvements in Haynes Stellite tools consisted of an increase in strength and a great increase in the ability to cut cast iron and similar materials. Both of these improvements were the direct result of research and development directed toward those ends. If Haynes Stellite produced in 1931 were compared with that made in 1924, additional increases in quality and uniformity would undoubtedly be noticed.

Tool-Steel Tools

By A. H. d'ARCAMBAL,[1] HARTFORD, CONN.

Metal-cutting tools offered the trade today are vastly superior in quality to tools of a decade ago. The factors that govern the life of metal-cutting tools made from carbon, alloy, and high-speed tool steels, namely, design, steel, and treatment, are discussed in this paper, particular stress being laid on the importance of correct design.

The important role played by cutting fluids or coolants as affecting the life of the tool, as well as the necessity of employing the proper grinding wheels and correctly using them, are also covered in some detail.

THE quality of metal-cutting tools such as drills, reamers, taps, dies, cutters, hobs, etc., in use today is vastly superior to that found in tools manufactured a few years ago. Marked improvement in machine-tool design, tougher materials to machine, together with the demand for greater accuracy and economy, all have been contributing factors in the development of more efficient small tools.

This paper covers only cutting tools made of carbon, alloy, or high-speed tool steels. Tungsten-carbide tools and Stellite tools are being covered in other papers.

The following three factors govern the quality of metal-cutting tools: (1) Design, (2) quality of steel used, and (3) hardening treatment. It will be noted that two of these three factors, namely, raw material and hardening treatment, are metallurgical problems. For this reason plants manufacturing metal-cutting tools should maintain a well-equipped metallurgical department. This department not only should prepare specifications for the different types of steels employed, inspecting all material when received, but also have full control over all hardening operations. Improved steels and treatments will be developed from time to time by a properly conducted metallurgical department, keeping pace with the increasing demand for better cutting tools.

Design

To cover properly this factor of design it is necessary to consider the various types of tool-steel tools most commonly used.

Drills

Twist drills have been standardized so well in regard to angle-of-lip clearance, point angle, etc. (see catalogs of drill manufacturers), that time will not be taken to discuss tools of this description in detail.

The high-speed steel twist drill of today is in every sense of the word a production tool. In special demonstrations at machine-tool exhibits twist drills have performed in a truly remarkable manner. One-inch high-speed steel drills have penetrated cast iron at the rate of over 100 in. per min. and steel at over 50 in. per min. with practically no effect on the drill point after drilling a number of holes under such grueling conditions.

Reamers

Reamers are used to produce smooth round holes that are as close to the desired size as it is possible to obtain. Many types of reamers are in use today, the following being the types most commonly employed:

Hand reamers (solid and adjustable)
Shell reamers (solid and adjustable)
Chucking reamers (solid and adjustable)
Expansion chucking reamers
Expansion hand reamers
Jobbers reamers
Locomotive taper reamers
Bridge reamers
Taper-pin reamers
Taper reamers for standard tapers.

Number and shape of lands, relief, back taper, finish, all are factors that must be carefully controlled. It is the usual practice to design reamers of various types with staggered flutes, or what is more commonly called uneven spacing of flutes, resulting in a freer cutting tool with chattering reduced to a minimum. Smooth true holes usually are obtained from reamers so designed.

The most efficient type of adjustable-blade shell reamer is of the serrated-blade design. The blades in this type of reamer are held securely over their entire length. Adjustment to the maximum diameter can be made without reducing the strength of the reamer. There is an increasing demand for expansion chucking reamers. Reamers of this type should be provided with a lock nut, the same to be located inside the reamer so as to permit its use on bottoming holes.

The helical or fast-spiral taper-pin reamer is rapidly supplanting the straight and slow spiral-fluted types. These fast-spiral reamers are very free cutting, producing smooth round holes. One or two designs on the market can be used successfully when either driven by machine or used by hand. Other designs possess such an extreme spiral that they can be used successfully only under power.

The duplex-spiral taper reamer (see Fig. 2), a fairly new design of tool, is meeting with favor by the trade. In this interesting design, one or two flutes cross the path of the other flutes resulting in the production of extremely smooth and round tapered holes. One manufacturer offers a spiral-fluted taper reamer with one straight flute; this design of reamer also produces very satisfactory holes.

The four-grooved high-speed steel twisted-type locomotive taper reamer has lost its popularity during the past two or three years, the majority of railroad shops now using the milled-type high-speed steel locomotive taper reamer with six to eight spiral flutes, depending on the diameter of the tools. While the twisted type of reamer is somewhat less expensive than the milled type, the latter reamer not only gives considerably more service, but produces a more accurate hole.

As in the case of taps, the size cut by a reamer is dependent to a considerable extent on the type of material being machined.

---

[1] Consulting Metallurgist, Pratt & Whitney Company. Graduated from University of Michigan in 1912 with degree of Bachelor of Chemical Engineering and entered service at Detroit Copper and Brass Rolling Mills, Chalmers Motor Co., and Dodge Brothers as Chief Chemist. Was employed at Wright-Martin Aircraft Co. for a year as Chief Metallurgist. Joined Pratt & Whitney Co. in 1919.

Contributed by the Special Research Committee on Cutting Metals and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

As a proof of this statement holes were recently reamed in several different kinds of materials, using a 2-in. serrated-blade reamer with a peripheral speed of 180 ft. per min., and a feed of 0.011 in. per revolution. The following results were obtained:

Machinery steel and heat treated S.A.E. No. 6150 steel	The 2-in. standard cylindrical plug gage just entered hole
Annealed high-speed steel	Gage fit sloppy. (Holes from 0.001 to 0.002 in. larger than gage)
Cast iron and bronze	Plug gage would not enter hole

Taps

The different types of taps most widely used include machine-screw taps, hand taps, nut taps, tapper taps, pulley taps, boiler taps, pipe taps, coupling taps, and staybolt taps.

The following variables affect tap life and so must be kept under careful control: (1) Number of flutes, (2) shape and depth of flutes, (3) width of lands, (4) chamfer, (5) relief, and (6) back taper.

Taps designed for work in steel will not always give satisfactory service when used on other metals such as brass or aluminum. Care also should be taken to see that taps designed for through-hole jobs, such as spiral-pointed taps that force the chips ahead of the tap, are not used on blind holes. Difficult blind-hole jobs that cannot be threaded satisfactorily with the regular design of straight-fluted tap often can be successfully tapped with a spiral-fluted tap, the direction of spiral being the same as the cut. Taps of this design bring the chips out of the hole, thus preventing chipping of the threads and breakage.

Demand for greater accuracy has resulted in the use of ground-thread taps by the majority of the automotive plants, as well as by other large manufacturers. These taps are ground on the outside diameter, root diameter, and in the angle of the thread. The shanks also are ground concentric with the threads. These taps produce threads that, under satisfactory operating conditions, will meet the N.S.T.C. Class 3 tolerance. Many Class 2 jobs can be produced satisfactorily with cut-thread taps. Unless great accuracy is desired, the high-speed steel cut-thread tap should be specified, due to these cut-thread taps in the majority of cases threading at least as many holes per grind as the more expensive ground-thread tap.

It must be borne in mind that the same tap will not produce the same size thread on all different types of material. The type and condition of the machine and tap holder used also will affect the size of the thread. The use of sulphur-base oils will result in a different sized tapped hole than when soluble oil is used, this being especially marked in the case of bent-shank tapper taps used in full-automatic tappers. With these facts in mind, it is not difficult to understand the reason for the tap manufacturers' refusal to guarantee the size of the tapped hole.

It is not uncommon today to find high-speed steel taps being run at drill speeds in many automotive plants. Taps which will operate successfully under such severe conditions must be correctly designed, made from a good quality steel, and be properly hardened.

Fig. 1 Representative Group of Tool-Steel Tools

Dies

The most commonly used types of dies are: Inserted-chaser

dies, adjustable round split dies, spring screw-threading dies, solid square-bolt dies, solid square-pipe dies, and hexagon re-threading dies.

The inserted-chaser die is the type most generally employed today for threading bolts, screw-machine parts, etc. The adjustable round split die or button die finds wide use in the threading of smaller sizes of threads. Dies are so well standardized as regards design that it is not necessary to go into details at this time.

Cutters

Rapid strides have been made during the past few years in cutter design, due principally to the machine-tool builders bringing out heavier and more powerful milling machines. The modern milling machine provides quicker change of speeds and feeds, improved mechanical control, etc. Increased demand for parts made of heat-treated alloy steels also has been a contributing factor in the vast strides made in the improvement in cutter quality. A few of the more popular types of cutters are: Plain milling cutters, side milling cutters, half-side milling cutters, staggered-tooth milling cutters, inserted-blade cutters, end mills (shell and shank type), formed milling cutters, thread milling cutters, metal slitting saws, screw slotting cutters, involute gear cutters, and helical cutters.

Number and shape of teeth, helix angle, rake, clearance, hole diameter, etc., are all important factors that govern cutter design. Plain milling cutters for heavy production work are provided today with a high helix angle, rake of 12 to 15 deg. sometimes greater, with just enough clearance to prevent rubbing back of the cutting edge. Helical mills of this design will take cuts at least $^1/_2$ in. in depth in ordinary steel, the abundant chip room found in this design taking care of chip disposal. The high helix angle results in the production of smooth surfaces due to the shearing action. Fairly recent developments in cutter design have brought out many efficient types of cutters.

Half-Side Mills

These cutters have spiral teeth, the face of the teeth being undercut, resulting in freer cutting than is obtained with the older type side mills. These half-side milling cutters give much greater service than can be obtained from the usual design of side mills due not only to a longer life between grinds because of the shearing action, but also to the greater number of grinds possible because of the deep recess on the cutting side. Half-side mills are ideal for straddle-milling jobs and similar operations.

Staggered-Tooth Milling Cutters

Cutters of this design have teeth cut at alternate right- and left-hand spiral angles. This construction, together with the considerable angle of undercut, produces cutters which can remove large amounts of metal without excessive chatter and vibration, producing a smooth, clean finish. These cutters are very efficient for milling deep cuts or slots in metal. The side teeth act as chip removers.

End Mills

Shell-and-shank-type end mills offered the trade today are of the deep-recessed type. Mills of this design have more chip clearance than the older design, as well as possessing considerably greater life due to the large number of re-grinds possible.

Inserted-Blade Cutters

A large number of railroad shops in this country have installed during the past few years modern milling machines, resulting in the demand for inserted-blade cutters of a more rugged and efficient design. Cutters with correctly hardened high-speed steel blades securely locked in heat-treated alloy-steel bodies, provided with large bores, are giving remarkable service in slab milling, channeling, shoe and wedge jobs, and similar operations. In properly designed slab-milling cutters the sections are so designed as to give either a continuous or herring-bone spiral, permitting cutters to be resharpened as a gang instead of individually, thus insuring a continuous smooth surface on the work. The majority of inserted-blade cutters offered the trade are so designed as to permit easy replacement by the customer of worn-out blades with new blades.

Metal-Slitting Saws

Just a few years ago there was offered the trade only one simple design of metal-slitting saw to be used on all types of material. Today there are several designs, the type to be used depending on the nature of the material being machined. Saws designed for slitting steel will not give the best of service when used on non-ferrous metals such as copper, aluminum alloys, non-metallic materials, and the like. Saws used on non-ferrous and non-metallic materials have fewer teeth, greater rake to cutting edges, and higher polished surfaces. A still different design works more efficiently on cast-iron jobs. Number and shape of teeth, amount of concavity, rake, and finish, all are factors that must be carefully controlled.

Fig. 2 Duplex Spiral-Taper Reamer

Form Cutters

Form milling has today been placed on a production basis due to the introduction of spiral-fluted form cutters eccentrically relieved and provided with rake-tooth form. The shearing action due to the spiral-flute form results not only in a longer life for the cutter, but also produces a smoother finish, all with less strain on the machine tool. Pieces so thin as to bend under the cut when straight-fluted form cutters are used, can be form-milled successfully with the spiral-fluted cutter.

Spiral-fluted thread milling hobs also are rapidly replacing the straight-fluted thread hobs on many operations. Increased speeds and feeds together with a longer life between grinds are obtained through the use of these spiral-fluted thread hobs.

There is an increasing demand for high-speed steel ground-thread milling hobs where great accuracy is necessary. As high-speed steel cut-thread hobs mill approximately the same number of pieces per grind as the expensive ground-thread hobs, the latter should be used only where the accuracy of the products demands this additional expense. Improved methods of threading hobs and the employment of modern heat-treating methods result in the production of high-speed steel cut-thread hobs of marked accuracy as regards thread form, lead error, etc.

It should be remembered that fine-edged metal-cutting tools designed for use on ferrous materials such as cast and malleable iron, machinery steel, alloy steels, etc., not always will give satisfactory service when used on non-ferrous materials such as brass, bronze, copper, aluminum alloys, and the like. General-purpose tools such as are usually listed by most tool manufacturers work fairly well, however, on most of the materials mentioned. Where production requirements warrant the use of a tool designed especially for the job, considerable savings

can frequently be realized through the use of such special tools. The increased inventory cost is often found to be more than compensated for by the greater efficiency obtained through using tools properly designed for the material being fabricated.

Quality of Steel Used

The second factor that governs the life of metal-cutting tools is the quality of the steel used in the manufacture of the tool. During the past 10 to 15 years many interesting types of steels have been introduced by the steel mills, the big majority of these steels not finding wide favor due to tools made from the same not performing more efficiently than tools made from steels of the more common types. The various types of steel most commonly used today in the manufacture of metal cutting tools are as follows:

PLAIN CARBON TOOL STEEL

Carbon Per cent	Manganese Per cent	Phosphorus Per cent	Sulphur Per cent	Silicon Per cent
1.10–1.20	0.30 max.	0.020 max.	0.020 max.	0.30 max.

ALLOY CARBON TOOL STEELS

Carbon Per cent	Manganese Per cent	Phosphorus Per cent	Sulphur Per cent	Silicon Per cent	Chromium Per cent	Vanadium Per cent	Tungsten Per cent
1.05–1.15	0.30 max.	0.020 max.	0.020 max.	0.25 max.	None	0.15–0.20	None
1.10–1.20	0.30 max.	0.020 max.	0.020 max.	0.25 max.	0.40–0.60	None	None
0.85–0.95	1.20–1.40	0.020 max.	0.020 max.	0.25 max.	0.40–0.60	None	0.40–0.60
0.85–0.95	1.60–1.80	0.020 max.	0.020 max.	0.25 max.	None	None	None
0.85–0.95	1.60–1.80	0.020 max.	0.020 max.	0.25 max.	None	0.15–0.25	None

The first type of alloy steel mentioned is excellent for tools where breakage is the usual cause of failure. This vanadium tool steel is also recommended for so-called shock tools.

The second type under the heading "Alloy Carbon Tool Steels" is at times used for tools where a slightly greater depth of hardening than can be obtained from the plain carbon tool steel is desired. Chromium also silkens the grain to quite an extent, thus producing a much more velvety type of fracture after correct hardening than is to be found in the simple carbon tool steel.

The last three types of alloy carbon tool steels are commonly known as oil-hardening, non-deforming steels. Tools that will permit of a minimum size change in hardening usually are made from one of these three types. Experience has shown, however, that the usual types of water-hardening tool steels stand up better in service than the oil-hardening brands.

High-Speed Steels

The big majority of high-speed steel metal-cutting tools in use today are made from high-speed steel of the following average composition:

Carbon	Chromium	Vanadium	Tungsten
%	%	%	%
0.70	4.00	1.00	18.0

This type of steel is the simplest to harden of all the different kinds of high-speed steels offered the trade. Tools made from it give satisfactory service when used under normal conditions, regardless of the type of material being machined. There has been an increasing demand during the past two or three years, however, for 18 per cent tungsten high-speed steel containing from 5 to 10 per cent cobalt, especially for use in lathe tools, boring tools, tool bits, etc. Tools made from this cobalt steel must be ground all over after the hardening operation, due to the deep soft skin produced in hardening. Turning tools made of this high-cobalt high-speed steel give excellent service on all different types of materials, but especially when used on heat-treated alloy steels and other materials that are difficult to machine.

There continues to be a slight demand for the so-called low-tungsten, high-vanadium type of high-speed steel (13 per cent tungsten, 2 per cent vanadium), especially for turning tools of various types. This steel is considerably more difficult to harden properly than the more commonly used 18 per cent tungsten material, its general use therefore being somewhat restricted.

The high-carbon, high-chromium type of steel is being used to a great extent today for blanking and lamination dies, as well as for parts where resistance to wear is of primary importance. This material contains from $1^1/_2$ to $2^1/_4$ per cent carbon and

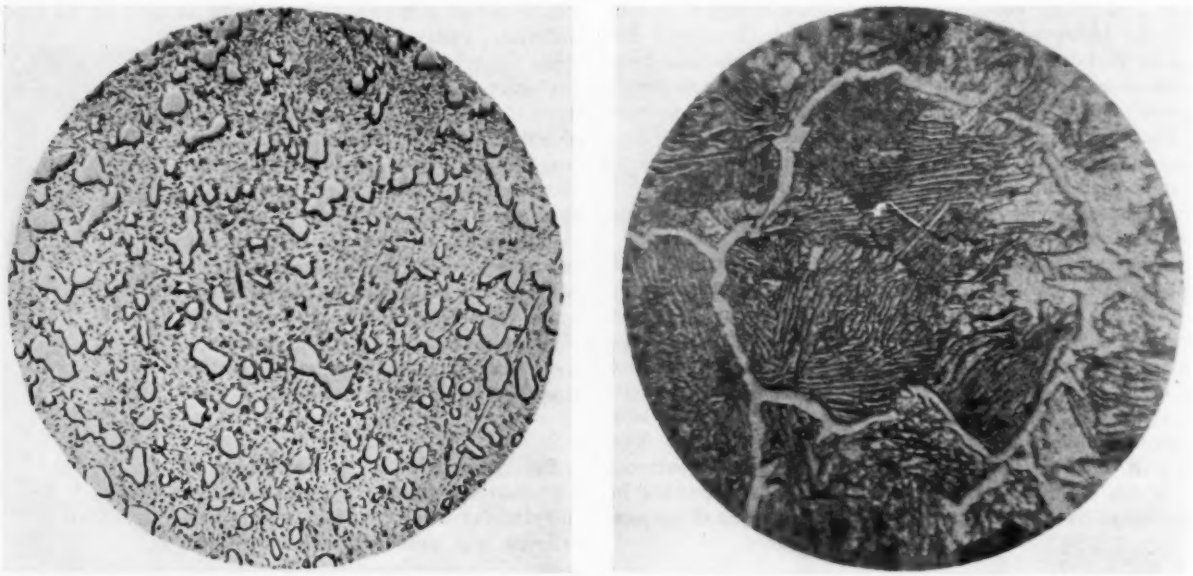

Fig. 3 Microstructures of Plain Carbon Tool Steel—at Left, in Proper Condition for Machining and Hardening; at Right, Finish Worked at Too High a Temperature by Mill and Improperly Annealed

11 to 13 per cent chromium. This high-chromium alloy does not possess the toughness, red hardness properties, and cutting qualities of high-speed steel, so is not recommended as a substitute for high-speed steel for metal-cutting tools.

Practically all carbon, alloy, and high-speed tool steels are melted today by the electric-furnace process, using the Heroult three-electrode type furnace. Ten years ago the crucible process was the one employed by the mills in this country for the melting of these high-grade steels. It is the opinion of the author that the electric-furnace-melted material is of a uniformly higher quality than the crucible-melted steel, this being especially noticeable in the alloy and high-speed tool-steel types.

From time to time, the small-tool manufacturer is requested to furnish semi-high-speed steel tools. A careful study of a large number of the various types of steels introduced by the steel companies during the past few years shows no steel possessing the necessary properties for this purpose. Just because a low-tungsten steel tool ($1^1/_2$ per cent to 2 per cent tungsten) gives a red spark when touched to the grinding wheel is certainly no reason for expecting the tool to have high-speed steel properties. In fact, tools made from this low-tungsten tool steel cannot be run at any higher speeds, feeds, etc., than can plain carbon-steel tools and moreover do not possess as great toughness, due to the increased hardness penetration. These remarks regarding red-hardness properties and toughness apply equally well to many other so-called semi-high-speed steels tested.

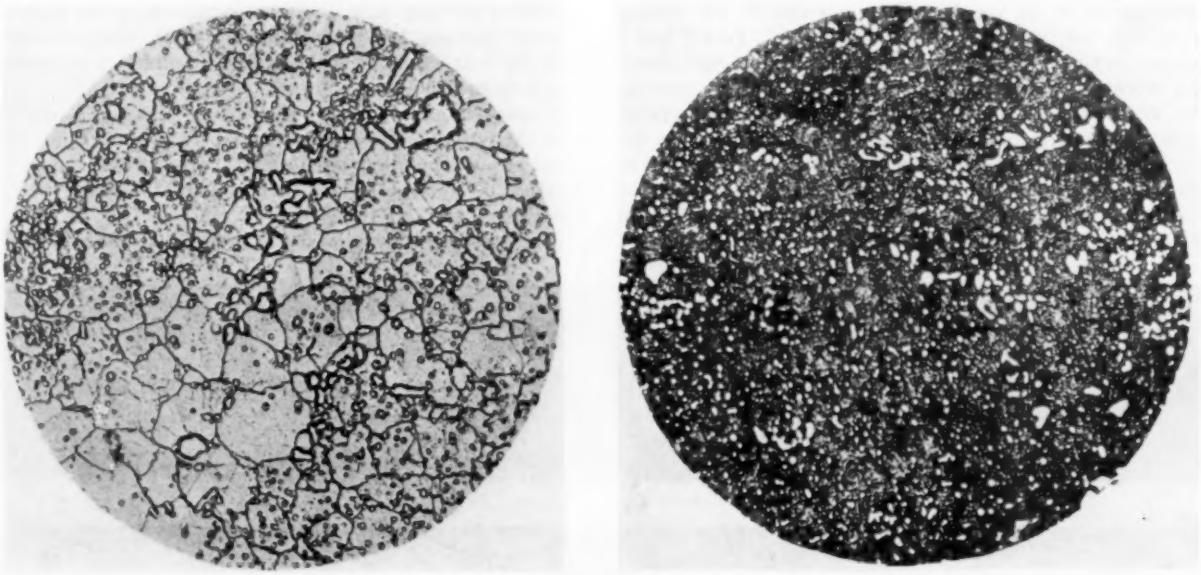

FIG. 4 MICROSTRUCTURES OF HIGH-SPEED STEEL QUENCHED FROM PROPER TEMPERATURE—AT LEFT, NOT DRAWN; AT RIGHT, FOLLOWED BY A 1100 DEGREE FAHRENHEIT DRAW

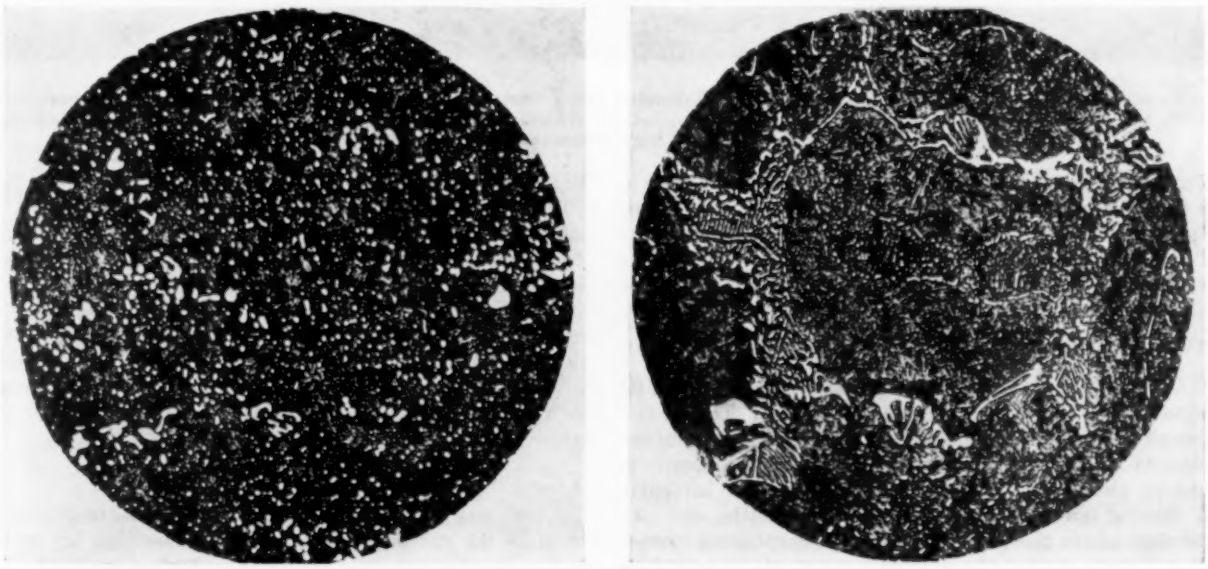

FIG. 5 MICROSTRUCTURES OF LONGITUDINAL SECTIONS CUT FROM $5^1/_2$-INCH DIAMETER STOCK—AT LEFT, HIGH-SPEED STEEL FORGED BLANK; AT RIGHT, HIGH-SPEED STEEL BAR STOCK

Incoming shipments of tool steel should be given a careful microscopic inspection. A lot of steel may be of the correct chemical composition, have the proper hardness, and possess a satisfactory fracture after the standard hardening treatment, but unless the structure as revealed by the microscope at magnifications from 100 to 1000 times is satisfactory, tools made from this material will not give satisfactory results. Figs. 3, 4, and 5 are representative of the important information one obtains only through the proper use of the microscope. Figs. 5 and 6 illustrate the necessity of using high-speed steel forgings instead of bar stock for the manufacture of cutters, hobs, etc., in the larger diameters. It is not possible at the present writing for the steel mills to produce high-speed steel-bar stock in the larger sizes that is free from harmful segregations, etc. The fracture of tools made from these larger bars is extremely coarse as compared with the velvety type of fracture obtained when forgings are used.

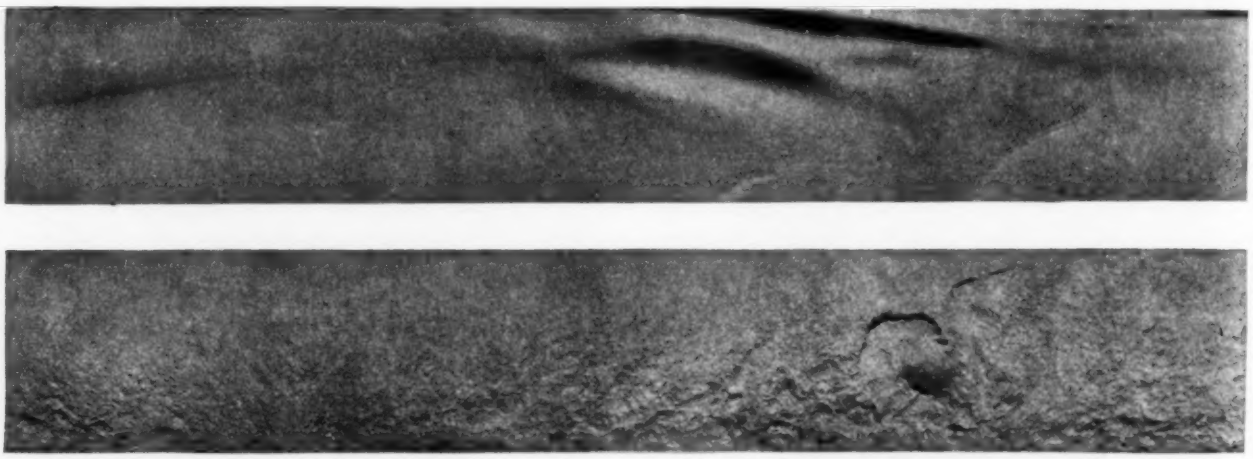

FIG. 6 ABOVE, FRACTURE OF A 5 1/2-INCH DIAMETER HARDENED HIGH-SPEED STEEL FORGING—NOTE FINE PORCELANIC STRUCTURE; BELOW, FRACTURE OF A HARDENED DISK CUT FROM A 5 1/2-INCH DIAMETER BAR OF HIGH-SPEED STEEL—NOTE COARSE-GRAINED WOODY STRUCTURE

The importance of using only steel of the best quality in the manufacture of high-grade metal-cutting tools cannot be stressed too strongly. So much depends on the kind of raw material used that every precaution should be taken to insure the use of only carbon, alloy, and high-speed tool steels of the highest quality obtainable.

HARDENING TREATMENT

Often one hears the statement, "a tool is no better than its heat treatment." A very true expression, indeed. The hardening room of a small-tool plant is one of the most important departments in the factory. Expense should not be spared in equipping this department with the best types of hardening and drawing furnaces, pyrometers, quenching baths, etc. All furnaces should be provided with automatic temperature control, time and program clocks for each operator should be furnished, quenching baths should be maintained at the correct temperature through efficient cooling systems, and all pyrometers should be frequently checked against master instruments, etc. Proper hardening instructions should accompany each order of tools, these instructions preferably being issued by the metallurgical department. Guesswork by the man at the fire thus is done away with. After hardening and drawing, the tools should be checked carefully for hardness, using special files provided for this purpose in conjunction with the Rockwell hardness tester.

The lead bath is used by most manufacturers in connection with the hardening of carbon-steel tools such as taps, dies, drills, reamers, etc. The temperature used varies from 1440 to 1500 deg. fahr., brine being the quenching medium most commonly employed. The oil bath, salt bath, or oven-type furnace may be used for the tempering of the tools after the quenching operation.

High-speed steel tools of the 18 per cent tungsten type should be hardened as follows: They should be preheated to a temperature of 1500 to 1600 deg. fahr. and then transferred to the high-temperature furnace, the temperature of which is approximately 2350 deg. fahr. As soon as the tool reaches the furnace temperature it should be quenched in oil.

Drawing should be from 1050 to 1200 deg. fahr., depending upon the type of tool, and then they should be air cooled. High-speed steels containing cobalt must be quenched from a temperature of approximately 2400 deg. fahr. to obtain the most satisfactory results.

High-speed steel containing the proper percentage of carbon and quenched from 2350 deg. fahr. will show the same hardness after a 1050 deg. fahr. draw as in the undrawn condition. Considering that high-speed steel tools properly hardened and high drawn possesses twice the strength of tools in the undrawn state, without any sacrifice of hardness, it is the practice of most manufacturers to give all high-speed tools the high-draw treatment. It is important that high-speed steel tools be heated to a temperature in excess of 2300 deg. fahr. when open-fire hardened, as the cutting efficiency of a high-speed tool increases with increased hardening temperature up to the temperature where slight coarsening of the grain takes place.

GRINDING OF TOOL-STEEL TOOLS

A few years ago an article appeared in one of the trade journals in which the statement was made that more tools are spoiled in the grinding operation than during hardening. While this statement is somewhat exaggerated, in the author's opinion, it is true that many tools are ruined daily due to improper grinding. The use of too hard a wheel, a loaded wheel, or improper cooling during the grinding operation, are all contributing factors to grinding checks, soft skin, and similar evils. Fig. 7 shows three tools purposely ruined through improper grinding, then given a hot-acid etch treatment to make the lacework of grinding checks more visible. It is more economical to use a few additional wheels of the proper grain and grade monthly than to attempt to economize through the use of harder wheels merely

because they do not wear away so rapidly. The grinding-wheel salesmen are in a position to instruct the manufacturer as to the different types of wheels best suited for the various grinding operations.

In connection with the grinding of high-speed steel tools, a few grinding-room foremen share the opinion that a straw or blue color appearing on the tool after the grinding operation will

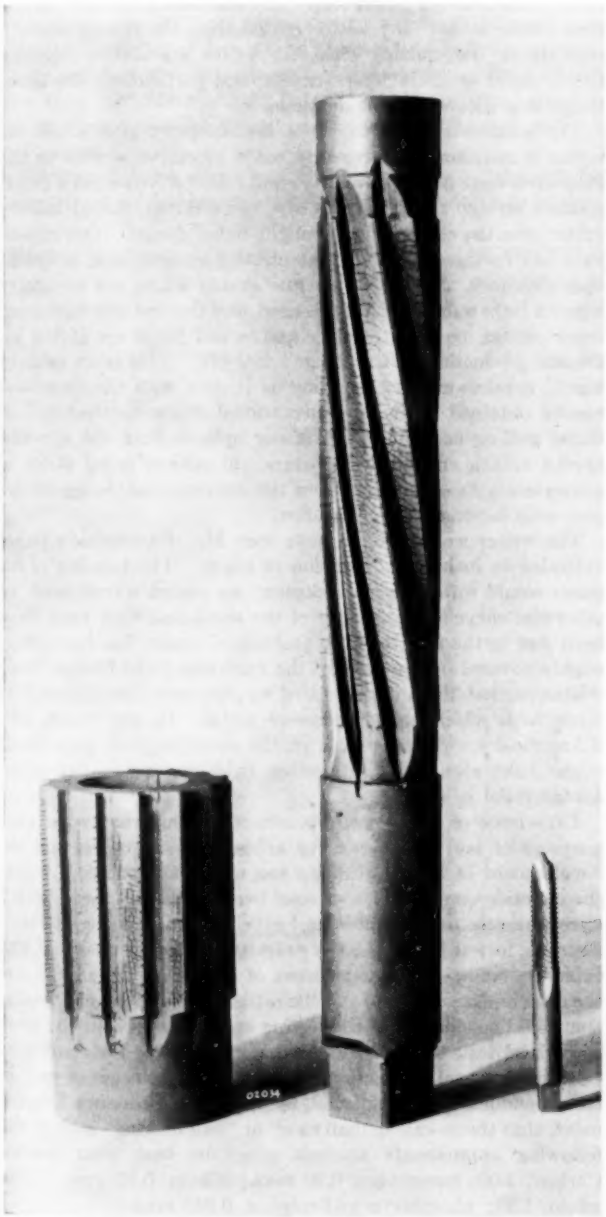

FIG. 7 CRACKS THAT RESULT FROM IMPROPER GRINDING

not affect the performance of the tool, considering that the tool had passed through that range when being high drawn. While it is true that a 1100 deg. fahr. draw is a much higher temperature than the blue color would indicate, frequently a high-speed tool showing color after the grinding operation can be filed readily along the cutting edges. This means that the cutting edges of the tools were heated to a temperature in ex-

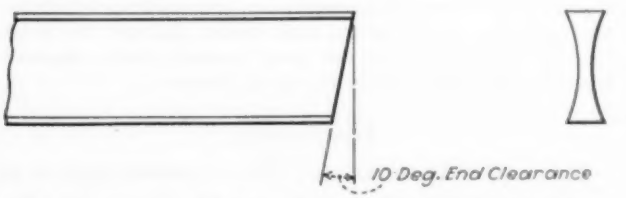

FIG. 12 JOHNSON CUT-OFF BLADE FOR GRIDLEY MACHINE

cess of the 1100 deg. fahr. draw during the grinding operation, thus ruining the tool.

Cutting Fluids

The cooling and lubrication of cutting tools is of such importance that The American Society of Mechanical Engineers appointed a sub-committee several years ago to prepare a report on this all-important subject. This committee has not completed

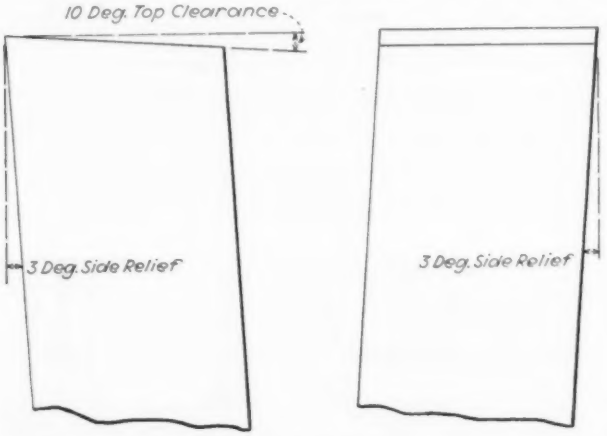

Fig. 13 Turning Tool for Carbon Tool Steel and S.A.E. No. 6150 Steel Used With Gridley Machine

its work as yet, but a progress report was presented about two years ago.

The failure of many metal-cutting tools is due to the coolant used. Some machining operations such as threading and milling require a good grade of sulphur-base oil as the cutting fluid; other types of jobs, a soluble oil; some special operations call for pure lard oil; aluminum-alloy jobs, kerosene plus a small amount of machine oil, etc. A generous flow of the cutting fluid should be directed properly on the work at all times. The kind of cutting fluid used not only affects the life of the tool, but has an important bearing on the finish obtained. On some threading jobs the size produced is dependent in some degree on the type of cutting fluid used.

Conclusions

The three factors that govern the life of tool-steel tools, namely, design, steel, and treatment, have all been covered in detail in this paper. The necessity of grinding tools correctly as well as the importance of employing the correct cutting fluid are also touched on.

Machine tools rightfully have been called, "The Master Tools of Industry." Of what use would these master tools be without their metal-cutting tools, unfortunately named "Small Tools." Many concerns, after careful study, will purchase a machine tool at a price running into four or five figures, and then use any make of small tool on this expensive machine that might be handy or that can be purchased at a deceptive price. "A machine is no better than its tool equipment," is a true statement, worthy of the careful consideration and study of the metal-working trade. While tremendous progress has been made in developing and improving metal-cutting tools during the past ten years, the author feels confident that proportionally greater improvements will be made during the coming decade.

Discussion

Frederick S. Blackall, Jr.[2] The d'Arcambal paper is an interesting survey of the high lights of the small-tool field. Because of the breadth of the subject, any brief comment must of necessity be specific rather than general.

It is refreshing to hear as eminent a metallurgist as Mr. d'Arcambal scouting the alleged merits of some of the so-called "alloy carbon tool steels." Where surface wear is a factor, many of these latter-day developments have distinct merit; but it is the writer's opinion and experience that for cutting tools any compromise between a true high-speed steel and a straight-carbon steel yields little if any better results than the straight-carbon steel itself. For cutting tools, the writer has always regarded the so-called semi-high-speed steels (and particularly the lower tungsten grades) as simple delusions.

The engineering department of the company with which the writer is associated has recently made extensive studies in the field of thread milling-cutter design. Mr. d'Arcambal's paper touches on the superiority of the spiral-fluted thread milling cutter over the conventional straight-fluted design. Our experience has further indicated that existing designs lack sufficient chip clearance, due to the narrow gashes which are necessary where a large number of flutes is used, and that cutters possessing fewer cutting teeth with wider gashes and lands are giving increased production and prolonged tool life. This is an entirely logical conclusion, corresponding as it does with the improved results obtained with the conventional coarse-toothed spiral-fluted milling cutter; and it is our opinion that the superior thread milling cutter of the future will possess spiral flutes in somewhat reduced number from the conventional design of the past with increased chip clearance.

The writer would like to have seen Mr. d'Arcambal's paper extended to include a discussion of gages. The heading of his paper would warrant such inclusion; its omission from such an otherwise encyclopedic survey of the small-tool field may have been due to the fact that the problem of design has been thoroughly covered by the work of the American Gage Design Committee or that the author desired to purposely limit himself to those tools which actually remove metal. In any event, Mr. d'Arcambal's wide experience in the metallurgy of gage steels might have shed some interesting light on one or two other controversial points.

Experience of recent years points to the superiority for gage purposes of tool steels over the milder carbon grades, and the development of thread grinding has made it possible to utilize the superior qualities of tool steel even in thread gages, which were formerly made almost exclusively of carburizing steels, a desirable forward step. A few years ago, several concurrent and extensive studies were undertaken of gage-wear factors. From the mass of data collected and the rather widely divergent results, one would conclude that the testing apparatus used in the more theoretical tests could hardly have approximated the conditions existing in actual production. It was the conclusion of certain tests, conducted, it is believed, by the Army Ordnance Department, that the so-called "ball race" or "ball bearing" steel of the following approximate analysis gave the best wear results: Carbon, 1.00; manganese, 0.30 max.; silicon, 0.25 max.; chromium, 1.40; phosphorus and sulphur, 0.040 max.

The disadvantage of this type of steel is its tendency toward a superficial surface softness—appropriately described as a soapy condition—which made gages of this material not only unpopular with the trade, but, in the writer's opinion, inferior to tools possessing a glass-hard surface. The painstaking if highly theoretical experiments of Messrs. French and Herschman, of the Bureau of Standards, produced an even more startling conclusion—namely, that a file-soft gage is superior to a file-hard gage.

Extensive study of the subject, corroborated by wear tests in production, which, in the writer's opinion, are the only wear

[2] Vice-President and General Manager, Taft-Peirce Mfg. Co., Woonsocket, R. I. Mem. A.S.M.E.

tests yet devised which yield accurate and anywhere near consistently uniform results, leads to stating the unequivocal opinion that the hardest gage is the best gage where wear factors alone are considered. Rockwell readings of C 63 to 65 for plain gages, C 60 to 62 for ordinary thread gages, and C 58 to 60 for pipe-thread gages appear to be desirable minima. A certain sacrifice of hardness is necessary in thread gages, where the element of toughness is necessary to prevent chipping.

For those who favor the chrome manganese steels for gage purposes, the second analysis under the heading "Alloy Carbon Tool Steels" in Mr. d'Arcambal's paper will be found to produce a very satisfactory steel, possessing the wearing qualities of ball race steel without the latter's tendency to soapy hardness. The chromium content should be kept nearer 0.40 than 0.60 for best results.

For thread gages, where lead changes must be minimized, the conventional oil-hardening tool steels prove quite satisfactory. The higher manganese, tungsten-free type has proved superior to the tungsten grade in our experience.

No discussion of gages at this juncture of engineering history should close without a fervent plea for the universal adoption of the gage design standards of the American Gage Design Committee, which have been recognized by this Society.

[NOTE: A discussion of this paper jointly with the paper of Becker, Gordon, and Wissler by A. K. Dean will be found with the discussion of the latter paper.]

AUTHOR'S CLOSURE

Mr. Blackall's comments were very much appreciated. The author agrees with Mr. Blackall that the value of this paper would have been materially increased should the discussion have included the all-important subject of gages. The author was requested, however, to confine his remarks to metal-cutting tools made of carbon, alloy, and high-speed tool steels.

MSP-53-12

A Survey of Surface Quality Standards and Tolerance Costs Based on 1929-1930 Precision-Grinding Practice

By R. E. W. HARRISON,[1] CINCINNATI, OHIO

In an earlier paper presented at a meeting of the Chicago Section of the A.S.M.E. on March 18, 1929,[2] the author reviewed the process of evolution through which the art of precision of cylindrical grinding had passed up to that date. This paper reviews some of the defects which exist in the present-day accepted standards of finish of mechanical components, and represents an endeavor to maintain continuity by carrying the discussion through to the present-day standards of finish attainable by the abrasive process. It is pointed out that it is useless to specify extremely close limits of accuracy unless the measurements are made across basically plane surfaces.

Size control and its effect on cost of production, as well as the length of useful life, is discussed, and better finishes are advocated as a means of reducing the ill effects of high initial wear. A scheme for the establishment of definite standards of finish is put forward, and a finish-calibrating instrument is described. Emphasis is laid on the fact that there is no available short-cut method of obtaining ultra-fine-finished surfaces with a minimum of initial wear, and the author points out that standardization of finishes can be attained at low cost with little disruption of present methods; also that the subject of longer useful life to mechanical components is closely interlocked with the provision of a better standard of finish and the attendant benefits derived from close adherence to true limits of accuracy.

THE urge for betterment which leads to perfection brings our past performances under the most critical review. Sometimes this is the result of failure measured in terms of longevity or the inability of some mechanical piece of work to fulfil its function; sometimes it is the urge of the designer to produce a more mechanically perfect and lasting job; sometimes it is the desire of the production engineer to excel in his art and produce something better than that which has gone before; and it is often the urge brought about by intensive competition which makes it a commercial necessity for one individual or concern to produce something better than that which has hitherto been presented in an endeavor to capture a market and its attendant profits.

Whatever the cause may be, the fact remains that the world is marching steadily forward. While the credo of many manufacturers is to make and produce within the widest permissible limits of accuracy and finish consistent with the established standards of efficiency for their product, there are others, and these latter probably constitute the majority, who, with a genuine desire to produce a better job, strive all the time to improve on past performance.

Ever since the first lathe and the first boring machine, and in fact the first tool of any of the now-established types, were put into operation, the finish and accuracy of their product have been matters of speculative discussion.

There of course has always been a compromise between the practical and the ideal. But although it is invariably conceded that perfection is unattainable, this fact has never prevented striving for that goal.

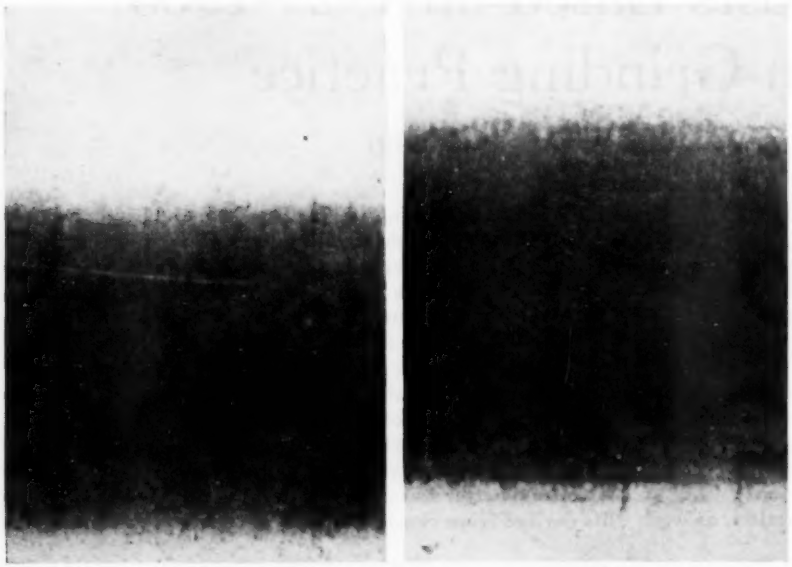
This paper represents an endeavor on the part of the author to record, in a useful way, some of the progress which has been achieved up to date.

SECTION A

1 Surface Irregularities on Ground and Lapped Work

The fact that so many engineers supplement their eyesight with eyeglasses and spectacles is in itself evidence of a growing

[1] Engineering Director, Cincinnati Grinders, Inc. Mem. A.S.M.E.; Chairman, Cincinnati Local Section. Mr. Harrison received his education at Grove House High School and Crescent College, both of Manchester, England, after which he attended Manchester College of Technology, where he took a regular course in mechanical engineering, including heat engineering. Mr. Harrison then entered the employ of the Churchill Machine Tool Co., Ltd., at Pendleton, Salford. Here he received training in erecting and machine-shop departments on regular schedule, and during 1911 he was appointed foreman of the turret-lathe and automatic-screw-machine department. Mr. Harrison held this position for about 18 months, and later was given charge of the jig-tool and work-progressing department, which position he held until the outbreak of the World War in 1914. In 1923 Mr. Harrison was appointed assistant works manager of the Churchill Machine Tool Co., Ltd., and was given the assignment of building and equipping the company's new works erected at Broadheath, Manchester.



Mr. Harrison was responsible for purchases, supervision, and all contracts, and generally functioned as assistant to the general works manager. He was made special technical representative of the Churchill company to spend six months in the United States and Canada, surveying the two countries as a possible outlet for British machine tools. During the remainder of 1923, Mr. Harrison visited France, Holland, and Belgium in a similar capacity. In January, 1924, he was appointed commercial manager of the Churchill company with responsibility for sales. Mr. Harrison joined the engineering staff of the Cincinnati Milling Machine Co. in July, 1926, and on the formation of the company's subsidiary, Cincinnati Grinders, Inc., he was made a member of the board of directors and assigned the duties of chief engineer.

[2] "Precision Cylindrical Grinding," Trans. A.S.M.E., Sept.-Dec., 1929, MSP-51-18.

Contributed by the Machine Shop Practice Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

dissatisfaction with the limitations of the naked eye. Hence the author feels confident that no one will feel that the discussion is being made of too academic a nature if the microscope is accepted as a highly desirable and, in many cases, necessary tool in the inspection department; for without the aid of this tool, the naked eye is insufficient to gage qualities of surfaces called for by present-day standards.

A *B*

FIG. 1 THE SAME PIECE OF WORK
(*A*, as viewed with the naked eye; *B*, defects revealed by the camera.)

A simple experiment with a camera, photographing a piece of ground work, will be sufficient to convince the most skeptical that the sight of the average individual can be deceived to a surprising and disconcerting extent.

The outside diameter of an 8-in. diameter ball race, when viewed by the naked eye, appeared to have a highly satisfactory surface, as shown at *A* in Fig. 1. It, however, took on a quite chattered or broken appearance, as shown at *B*, when photographed. This photograph is not an enlargement and represents the actual size of the work.

It might be argued that in the quest for the true plane surface, one is getting out of the realm of practical workshop possibilities and introducing laboratory methods and discussions. But, in the author's opinion, the answer to this is the increased mileage available on the modern automobile due to the higher initial finish and accuracy built into the components generating the power and carrying the load, as compared with the relatively short total of mileage and noisy, inefficient performance of the automobile of even three years ago.

That there is an appreciation of the fact that minute surface irregularities result in rapid wear, irrespective of lubrication, and that there is a definite though now limited market for the near-perfect piece of mechanism, is borne out by the fact that there are a few automobile manufacturers who have built up a profitable business by building this type of mechanism only.

It is generally known and accepted that the method of removing metal which involves the use of a hardened tool, the nose of which penetrates the surface to be machined to the required depth, leaves a relatively torn and disrupted surface which has a high coefficient of friction and a relatively high initial wear.

It is not proposed in this paper to discuss the relative merits of machined and ground work, but to deal with the finer irregularities produced by the accepted finishing operation of today, i.e., grinding. Whether the work be hardened or soft, or cast iron, steel, or bronze, it has been proved that the cheapest way of securing accuracy within the closely specified limits and finish, up to an acceptable standard, is by means of the precision grinding machine.

This, then, is the starting point.

The modern grinding wheel, which is built up from an accurately sized, accurately spaced, and carefully bonded abrasive, is in itself a tool of precision, produced by its makers to within limits of accuracy controlled within thousandths of an inch. Examined by the naked eye after being mounted and trued in a modern precision machine, the working surface of this wheel presents a smooth and precise appearance. However, when this wheel and the work on which it is operated are viewed through the microscope, it will be realized that modern precision grinding is nothing more or less than a closely controlled milling operation in which each of the particles of abrasive presented to the work plows its quota of metal and leaves its resulting furrows.

While one may overlap and overlap the path taken by succeeding particles of abrasive, the resultant surface under a powerful microscope has much in common with a plowed field, Fig. 2. Sharp ridges of steel or iron exist on the surface of the work, and these must be removed before one can arrive at a plane surface which will have a maximum resistance to wear.

FIG. 2 PHOTOMICROGRAPH × 75
(Surface of cylinder ground to generally acceptable finish with 80-grit wheel.)

Some few years ago the research engineer of one of the auto-

mobile concerns making cars in the highest price class, in a fit of discontent with his company's product, inserted an electromagnet in the oil stream while a standard engine was undergoing its dynamometer test. The result of this simple little test was so startling that this concern almost ceased manufacturing until means could be found to solve the problem which was thus so suddenly thrown up to them. The electromagnet had drawn a considerable quantity of ferrous particles from the oil stream, and this was proof positive that the initial wear on all contacting members was astonishingly high. The remedy was obviously a better quality of finish than any which had hitherto been considered acceptable.

It was realized that a lapping compound composed of particles of iron, steel, and bronze was a dangerous element to introduce into any piece of high-class, high-speed machinery.

A world-famous maker of Diesel engines, of both the marine- and the land-operating type, found that reduction in initial wear due to bettered methods of finishing enabled him to control his sizes so accurately that he reduced the running-in time of his engines to one-third of that previously found necessary, and at the same time increased the power-producing efficiency of his product by 8 per cent.

A world-famous builder of locomotives made a test on a locomotive equipped with one cylinder which had been bored and another which had been bored and afterward ground. The locomotive was put on the road, and the cylinder heads were not removed for 14 months. Within two days of the inspection of this locomotive the process of finishing cylinders was changed to embody the improved method of finishing.

Much is heard about the appalling cost of rust or oxidation. Optimistic statisticians have even dared to put a figure on this wastage, which runs into billions of dollars. In the author's opinion it is not an exaggeration to say that this figure is at least equaled by the cost of largely avoidable wear. Hence there is what appears to be a sufficient and valid reason for the time given to the consideration of a subject, the economics of which involves such an immense sum of money.

Consider, for example, surfaces produced on cylindrical work, and discard for the moment the questions of accuracy as regards roundness and parallelism.

Fig. 3 shows a representative plan view of an automobile wristpin ground to a finish which is generally considered good and acceptable by manufacturers who judge their product only by the naked eye. The finish-grinding operation was performed with an 80-grit grinding wheel.

Fig. 4 shows the same piece reground with a 500-grit grinding wheel.

Fig. 5 shows the same piece after being put through a lapping operation in which the pin is held on a spider between abrasive disks that were mounted on vertical spindles.

Fig. 6 shows the same piece after being again passed through the grinding machine following on the lapping operation. It will be noted that the grinding operation with the 500-grit grinding wheel has not been continued long enough to remove all the marks left by the laps.

The hitherto frequent renewal of automobile wristpins resulted in intensive study being given to this member, with the result that a very large percentage of pins built into new automobiles and those used as replacements are either ultra-finish-ground with a 500-grit grinding wheel or are lapped.

FIG. 3 TYPICAL EXAMPLE OF A WORKING SURFACE ×100
(A good job of grinding, with no defects visible to the naked eye; ground with an 80-grit wheel.)

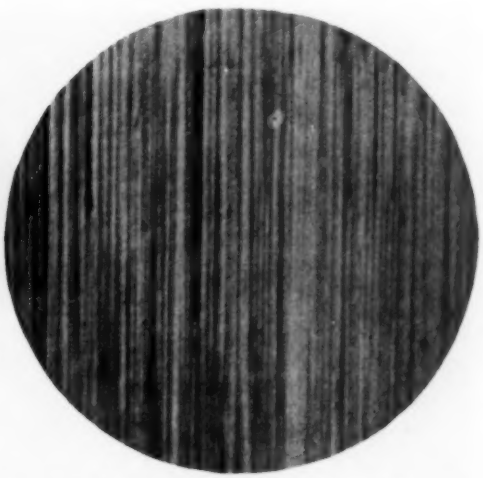


FIG. 4 A WORKING SURFACE PRODUCED WITH A 500-GRIT WHEEL ×100

FIG. 5 LAPPED SURFACE ×100

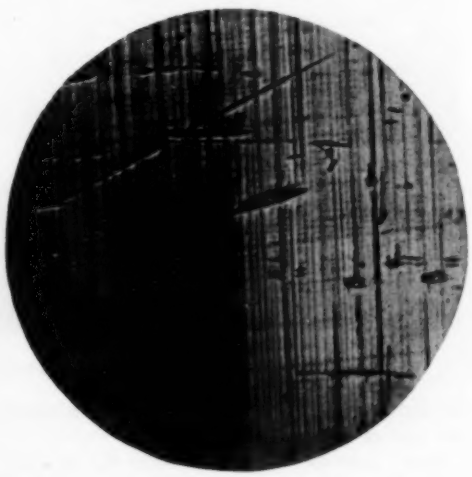

FIG. 6 APPEARANCE OF WORKING SURFACE AFTER LAPPING AND SUBSEQUENT GRINDING WITH 500-GRIT WHEEL ×100

The surfaces on automobile crankshafts also have come in for much critical review, and at the instance of one of the leading automobile manufacturers, Dr. C. B. Sawyer, of Cleveland, has made some interesting cross-sections which emphasize the necessity for better methods of finishing. (See Appendix 1.)

The method of obtaining these interesting specimens was to immerse the samples in a copper-cyanide plating bath and give an initial coating. This is followed by immersion in an acid copper-plating bath where a heavy deposition of copper is made. The samples are then removed and cut, using a hacksaw, the cutting being so performed that the copper is forced toward the iron or steel.

These samples clearly illustrate the amount of irregularity which must be removed from the surface of an automobile crankshaft before the pin can establish a smooth and unobstructed path. (See Appendix 1.)

Experience indicates that there is no royal road or shortcut to a really high finish. Such finishes must necessarily be built up by successive stages.

Grinding wheels designed for producing the highest class of finish are incapable of an attractively high rate of metal removal. Hence, a practice has grown up whereby the bulk of the grinding allowance is removed with a wheel of from 60 to 80 grit. An intermediate finishing operation utilizing a wheel of 120 to 250 grit is interposed to top off the ridges caused by the grain depth of cut of the roughing wheel, and the final finish is imparted to the work with a wheel which may vary from 250 to 500 grit, the final result depending upon the standard of finish necessary for the satisfactory accomplishment of the work.

Attempts have been made to effect a shortcut, but these have all resulted in the building up of a false finish. In other words, the ridges are turned over into the hollows, and in actual service the results obtained are unsatisfactory.

2 Scheme for Establishing Standard Finishes in General Engineering Practice

Through the period of years in which mechanical processes have been developing, no satisfactory method of gaging finishes, other than with the eye, has been developed. This means, also, that there is no definite standard of comparison on either a world, a national, or even a local basis.

Fig. 7 Rack of Plugs Used as Reference Standards of Finish

It is unfailingly true that, in those countries where high standards of workmanship have been established, engineers are more critical and demand a higher finish, but this in turn is again, and has always been, a matter of mental comparison, with no established basis on which to allocate a place to any one particular finish.

This matter has exercised some of the keenest minds in the industry and has been given very careful consideration by the American Standards Association.

In an attempt to obtain a solution to this problem in a practical workshop way, the author has adopted the following procedure:

A small rack, Fig. 7, carrying 1-in. diameter cylindrical plugs ground to the various progressive standards of finish has been placed in each of the following departments for reference: en-

gineering, grinding, inspection, standards, and laboratory.

The question at once arises as to how these standards are established, and this has been accomplished in the following way:

A finish-measuring device has been put into use, embodying an electromagnetic type sound detector or pickup as used in the better makes of electrically operated gramophones.

This instrument is connected up with a radio-amplifying unit and records minute vibrations caused by irregularities on the surface of the work to be inspected, reproducing them through a loud speaker.

with a piece to be tested, the loud speaker, and the millivoltmeter unit.

Fig. 9 shows a diagrammatic view of the instrument.

Attempts to measure the finish obtained on ground work by means of instruments based on the ability of the work to reflect from a measured source of light have proved inadequate, inasmuch as it is too easily possible to obtain false readings from surfaces which, while having the appearance of being highly polished, nevertheless contain comparatively deep furrows or scratches.

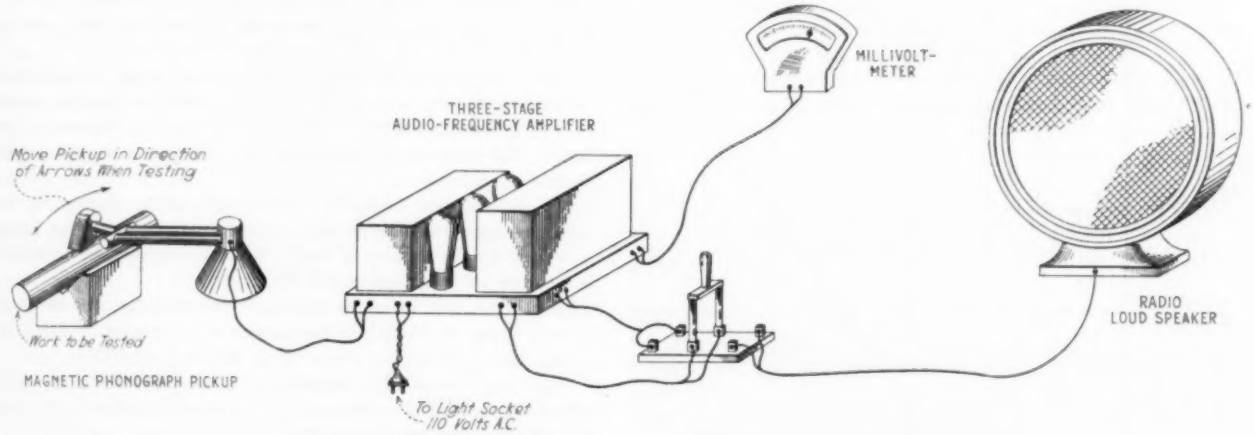

FIG. 9 DIAGRAMMATIC VIEW OF FINISH CALIBRATOR

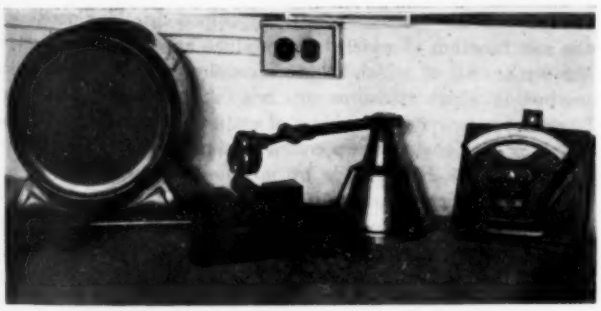

FIG. 8 FINISH-CALIBRATING INSTRUMENT WITH SOUND AND VISUAL RECORDERS

The contact with the work is made with a chisel-edged sapphire, and a millivoltmeter records the amplitude of a current which is directly proportional to the vibration, and which passes across the grid of a supplementary radio tube.

Work which is relatively roughly ground produces a deep, harsh vibration in the loud speaker and a relatively large movement of the needle on the millivoltmeter scale. A finely ground piece of work produces a keen high note characteristic of minute vibration, and results in a relatively small swing of the millivoltmeter needle.

From the foregoing description, therefore, it will be seen that there is available both sound and visual measurement on a definite scale to supplement the microscope and the naked eye.

The instrument is extremely sensitive and particularly well suited to picking out that class of unsatisfactory work which, in the every-day phraseology of the mechanic, is "highly polished and deeply scratched."

Fig. 7 shows the rack of finished samples, with three tiers each, containing soft, case-hardened, and oil-hardened steel samples.

Fig. 8 shows the work-finish-testing instrument in contact

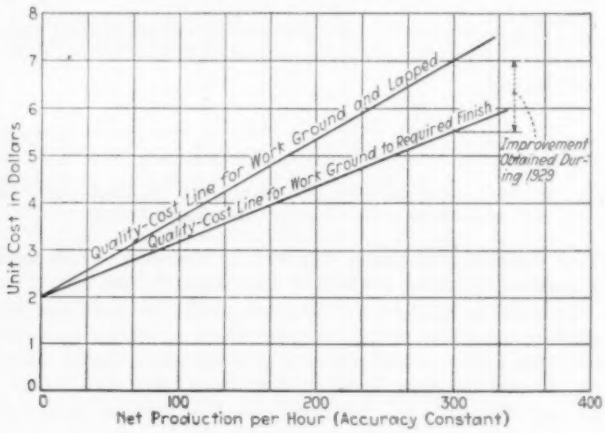

FIG. 10 QUALITY COST DIAGRAM ILLUSTRATING REDUCED COST OF IMPROVED FINISHES DUE TO IMPROVED METHODS

(Substitution of high-production grinding operation in place of lapping and polishing; use of heavier and mechanically improved machines; use of greatly improved fine grit grinding wheels; improved methods of truing grinding wheels.)

3 RELATIVE COSTS OF PRESENT-DAY STANDARDS OF FINISH

It being accepted that there is no available shortcut to high finish, it logically follows that the higher the finish the higher the cost on any given piece of work. However, much has been done in an endeavor to improve the standard, and the diagram in Fig. 10 serves in a general way to indicate what has been accomplished during the last year or eighteen months.

Case-hardened finish No. 3, which is equivalent to what is now generally known to the trade as a commercial finish, is accomplished on either the centerless or center-type cylindrical grinding machines, by rough and finish grinding the work with the same wheel, dressing the grinding wheel openly for the roughing operation and closely for the finishing operation.

Finish No. 2 is obtained in an identical way, but calls for the expenditure of from 15 to 20 per cent more time in the finish-grinding operation only.

Finish No. 1 is a refinement of finish No. 2 and calls for an additional grinding operation with a wheel of approximately 250 grit. This finish doubles the time required for the previous finishing operation, but does not in any way affect the time required for the rough-grinding operation.

The ultra-fine finish represented by the samples in the top row of the case calls for still another grinding operation, utilizing a ma-

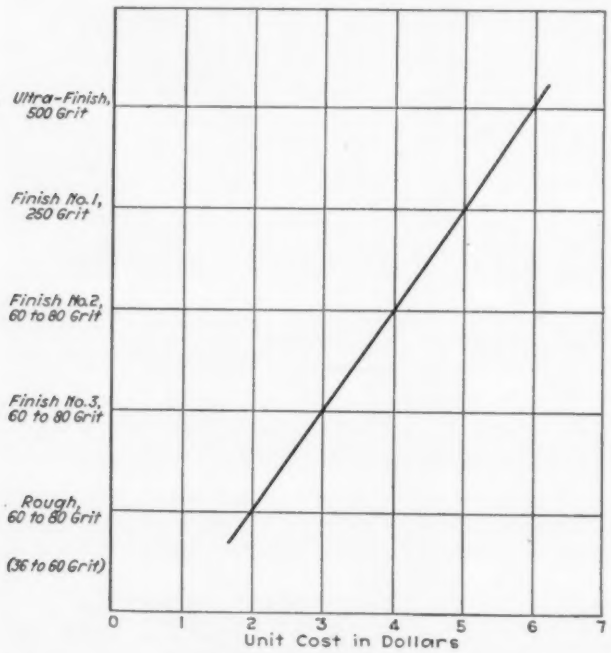

FIG. 11 QUALITY COST DIAGRAM INDICATING PROGRESSIVELY INCREASING COST OF VARIOUS GRADES OF FINISH

chine designed and closely adjusted for this work. This finish is obtained by using a wheel of approximately 400 grit.

To state the matter in another way, finish No. 3 calls for two grinding operations with the same wheel. Finish No. 2 calls for two grinding operations, also with the same wheel. Finish No. 1 calls for three grinding operations using two different wheels. The ultra-fine finish calls for four grinding operations involving the use of three different wheels. All the finish-grinding operations occupy about the same length of time and the cost of production is in proportion to the finish produced. This is illustrated graphically by Fig. 11.

SECTION B

1 ACCURACY CONSIDERED AS A COMMERCIALLY ATTRACTIVE FACTOR IN WORKS MANAGEMENT

The relationship between quality and finish, as discussed in the foregoing section of the paper, and accuracy, considered as a commercially attractive factor from the point of view of the works management, may at first appear to be somewhat obscure.

However, experience indicates that the two subjects are very closely related by that relatively indeterminate factor known as initial wear. Until one is in a position to commercially produce work with practically no initial wear, it might justly be said that he is being deceived in the belief that work is being held within the specified limits of accuracy stated on the drawing.

The effects of this knowledge of the existence of high initial wear can be seen on every hand.

(*a*) Designers frequently tighten up their limits in the hope that when the initial wear has taken place they will still have mechanisms which operate without shake or without losing gas, air, or oil pressure.

(*b*) Designers frequently call for extremely expensive hand-lapping operations, knowing that this, being a slow process, offers maximum insurance against the assembly of parts which would otherwise retain possibilities of high initial wear.

(*c*) Makers of twist drills and plug gages insure that their products have a maximum useful life before the fuzz is worn off them and they are reduced to the low limit.

(*d*) Engine builders make their pistons larger in diameter in relation to the bore to insure that when the engine comes off the dynamometer test it will not have too much piston slap.

(*e*) The preloading of anti-friction bearings is another effort in this direction.

(*f*) Builders of high-class machinery erect, dismantle, inspect, reerect, run, dismantle, inspect, reerect, and run again to check up the results of initial wear known as the bedding-in process on their shafts and bearings.

In other words, it might truthfully be said that the test run of any piece of high-class machinery is a species of teething period during which its whole future lies in the balance.

That the commercial hazards of this process are to some extent recognized is evidenced by the rapid increase in the use of high-class honing equipment.

A high-class company has built up an attractive and economically sound business in lapping machines. Another company has put on the market specially equipped grinding machines, the sole function of which is to produce an ultra-fine finish on the work. All of which is proof conclusive that accuracy of product in which measurements are taken between plane surfaces and not over rough ridges of material is recognized by the discriminating engineer as a commercial necessity.

The practice, however, is by no means general, and so far has been restricted to relatively few of the many thousands of manufacturers producing what they honestly believe to be a quality product.

2 THE COST OF ACCURACY IN GROUND WORK

One of the factors most closely affecting the manufacturing success of any modern organization is the intelligent use of the limit system, for in the specifying of close or wide limits the engineering department either can make or break the successful operation of any plant.

It is obviously most sound for the designer to specify the widest possible limits of accuracy consistent with the satisfactory functioning of the piece or mechanism under consideration.

There is evidence, however, that the question of initial wear does not always receive the consideration which its importance entitles it to, and it is becoming increasingly necessary for designers also to specify the class of finish on the bearings and sliding surfaces which operate under load.

The absence of a definite standard of finish has been a great obstacle, but it is hoped and anticipated that research work will shortly clear away this barrier.

Unfortunately, the subjects of finish and accuracy within closely specified limits have been somewhat confused in the minds of many designers, and this has led to the belief in many quarters that because, say, a locomotive is built up of parts with wide limits of accuracy as compared with, say, a printing machine or a machine tool, the finishes on locomotive work can be relatively rough.

No greater fallacy exists, and although it is readily admitted that wide clearances are necessary to enable the motion gear of a locomotive to accommodate itself to a non-precision roadbed, the effects of high initial wear, due to lack of finish, are so costly and serious that it might be said that the bearings and wearing surfaces of a modern locomotive, while operating with greater clearances, at the same time demand on the score of economics a higher degree of finish than almost any other piece of mechanism.

Where the load as measured in pounds per square inch is intensive, initial wear can easily develop into permanent and continuous wear if the mechanism is not started out right in the first place.

In these days when a variance of sizing within 0.0002 in. may mean the difference between automatic assembly and hand selection, and this in turn may mean the difference between success and failure to make a profit, and therefore for the firm to remain in business, it logically follows that the problem of accuracy and automatic sizing control has been put up to the machine-tool manufacturers in a very intensive way.

Conclusion

The conclusions which the author wishes to draw from the foregoing notes, data, and records of experiments are the following:

1 It is desirable that our efforts to work to close limits of accuracy be strengthened and improved by taking measurements across basically flat surfaces rather than across surfaces which have a relatively high factor of initial wear.

2 To enable this to be done, standards of finish should be established and these standards accepted in at least a national way.

3 The author submits for consideration a means whereby finishes can be calibrated and easy and accurate duplication of results be obtained.

4 A practical scheme applicable to most organizations carrying on engineering work is discussed and provides a basis on which refinement and special applications can be worked out.

5 A general guide to the requirements as regards the number of machine-shop operations to secure the different qualities of finish is discussed and submitted as representing the best available practice of today.

6 An endeavor has been made to show that there is at present no available shortcut to high-quality work with a low factor of initial wear.

7 The various means whereby surfaces with low initial wear can be obtained are indicated.

8 Finally, the author has shown that standardization of finishes can be attained at low cost and with practically no disruption of present methods; also, that limits of accuracy which control length of useful life are interlocked with the obtaining of a better quality and standardized finish.

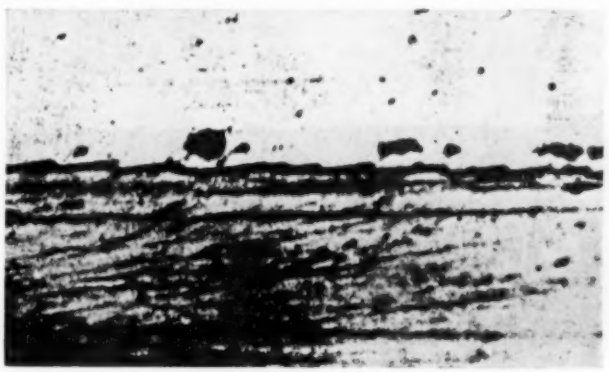
Appendix 1—Microscopical Examination of Cross-Section of Surfaces

By DR. C. B. SAWYER,[3] CLEVELAND, OHIO

IN the recording of the shape of design of objects in general it has been found most practical to take a series of cross-sections of the object on different planes through it. The number of such cross-sections necessary is determined by the irregularity of the object and the detail required. Such cross-sections may be made by a draftsman and filed away as blueprints.

When it is desired to obtain a similar record of a surface filled with very fine scratches or surface irregularities, it is necessary, first, mechanically to section such surface and, subsequently, to magnify and photograph its cross-section. Where ground surfaces are concerned, two or three sections are generally adequate to give a very fair idea of the dimensions and nature of irregularities existing thereon. For many purposes a single cross-sectional photomicrograph is adequate. A method for obtaining photomicrographs at magnification up to 1000 diameters of cross-sections of surfaces produced by grinding, honing, polishing, and the like is here described.

So far as is known to the writer, the method was first employed by the famous metallurgist, Walter Rosenhain, in his study of the dimensions of slip planes produced on polished metallic surfaces during deformation of the metal. For a general description of the method it would be difficult to find better words than those of Rosenhain himself,[4] as follows:



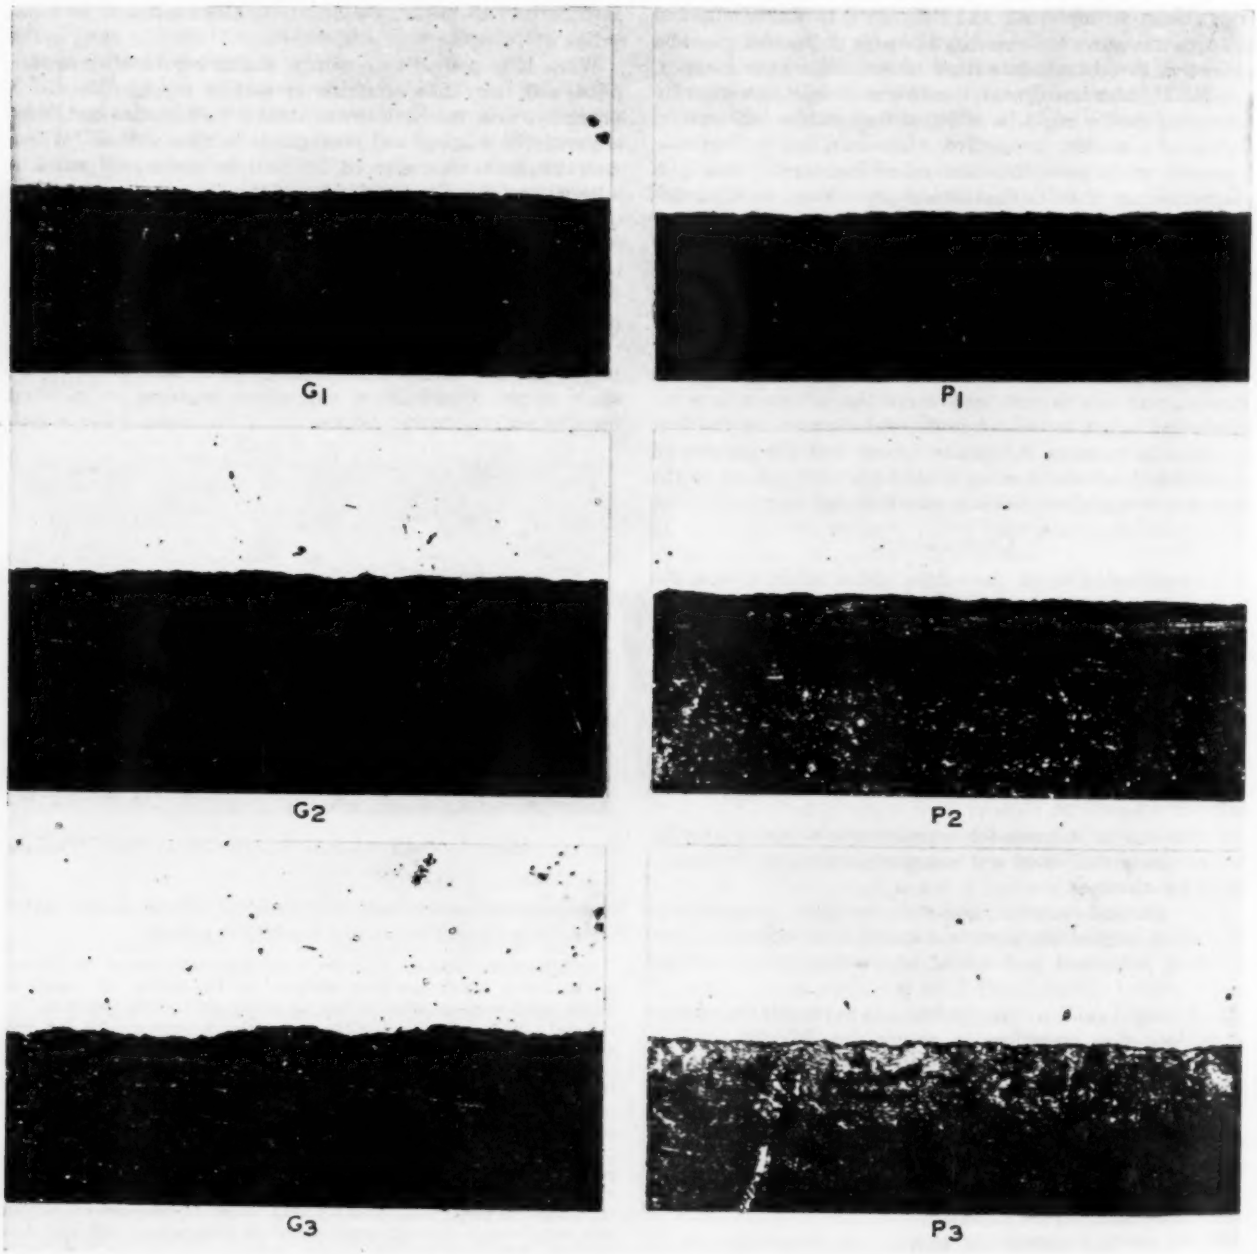


Fig. 12 Magnification Showing Slip Bands as True, Though Minute, Steps

> Still more conclusive, . . . is the demonstration of the nature of slip bands which has been obtained by the author by means of actual cross-sections of a surface on which slip bands had been developed. The difficulty in obtaining such a cross-section lay not alone in the minuteness of the surface features looked for, but also in the fact that, when a specimen is cut and polished, the edges of the surface are always more or less damaged and rounded off. Sharp images at high magnifications, therefore, could not be obtained by simply cutting a previously polished and strained specimen through at right-angles to the original surface and then polishing the cross-section thus obtained. The author overcame this difficulty by first coating the surface on which slip bands had been formed with a thick layer of electrodeposited copper. When subsequently a section was cut through the compound mass—in this case of iron and copper—the boundary on this section, between copper and iron, gave the exact outline of the section of the original surface. When observed at a high magnification, such a section shows the slip bands as true, though minute, steps. The appearance, under a magnification of 1200 diameters, is shown in Fig. 106. [See Fig. 12, which is Fig. 106 of the Rosenhain work.] It is of interest to note that the approximate depth of the minute slip-band steps seen in Fig. 106 is $^1/_{50,000}$ of an inch, which is about the length of a wave of sodium (yellow) light.

For the practical examination of iron or steel surfaces produced by grinding, it is first necessary to obtain a small sample of such surface, measuring perhaps an inch square, and as thick as general conditions may require. Such sample must have been preserved from rusting, corrosion, etc., after grinding. Before copper plating can be commenced, the surface of the sample must be freed from every trace of dirt and grease, without, however, damaging the surface. Cast-iron cylinders which have been subject to oil lubricants or preservatives present

FIG. 13 PHOTOMICROGRAPHS OF SURFACE CROSS-SECTIONS × 200

the most difficult cleansing problem, for the oil enters the graphitic pores and is very difficult to wash out. Long soaking in petroleum ether or pure ethyl ether is effective, or the sample may be placed beneath a reflux condenser so that freshly distilled clean ether is constantly dropping on its surface. It may be necessary to continue such treatment for 24 hours. Even when so cleaned the surface may still be covered with a very thin film of oil, and is best dipped in a hot (not boiling) dilute solution of sodium carbonate or sodium hydroxide. Such sample is then transferred quickly to distilled water before the caustic solution can evaporate. After rinsing in distilled water the sample is ready for copper plating. Non-porous materials, such as steel, are much more easily cleaned.

The copper plating is carried out with two baths. Were a steel sample to be dipped at once into the ordinary acid plating bath, "plating by contact" would ensue, and a non-adherent coating of copper would result, with corresponding solution of the steel sample and blurring of the minute outlines of scratches, etc. Consequently, it is necessary to start the plating operation in a cyanide bath in which "plating by contact" will not take place. Unfortunately, it does not seem possible to obtain, with a cyanide bath, a sufficiently thick coating of copper to serve the whole purpose. Therefore, the cyanide plating must be followed by plating in the ordinary acid bath.

A suitable cyanide bath is obtained by dissolving cuprous cyanide in potassium cyanide to form about a 5 per cent solu-

Ground Surfaces Polished Surfaces

FIG. 14 PHOTOMICROGRAPHS OF SURFACE CROSS-SECTIONS × 800

tion, with the addition of about one-half of 1 per cent of sodium carbonate. Plating is carried out at a temperature of about 50 deg. cent., and with the usual copper anode. The current density should be sufficient to produce a considerable evolution of gas. After about an hour, and while the surface is still smooth and uniformly salmon-colored, the sample is lifted from the copper cyanide and quickly washed in distilled water, before the adhering solution has time to evaporate. It is then at once transferred to the acid plating bath, where the plating is continued without danger to the surface, because of the protective coating of copper laid down in the cyanide bath. A suitable composition for the acid bath is that used for copper coulombmeters, as follows: 1000 grams of water, 150 grams copper sulphate, 50 grams concentrated sulphuric acid, and 50 grams alcohol.

Plating takes place at room temperature, and is greatly expedited if the solution is strongly and continuously stirred, as by an electric motor. Deposition continues until the thickness of copper overlaying the surface to be examined is about $^1/_8$ in. The time required varies from two days to a week, depending on the degree of stirring, which in turn controls the maximum current density at which adherent copper is deposited.

When the copper coating is of adequate thickness, the sample is removed, washed, and cut with a hacksaw along the plane desired. As the copper coating is not extremely adherent,

it is best to have the saw teeth move from copper toward steel, thus avoiding as much as is possible any tendency to tear the copper away from the surface. After so cutting, the specimen is polished by the usual metallographic methods. As copper is very much softer than steel, there will result at best an inequality in the level of the copper surface and the steel surface, but this can be reduced by the use of emery paper as much as possible in the polishing operations.

Results obtainable with this method are illustrated by the accompanying photomicrographs made several years ago in studying the bearing surfaces on two crankshafts. The surfaces on the one crankshaft were finished by grinding; on the other by "polishing." Three samples from the bearing surfaces of each crankshaft were copper-plated and prepared as described.

Each group of three samples was photographed at a magnification of 200 diameters (Fig. 13) and at a magnification of 800 diameters (Fig. 14). The first group of photomicrographs are at 200 diameters. They comprise samples G1, G2, and G3 from the ground surfaces and P1, P2, and P3 from the polished surfaces. The second group at 800 diameters is similarly designated, G1′, G2′, and G3′ and P1′, P2′, and P3′.

In these cross-sectional photomicrographs the copper plating appears white, while the steel is black, due to etching in the usual nital to accentuate the contrast between the steel and the copper.

As before stated, there is a slight difference in level between copper and steel, which results in a blurred appearance of the steel structure, as the camera was necessarily focused on the copper. Nevertheless, all boundaries, even at 800 diameters, are sharply defined and give the exact shape of scratches as little as 0.00001 in. in depth.

In the case of these crankshafts it is evident that the polishing operation produced a more uniform product. The ground surfaces varied from bearing to bearing, probably with the truing of the wheel. Sample G3 was probably produced with a freshly trued wheel, which became somewhat glazed by the time it reached G1. Such a partially glazed or filled wheel polishes somewhat as it grinds, and the surface produced by it approaches a polished surface.

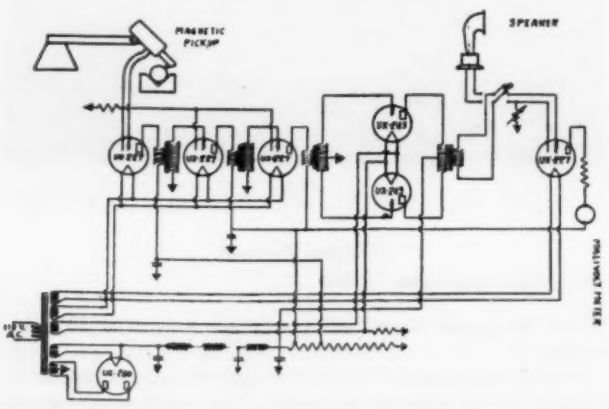

FIG. 15 CIRCUIT USED IN MAKING VISUAL AND SOUND RECORDS

Appendix 2—Circuit Diagram of Finish Comparator

The diagram (Fig. 15) represents the circuit used when making the visual and sound records. A further refinement and a permanent record can be obtained by connecting an oscillograph instrument to this circuit.

Appendix 3—Oscillograph Records

Fig. 16 shows oscillograph records made from a set of plugs similar to those shown in Fig. 7. It was ultimately found advisable to include a set of plugs of cast iron in addition to the soft-steel, case-hardened steel, and oil-hardened steel plugs. These records clearly show the varying equality of finish in each material, and are of great value in those cases where it is considered desirable for a record of the quality of surface to be kept for future reference.

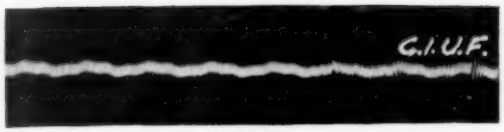
Discussion

CHRISTOPHER H. BIERBAUM.[5] This paper is certainly timely and interesting, since further improvements of machine tools and their operation necessitate a higher grinding practice, especially so for bearing surfaces.

The photographic method for determining the roughness of a ground surface is not at all conclusive; it leads to many inaccuracies and incongruities, for the reason that it is subject to so many variations and interdependent factors. Of these the illumination is of primary importance; its intensity, direction, and degree of diffusion all have a very material bearing upon the final result. The inherent degree of contrast in the photographic plate and also that of the printing paper are very distinct factors, as well as the personal equation and chemicals used in their developing; all affect the final result in a marked degree. The procedure for determining the smoothness of ground surfaces presented in this paper overcomes all of the photographic difficulties and seems altogether practical and accurate.

In the present grinding of metallographic specimens a high degree of grinding perfection has been attained. This work has clearly shown that for economy an increasing degree of fineness of abrasive is necessary for successive grindings and that for the greatest accuracy of finish a final material must be used that is both sharp and cutting. This work also shows that the directions of grinding should be continuously changed; this, however, is not readily possible in the grinding of cylindrical surfaces. The value of more accurate and perfect grinding cannot be overestimated; it reduces the time for the running-in of bearings; it reduces the aggregate amount of wearing down that is necessary during such running-in, thereby very materially reducing the liability of introducing inaccuracies in the bearing surfaces during the period of running-in.

Many manufacturers have found that the highest degree of accuracy of finish in their bearings is an economic investment. This is especially true for bearing alloys that cannot be finished as easily as steel by grinding, and for that reason they have resorted to finishing with a diamond cutter, taking a depth of final cut of 0.001 in. or less, at a very high speed, and thereby leaving all of the bearing crystals upon the surface in an undisturbed condition,[6] leaving these hardest crystals flush with the finished surfaces, that is, in a state that most nearly approaches a run-in surface. By such procedure they have found that bearings can be produced which require very little or no preliminary running-in. This, together with the further improvement of the grinding of steel journals, should have a very marked effect upon the success of sliding-surface bearings.



JOHN GAILLARD.[7] The paper makes it clear that a high quality of surface finish should not be confined to fits requiring

small allowances and close tolerances, but that it should also be applied to less exacting fits in cases where strong initial wear of the mating parts is to be avoided. This view accentuates the fundamental difference, too often disregarded, between the concepts "quality of fit" and "quality of surface." The quality of a fit depends on the ratio between the maximum and minimum permissible clearance or interference, or in other words, on the permissible variation in looseness or tightness. This again depends directly on the sum of the tolerances on the mating parts. The quality of a surface depends among other things on the maximum variation of its points from a true cylindrical plane. One could say that for a specific quality of finish all points of the surface concerned must lie within a definite "finish tolerance." For a surface of high quality this "finish tolerance" is of a smaller order of magnitude than the tolerances on the size of the parts. Dr. Sawyer's micrographs with a magnification of 800 times illustrate this. Although, in principle, quality of fit and quality of surface are different concepts, there is a practical relationship between the two. Close tolerances naturally demand a good quality of finish. The opposite is not necessarily true, however. Fits with large clearances and tolerances may be established without the parts receiving a high-grade finish. However, as the author points out and illustrates by practical examples, it often will be desirable, if not necessary, to give the parts a high-grade finish anyway in order to prevent rapid initial wear.

The paper shows that the art of producing good fits is progressing consistently along lines leading to greater refinement. Without being able to forego high speed of output, mass production has arrived at an accuracy of sizing parts and at a quality of surface finish that would have been impracticable in the workshop a few years ago even for serial production. The indications are therefore that the time is near when specification of a definite quality of finish by the designer will be regarded as just as necessary as the specification of tolerances on the sizes of the parts. It will not be sufficient to state, for example, that a part should be ground, but it also will be necessary to mention by class the quality of surface desired, and this again raises the problem of classifying surface finishes. This requirement is analogous with the necessity of standardizing classes of fit based on definite values of allowances and tolerances. So long as the nature of a fit is merely expressed by such terms as "snug," "wringing," "push," or "tight," no fit can be definitely specified. These terms have different meanings in different shops, and even with different individuals. If they have the same meaning, their interpretation is still dependent on the personal factor. A fit defined as a "wringing" fit by a husky fellow may feel like a "tight" fit to a man with less manual "torque."

The first step taken to eliminate the human factor in determining the class of a fit was to use a "standard" plug and ring giving practically a "metal to metal" fit together. That is, a physical example of a fit was created which could be imitated (or at least approximated) or varied from in a definite direction, as the case may be. The author's first step toward standardizing the class of a surface has been a similar one. Sets of plugs finished with different qualities of surface were established to serve as visual guides. However, in addition to this, the author struck upon the very ingenious idea of translating the frequency of unevenness of a surface per unit of length into frequency of sound waves per unit of time—that is, into the pitch of tone. This method has the great advantages of being easily applicable and of giving an immediate answer to the question what the quality of a surface is. The author must be congratulated on the simplicity and originality of this development. In addition to establishing a basis of measurement with consequent possibility of standard classification of surface finishes, it has the charm of containing a promise that in the future the surfaces of component parts may literally be tuned together for greater harmony in the assembled product.

As stated in the paper, the need for a basis of classification has been growing in recent years. Investigation of the nature of different surfaces was a basic requirement in trying to solve the problem. Different methods for doing this have been worked out. One of these, developed by Professor Berndt, of the Engineering Academy, Dresden, Germany, whom the writer visited this summer, may be of interest here. It complements Mr. Harrison's method in a remarkable manner and shows again how the existence of a problem may lead to its solution by independent experts at almost the same time. In the present case the solutions are different, but they show a similar basic feature.

Professor Berndt has developed a method of recording the minute irregularities of the profile of a finished surface. He lets a fine needle (so far he has used a gramophone needle) travel over the surface at such a slow rate of speed that the point follows all of its ups and downs. To do this, the part whose surface is being investigated is moved and the device carrying the needle is stationary. The needle is attached to a spring on which is mounted a small mirror. A beam of light is thrown on the mirror through a very fine slot and is reflected on a slowly moving film of sensitive paper. The beam thus traces a latent curve on this strip representing the magnified outline of the surface investigated. The strip is developed and oiled to become printable. The graphs thus obtained which were shown to the writer represented the outline of the surfaces investigated to the scale of either 400 to 1 or 1000 to 1.

One of Professor Berndt's students has used this method in the investigation of a large number of surfaces finished by different methods of machining, such as turning, grinding, lapping, broaching, and honing. Also the surfaces of parts tapped with cut taps and with ground taps were investigated. The study formed part of a "doctor of engineering" dissertation, and no details are as yet available for publication. The writer hopes to be able to report about the details in the near future when they are released.

Professor Berndt said that the needle method had given very good results, but that with increasing precision in surface finishing a point sharper than that of a gramophone needle was now required. Before developing this method, he had used two others. One of these, invented by a British expert, consists in making gelatin casts of the finished surfaces. These are cut to very thin slices, which are viewed under the microscope. This method appeared to be unreliable, as the casts warped when and after being removed and therefore did not represent true negatives of the surfaces. The interesting method of making the outline of the surface visible in cross-section described in Dr. Sawyer's paper, appended to Mr. Harrison's, marks great progress in this respect. The other method applied by Professor Berndt consists in measuring the maximum angle at which the surface still gives a fairly sharp image of a series of geometrical figures placed in a comparator, the surface under investigation deflecting the rays of monochromatic light sent out by the figures. Past a certain angle the image becomes decidedly blurred. This method has been checked by Professor Berndt with the needle method, with satisfactory results. Of course, the reflection method does not give details of the surface as the needle method does. In this connection it is interesting to note that Mr. Harrison refers to the occurrence in practice of "highly polished and deeply scratched" work possessing rather smooth surfaces located between pronounced ridges, which work gives a higher rating when subjected to the reflection test than it really merits from the viewpoint of quality of surface.

The practical solutions of the problem independently arrived at by Mr. Harrison and Professor Berndt are different and complementary. Mr. Harrison's method makes it possible to get an immediate but general answer regarding the quality of a surface. Practically, such an answer will probably be quite satisfactory in the large majority of cases. The application of Professor Berndt's method requires considerably more time and effort, but it gives a detailed and permanent record of the surface investigated. There will be cases in which one of the two methods should preferably be applied, and other cases where both should be used for the sake of completeness. Viewing in general the art of finishing surfaces and classifying their quality, both developments constitute a genuine contribution to the art by laying a basis for the substitution of judgment by measurement and consequent possibility of standardizing the practice.

The writer has followed the developments in this field with the deepest interest, both as a mechanical engineer and as a staff member of the American Standards Association (A.S.A.). When the time is ripe, in the opinion of the experts in this field to discuss the matter with a view to the possibility of establishing a national standard method of classifying surface finishes, the A.S.A. will be very glad to lend its assistance in organizing the work. For the present the writer wishes to congratulate Mr. Harrison on the great value to industry of his findings and on the exceedingly lucid manner in which his presentation has been made.

Sanford A. Moss.[8] Mr. Harrison properly distinguishes between truth of a surface and finish of a surface. A surface may have a low grade of finish and yet the high spots may be on a surface which is flat or true within a few tenths of a thousandth. On the other hand, the surface may have a high-grade finish according to Mr. Harrison's standards, and yet it may be out of round or out of truth by 0.0005 in. or even 0.001 in. Is it not possible that some of the benefits due to wearing-in are due to correction of errors of truth rather than errors of finish? In case of perfect film lubrication, there is supposed to be a layer of oil separating the surfaces. If the surfaces are perfectly true, it would seem that the finish is not a major item. There is of course another class of lubrication where there is not a perfect film, but merely a sliding of two greasy surfaces. For this sort of thing the finish is no doubt highly important. Of course, a first step toward finding out the cases where the finish is the major matter and the cases where truth rather than finish is the major matter, is the standardization of quality of finish, just as Mr. Harrison proposes. It is to be expected, therefore, that the pioneer work which Mr. Harrison has done will be followed up to a conclusion.

G. A. Bouvier.[9] The electrical method described in the paper, of calibrating the character of a surface, is not only new and novel, but apparently promises greater opportunity for general use in industry than methods suggested heretofore. While the author has stated that his work can only be regarded as preliminary, it is hoped that other investigators will take part in further research work. No doubt Mr. Harrison himself, if he has not already done so, will discover further advantages of the method.

A number of limiting factors have occurred to the writer which affect the method and which should be evaluated for a complete understanding of the subject.

Fundamentally, the proposed scheme consists of the generation of electrical energy by the movement of a phonograph needle over the surface whose character we are interested in. The phonograph needle, in this instance, is attached to an ordinary magnetic pick-up as used on phonograph records; in other words, a type of electrical generator. The movement of the needle over a hill-and-valley surface at a definite rate will of course result in the output of an electric current having a certain frequency relation to the number of hills and valleys over which the needle moves. Obviously, the power or energy generated will also have a definite relation to the character of the surface, because the hills and valleys not only differ in spacing but also in depth. The frequency would show up on the loud speaker as a complicated pitch or tone, and the energy as volume. Obviously, such a complex audible sound made up of overtone and discords can give to the investigator only a very rough indication of the real character of the surface. The writer would like to learn the results of further investigations of this method made with a recording oscillograph. This would supplement, in greater detail, the millivoltmeter readings which average the electrical output and hence give an index of the average roughness.

In ordinary ground work, as illustrated in Fig. 2, the scratches all run in the same direction. These scratches constitute the major surface imperfections, so that drawing the needle point at right-angles to them, as done by Mr. Harrison, would give the maximum energy output and the best index of surface roughness. On certain types of surfaces, however, such as the lapped surface shown in Fig. 5, the surface scratches possess no definite direction. On a surface of this type it appears that millivoltmeter readings should be taken for needle movements in two directions at right-angles to each other, and the results averaged.

It is apparent that such factors as the type of point, the weight on it, and the electrical constant of the amplifier will affect the results obtained. These factors must be standardized to make the device of general utility to the industry. The development of more knowledge concerning the limitations of this new method and the establishment of standards certainly will result in its ordinary and regular use in the shop for controlling the character of the finish on a definite standard basis instead of by the visual determinations now attempted. This method is especially suitable for measuring finishes so fine that methods employing the reflection of light cannot be applied. The writer hopes that Mr. Harrison will continue without interruption the development of this idea.

Luther D. Burlingame.[10] The presentation of this valuable paper emphasizes the fact that there has in recent years been a transference of skill from the workman to the machine so that precision work and that having a high degree of finish and accuracy, emphasized by Mr. Harrison, can be produced commercially. In the early days of grinding, the producing of such results depended on the skill of the workman.

In investigating historical matters relative to the origin and early use of grinding processes, it has come to attention that in those days grinding was done on an engine lathe with a grinding wheel mounted on the carriage, and personal skill was required in order to produce the desired grade of work; one of the workmen being so expert in this that he commanded a wage which placed him with the proprietors of the business, so that he came to the shop, as did they, in a tall silk hat. Skill in those days depended on knowing where to stand on the floor and where to tap the machine in order to secure satisfactory results.

This led Joseph R. Brown to invent the universal grinding

machine, which he brought out in 1875 and which was first shown at the Centennial Exposition in 1876.

During the period since that time continued improvements have been made in the grinding art and in the machine connected therewith, so that today results can be obtained such as those pointed out by Mr. Harrison in his comprehensive paper.

Author's Closure

By Dr. C. B. Sawyer.[11] Mr. Gaillard's remarks concerning the appearance of a technique for studying production results at such time as the demand for better control arises in the producing industry itself seems well illustrated in the present case. The work on microscopical examination of cross-section of surfaces here described was completed some five or six years ago, and has lain dormant from that time forward, until brought to the attention of Mr. Harrison. It now appears that the demand for better production control of surfaces has resulted not only in the appearance of the two methods described in this paper, but also of Professor Berndt's, and doubtless of others to be heard from later.

With reference to the time required for copper plating surfaces, two days is probably the minimum so far attained, but new methods for copper plating are accelerating the rate of deposit, and doubtless such time can be further very considerably reduced. Probably the time required for copper plating and examination of the surfaces can ultimately be reduced to an amount at least comparable with that required for an ordinary metallographic examination of steel structure.

From the photomicrographs shown, it is apparent that the method of copper plating surfaces gives details in contours attainable by no other method so far suggested. It is therefore at once evident that the copper-plating method should be very useful in correlating or calibrating the indications obtained by other methods which may be much quicker.

Further, it is evident that with the lessening of time required for preparing copper-plated cross-sections, the method becomes more and more useful for routine control of machine-shop production. It approaches the type of control furnished by ordinary metallographic examinations. Such type of examination may be applied to specimens selected from a run of any specified number of units.

Mr. Harrison has asked me to make a few observations on the acoustic method described by him, and in this connection it is well to consider the characteristics of the human ear.

In the perception of quality of tone, the human ear is truly remarkable. It possesses the ability to resolve a complex tone into its various components, and for a true qualitative match of electrical impulses derived from ground surfaces of repetitive characteristics by Mr. Harrison's phonograph pick-up and amplifier, the ear is probably irreplaceable by any instrument such as an ammeter, or even recording oscillograph, because this latter requires time for the development of images. Unfortunately, on the other hand, the human ear is not especially sensitive to changes in tone intensity. At fair volume proceeding from a radio speaker, the ear can, under most favorable conditions, detect a minimum of a 10 per cent difference in intensity, but the attainment of this minimum requires instantaneous switching from one tone to another at least once a second, and preferably four or five times a second. Moreover, there should be a low level of extraneous noise. Such low level of sound would be difficult to obtain in an ordinary machine shop, and the requirement for quick comparison of tones predicates a more elaborate apparatus than that described by Mr. Harrison. Probably under most conditions of use with apparatus like Mr. Harrison's, the ear would do well to detect a 50 per cent difference in sound intensity, this arising in turn from like differences in the ground surfaces. In a sense, this is advantageous, as any real difference detected by the ear will certainly proceed from a very real difference in the surfaces.

With proper precautions, such as a soundproof room, two phonograph pick-ups adapted to be drawn at identical speeds over the samples under comparison, and mechanical motorized switching devices, Mr. Harrison's method could be refined to give very quick and accurate comparison of surfaces. However, for the great differences prevailing in ground surfaces at present, the method just as described by him is very useful, and it can be borne in mind that, when conditions warrant, refinements such as indicated can be worked out.

The question has been raised as to the effect of harmonics introduced by amplifier and speaker. In my opinion, the perfections lately incorporated in phonograph pick-ups, amplifiers, and loud speakers should eliminate cause for worry on this point when the application is limited to simultaneous comparison of samples.

For those further interested in the effect of sound on the human ear, reference can be made to "Speech and Hearing," by Harvey Fletcher, Ph.D., published by D. Van Nostrand Company.

By Mr. Harrison. The author readily agrees with Mr. Bierbaum regarding the limitations which apply to the photographic method of recording imperfections in machined surfaces.

He was particularly pleased to see the reference to the effect that, in the preparation of metallographic specimens, the material used for the final finishing operation must be both sharp and cutting. This is additional confirmation of the author's invariable claim that finish should never be obtained other than with a sharp and precise tool, as otherwise the surface produced has a false finish and is untrue either as a cylinder or a plane.

There are of course many applications where precision is not of prime importance, but in those cases where precision requirements are paramount, there can be no compromise, i.e., the final operation, either grinding or polishing, must be performed with a tool which is just as precise as the finest limit required on the work, and this tool must be held with maximum rigidity and guided with an accuracy which will permit the desired degree of tolerance to be maintained.

Mr. Bierbaum's remarks under the heading of artificially matured bearing surfaces also are of special interest, inasmuch as, in the author's experience, a considerable number of very accurate and high-finished spindles have been ruined in a short time by inserting them in bearings which have been scraped in such a way that the actual contact points between spindle and bearing have been the hard crystals in the bronze.

This has resulted in high unit pressure, disruption of the oil film, and all the troubles which go with excessive heating and carbonization of the lubricating oil.

The diamond boring tool seems to offer the solution, as it will perform the same function as a properly graded grinding wheel, and instead of exposing the hard crystals, will leave them flush with the surface where they properly belong and where they can exert their best influence in supporting the spindle.

Mr. Gaillard's remarks regarding the experimental work carried out by Professor Berndt are also extremely interesting, and it is a remarkable coincidence that Professor Berndt should be engaged in an endeavor to find a solution to this problem simultaneously with ourselves.

It has been the author's endeavor to devise an instrument capable of practical workshop application, the principle on which this instrument is designed being capable of expansion to take care of the greater refinements which are desirable and permissible in a laboratory investigation.

[11] President, Brush Laboratories Company, Cleveland, Ohio.

The main virtue which might be claimed for the author's scratch test is the ability of the instrument, both visually and orally, to detect and record the spurious finish, i.e., the one with high luster but serious mechanical imperfections.

It is the author's hope that the American Standards Association will continue to give practical expression to its interest in this subject to the point where national standards can be set up.

In reply to Mr. Moss's contribution to the discussion, the author would state that he considers it a major requirement that any piece of work should have all practical mechanical imperfections removed before there is any discussion with regard to its finish. The question of finish is raised in conjunction with durability of accuracy.

In other words, it has been repeatedly proved that extremely fine limits of accuracy, with their proportionately increased cost, are wasted on articles produced with a coarse finish, this being due to the high initial wear inseparable from a coarse finish.

The author readily agrees with Mr. Bouvier that the method which is put forward is not free from technical imperfections. However, as pointed out by Dr. Sawyer in his joint closure, the method of calibration has proved sufficiently accurate to enable a control to be set up which is generally commercially acceptable.

In line with Mr. Burlingame's comments, the development of the grinding wheel has been concurrent with that of the grinding machine. However, despite the high standard of attainment which has been reached by both elements, so far no definite standard of performance has been set up for either.

The author appreciates and acknowledges the enormous value of the pioneer work accomplished by Mr. Burlingame's company.

The author gratefully acknowledges the encouragement contained in these discussions, and in reply to the hopes that have been expressed that experiments will be continued, advises that

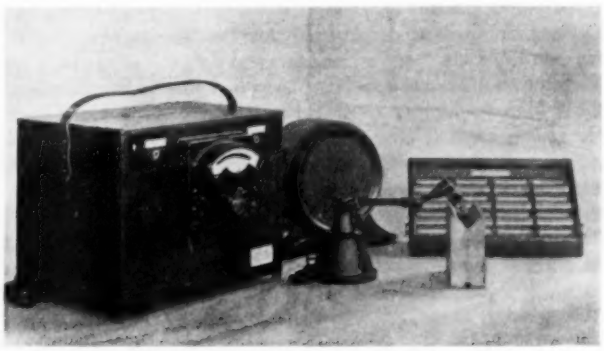

FIG. 17 NEW CALIBRATION INSTRUMENT

work on both the instrument itself and the technique of finish calibration has gone forward to the point where an instrument has been produced, as shown in the accompanying illustration, Fig. 17.

The instrument shown at the left of this illustration is portable and durable, and it is anticipated that it will shortly be made commercially available to all concerns having an interest in this subject.

Refinements in Finishing Cylindrical Bores

By J. W. HINDES[1] and JAMES G. YOUNG,[2] DETROIT, MICH.

THE limitations of boring, reaming, burnishing, and broaching as finishing operations on cylindrical bores have led to the general use of abrasives for such work. Improvements in manufactured abrasives and study of operating data, together with improved methods of application, have made grinding a precision process. The cost of operation and the difficulty of bearing maintenance of planetary-type grinders have brought about the use of the expanding grinder or so-called "honing" method. The latter method has the advantage of speed, improved accuracy and finish, and low cost. It also makes possible the precision grinding of long tubes, gun-barrel rifling, and bores with ports, keyways, and relieved portions.

THE problem of producing cylindrical bores held to ever closer limits of accuracy and finish has given industry no little concern. The bore produced must not only be round, straight, and smooth, but also of even texture with full metal surface, as nearly as possible identical with a run-in bore. A thorough discussion of the finishing of cylindrical bores by means of the expanding grinder or honing method must necessarily make reference to other practical methods of finishing and to the limitations of these methods.

Boring, reaming, burnishing, broaching, grinding, lapping, and the so-called honing method have been used with varying degrees of success.

Limitations of Boring, Reaming, Burnishing, and Broaching

Boring, although indispensable for the rapid removal of large amounts of stock, has been practically discarded as a finishing operation where close limits are required. Although the use of tungsten-carbide cutting tools has made it possible to produce a much better finish on many boring operations than was formerly possible, the nature of the operation itself prevents it from becoming a satisfactory finishing method.

The surface generated by boring is always a helical groove, varying in depth according to the overlap of the tool, the condition of the cutting edge, and the evenness of the metal. Such a surface has a series of ridges or crests, commonly termed "fuzz," which shear off or wear down quickly, causing excessive initial wear.

The accuracy of the bore as to straightness and roundness is also dependent upon the accuracy of the piloting, the evenness of the metal, the condition of the tool, and the skill of the operator.

Reaming is subject to a less degree to many of the limitations of boring. Out-of-roundness and taper are quite common, and considerable difficulty is found in producing cylinders of uniform size.

Burnishing or rolling has been used quite widely on metals which lend themselves to cold working, and on these it gives a smooth, hard surface.

When used on cast iron the fuzz is merely pressed into the wall and does not become an integral part of the surface. Bores are frequently out of round, especially when not having uniform external support over the entire length or circumference. Walls of varying density are necessarily produced as the metal is not displaced, the irregularities being pressed into the walls.

Broaching has found many applications where walls are heavy and uniformly supported. When properly fixtured, accuracy is not dependent upon the skill of the operator. As with other cutting tools such as in boring and reaming, the uniformity as to size and finish is influenced by the wear of the tool.

Broaching has not proved satisfactory for finishing bores with thin walls, or those having varying support such as cylinders with ports, cut-away sections, or flanges. The metal being pushed out under high pressure, rigidity of material is essential.

The limitations of the above methods of finishing cylindrical bores have led to the constantly increasing use of abrasives for that purpose.

Grinding Practice

Engineers and others who have followed manufacturing methods over the past 25 years will have noticed the ever-widening scope of grinding. Confined at first almost to the cutlery trades, and to the comparatively few parts which required precision, its machining value was not understood, nor its application to mass production appreciated. This of course was very largely due to the fact that in the early days of grinding, artificial abrasives were unknown, and quarried stone and emery so limited the choice that to obtain a really suitable abrading agent for every operation was impossible.

The wide range of carefully graded wheels and stones now available, and the data obtainable on speeds, feeds, etc., have changed practically all grinding operations from speculation to certainty. In addition to this the value of grinding as an agent for removing stock has been realized, and as the need for refinements and closer limits has been developed and demanded, machines have been evolved to meet the growth and perform an increasing range of operations.

Maximum speed for production and accurate working to limits is now possible with suitable grinding equipment, so that grinding is an essential factor in the manufacture of standardized duplicate parts. In the enormous field of mechanical industry it is being daily demonstrated that greater speed, closer accuracy, and reductions in operating costs can be obtained by introducing the most up-to-date grinding equipment, and this is possible and noticeable in every phase of manufacture.

The manufacture of abrasives and grinding wheels, and the several factors affecting their selection, would require a paper in themselves, but these subjects must be briefly dealt with in order to bring out the applications of grinding touched upon in the present paper.

Grinding wheels, distinct from natural grit stones, are usually manufactured from two types of abrasives, an aluminous abrasive, with bauxite as a base, and a silicon abrasive, with silica sand and coke as a base.

The bonding of abrasives is done by varying processes, and at least 75 per cent of the manufactured wheels and sticks are vitrified. It was found necessary to vitrify abrasives in order to remove metal quickly, and the amount of metal removed per cubic inch of wheel wear is very high due to porosity and strength

Contributed by the Machine Shop Practice Division and presented at the Semi-Annual Meeting, Detroit, Mich., June 9 to 12, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

of the bond. Vitrified wheels are not affected by water, acids, or changes of temperature.

Aluminous-abrasive grains are much tougher than silicon carbide grains, do not break apart easily, and withstand greater stress and are used on materials of high tensile strength.

In describing grinding wheels they are sometimes compared to milling cutters having a greater number of teeth or cutting points, and on a normal-size grinding wheel, millions of grains act each minute.

It is customary for wheels to cut freer after wearing down a little; this is explained by the reduction in the arc of contact, which results in the grains leaving the bond more quickly as the strain increases—for by maintaining the same surface feed, each grain has to do more work in a given time and that wears down more quickly.

Correct wheel selection is all-important, an error in one or two grades in density or bond having an enormous bearing on production, the latter being sometimes doubled by the difference of a grade or so in hardness of bond.

The advance of precision grinding machines in recent years is one of the important developments in present-day production methods, for in order to produce the greatest number of parts the exact limits for size and finish must be set, and modern production grinding has to conform to given rules and standards of precision.

The most common form of precision grinding is the grinding of cylindrical parts. In studying cylindrical grinding it is necessary to remember the close connection of previous operations. Often the grinding operation will correct imperfections, but careless use of this rule leads to excessive wheel costs, and where materials are hardened there is danger of surface cracks and local heating, resulting in inferior products and often heavy increases in scrap percentages.

There are a number of high-grade cylindrical grinding machines, of which several features worthy of mention to production engineers are: massive wheel spindles, ample speed changes, table and work speeds controlled independently, and rapid power traversing, operating in either direction. Some machines are fitted with an oscillating table motion that preserves the wheel face for form grinding. Other machines operate on a different principle, the wheels traversing the work, which latter rotates in a fixed position. As to the relative merits of traveling work tables or traveling wheel heads, there is room for discussion.

The introduction in quite recent years of hydraulic drives for grinding machines has also resulted in more convenient control mechanisms for all classes of grinding machines.

Some useful points to note for cylindrical grinding are: Be sure the speed is right; tap new wheels to be sure of soundness; never force wheels on to spindles, and where lead bushes are used, these should be a sliding fit on spindles, and thin rubber or thick paper washers should be fitted between the wheel faces and flanges; always watch the speed as the wheels wear down; and it is better economy to change to the right grit and grade of wheels, as the time required for changing is very soon made up on quantity production.

Automatic feeding insures economy in wheel wear, allowing regular advancement of the wheel and thereby permitting it to act under normal effective conditions. Highly skilled operators, however, exercise great care in applying cuts by hand, and are successful in preserving wheel wear.

The strengths of abrasive grains and bonds are effective only to the limit of their ability to withstand the shock forced upon them in grinding. By overloading or forcing, the grains become loose before actually serving their real purpose as a cutting medium, and correctness of the wheel face is lost.

Any wheel that is correct as regards its speed and that of the work piece being ground, will stand a given amount of feed, and can be automatically fed that amount with each stroke of the traverse.

It is fairly well agreed that production is at its highest point and quality when automatic feeding of abrasive wheels is adhered to. Excuses are made that automatic mechanisms get out of order; however, attention to the upkeep of these mechanisms reduces errors to the very minimum. Lack of lubrication is often the greatest cause of improper functioning of automatic feeds and mechanisms.

Truing up the faces of the wheels is a matter needing careful attention and study. A very light cut with a diamond is sufficient to true wheels that have been properly used, but by rough usage of wheels considerable abrasive is wasted; for example, the loss by removing, say, twenty thousandths from the face of a wheel 20 in. $\times$ 2 in. is $2^1/_2$ cu. in. Diamonds passed quickly over the faces of the wheels break up the surface for roughing, leaving the abrasive grains somewhat irregular, but for finishing, light cuts with the diamond over the wheel faces gradually wear the grains down to uniformity in height.

Copious flow of lubricant is essential for the precision grinding of cylindrical work; it serves to reduce the heat generated by the work and wheel, carries away the dust, and reduces the friction of the cutting particles of the wheel.

The correct use of steady rests is essential in the cylindrical grinding of many types of parts, and care should be taken that these are set right. The type of steady rest used varies with the work being done; often hardwood blocks suffice, but sometimes hardened steel shoes are necessary. Efficient steady rests insure high production, accuracy, good finish, and ease in operating. Incorrect supporting of the work sets up chatter in the wheels quite as much as do incorrect work speeds.

Attention should also be given to the driving units or dogs, as torsion in the driver when heavy cuts are taken will set up vibration, and when the chatter marks appear in spiral form the cause is usually traceable to vibration of the work spindle.

Chatter is also caused by glazed wheels and uneven thicknesses of driving belts, and wheels often glaze because of incorrect relation of the wheel and work speeds.

Care must also be taken with the tapers for work centers; sometimes larger center holes will overcome chatter, but it is important always to see that the tapers on the machine centers correspond absolutely with those in the work centers.

When chatter takes place after every precaution has been taken to insure perfect machine conditions and the wheels have been dressed and balanced, then inefficient supporting of the work is invariably the cause.

Centerless Grinding

Centerless grinding has made enormous strides in recent years. The principal elements are a grinding wheel, a feed wheel, and a work rest. The advantage of this method is the continuous passage of work pieces across the wheel, with the elimination of centering and driving units.

The work rotates at the speed of the feed wheel, this wheel being an abrasive bonded with shellac or rubber and having a coarse surface to prevent slipping.

In cutting, the grinding wheel keeps the work firmly against the feed wheel, and traversing is controlled by setting the feed wheel at a slight angle so that the centers of the feed and grinding wheels do not fall in the same plane; by slightly changing this angle and the speed of the feed wheel the traversing speed may be varied.

A great advantage of centerless grinding is that a smaller grinding allowance is possible as compared with the ordinary cylinder grinder, owing to the fact that the centerless grinder works to the

nearest full diameter, whereas the center-driven machine works from a radius only. Because of the rigid support given the work, heavy cuts are possible and uniformly accurate work assured. The increase in production on many parts now centerless-ground over the output of the ordinary cylindrical grinder is several hundred per cent.

Wheel Grinding and Its Limitations

Every one is more or less familiar with the operation and applications of the planetary-type grinder. It is widely used and has many advantages over boring, reaming, burnishing, or broaching. Bores can be held to size and free from appreciable taper, and a smooth finish obtained. Where the stock to be removed is not too great, it is frequently used to correct or produce the axis of the bore. Although it has been almost entirely replaced by honing in the finishing of internal-combustion engines, it is still the means used in finishing many sizes and types of cylinder bores which are not adapted to honing.

There are, however, objections to ground bores. The finish produced by an abrasive wheel rotating at high speed and fed slowly through the bore is a helical groove, the pitch of which is the amount of wheel advanced per revolution of the cylinder. The fuzz so generated is usually so minute that its shearing off on initial wear does not prove detrimental except in cases where a tight working fit is required. In such cases it is often followed by a honing or lapping operation.

The accuracy of this form of grinding depends considerably upon the skill of the operator and the condition of the machine. Owing to the difficulty of protecting spindle bearings from abrasive grit, it is extremely difficult to maintain them in condition to avoid play, resulting in out-of-round cylinders, where hard spots are encountered, and a tendency to chatter. Chatter marks may also be produced by glazed or unbalanced wheels.

A further objection lies in the operating cost, a fairly high degree of skill being required for operation of the machine. This type of grinding does not lend itself well to multiple operating as do boring, reaming, burnishing, or honing, so that work on multiple bore blocks is relatively slow and correspondingly costly.

Objections to Lapping

Lapping has been generally used to produce cylinder bores to the closest possible limits in accuracy and finish, but it is always slow and costly, and to a great degree dependent upon the skill of the operator. It has the additional disadvantages attendant upon the use of a free abrasive, and great care must be exercised in order to prevent cylinder walls from becoming enlarged with the grit. Its best application is in lapping two parts together. Honing, however, is the more satisfactory practice where parts of uniform size are to be produced independently of the piston or fitted part.

The Expanding Grinder or Hone

One of the most interesting developments in the finishing of cylindrical bores has been the introduction of the expanding floating grinder or so-called hone. The type of tool generally used is in the nature of an expanding segmental wheel, the grinding surface being composed of a series of abrasive stones placed longitudinally upon the circumference of a metal body with an adjusting means for expanding the stones to the walls of the cylinder being ground, and holding them under pressure against the wall, the tool itself being rotated and reciprocated simultaneously. A positive backing is given to the stones to prevent their contraction when meeting some resistance such as a high or hard spot in the bore, as spring-tension tools would ride over the high spots and dig into low or soft spots. Some idea of the extent of the application of this method can be gained by noting the type of work for which it is used.

At the present time the bores of nearly all internal-combustion engines are so finished, as are compressors of all sizes, in both household refrigerating units and large refrigerating plants, as well as commercial compressors of various types.

It is also widely used for finishing bushings, bearings, hydraulic cylinders, a variety of pumps, push-rod guides, connecting rods, gear hobs and bores, wristpin holes in pistons, long tubes, pneumatic drills and hammers, and air motors.

Although not yet the generally accepted method, it is finding a rapidly increasing use in finishing locomotive cylinders of numerous types, such as piston valves, air compressors, reverse-gear cylinders, fire-door closers, link-motion bushings, etc. It is not limited to cast iron, being used as well for grinding various steels, bronze, brass, aluminum, ebonite, stellite, and numerous alloys.

Advantages of Honing Methods

The chief advantage of the expanding-grinder or honing method is the ease with which close limits of accuracy are maintained, giving any desired finish at a high production rate and at a low cost. The accuracy of the work is not dependent upon the skill of the operator, and the method lends itself readily to multiple operation. It has a wide range of application as regards size of cylinders finished. It is being used for finishing the rifling of large guns as large as 16 in. in diameter and 65 ft. in length; seamless steel tubing 3 in. in diameter and 20 ft. in length, also push-rod guides $^1/_2$ in. in diameter, cornet valves, and slide trombones. It has proved especially applicable to the grinding of bearings having oil grooves, cylinders with keyways such as bores in gear hobs, cylinders with ports such as Diesel-engine liners, rotary valves, sleeves for sleeve-type motors, two-cycle engines, large air compressors, slotted push-rod guides, etc.

The successful finishing of such cylinders has been due to the type of construction employed, tools for such work having a minimum of six stones, so that while any one stone is passing over a keyway or port it is supported by the stones on either side of it, thus preventing its dropping into such depression. With this type of construction, tolerances of 0.0005 in. are easily maintained on most bores, and on many bores tolerances of 0.0002 in. are held.

Another type of work for which this type of tool has been found peculiarly suited is that of obtaining alignment between two bores such as in the finishing of piston bosses, machine-tool bearings, headstock bearings (plain bearings and seats for roller or ball bearings), piston-valve bushings, and printing-press bearings. This result is obtained by the use of a single grinder with a set of stones at either end, or by two independent grinders rigidly connected and used for grinding two cylinders of either the same or different sizes.

Compensation for Uneven Stone Wear

In order to obtain cylinders both straight and round some means must be provided for taking care of uneven stone wear, as it is evident that even though the abrasive be absolutely uniform and the stock to be removed be evenly distributed (either of which conditions seldom obtains), in the grinding of long bores the end of the stone in the direction of travel is worn down the more. This is compensated for by the use of floating cones which feed out the stone, keeping the grinding faces parallel. Accurate work with this type of tool has often been obtained when one end of each stone has been worn away $^1/_{16}$ in. more than the other.

In the operation of this type of tool it is necessary to reciprocate the head while rotating it, a ratio of reciprocating to rotating speed of roughly 1 to 3 having been found the most suitable for cast iron (65 to 70 actual surface feet per minute reciprocation

to 200 feet rotation). The purpose of combining these motions is to obtain greater cutting speed, the action of the stick being in a number of respects similar to that of a file in that by rotating the grinder only the stones will load with metal and glaze. The same would be more or less true of reciprocation only, as would be the case if a file were pushed straight across the work either sidewise or lengthwise. By combining these motions a shearing action takes place which produces faster and easier cutting, at the same time cleaning the face of the stone and preventing its glazing.

It has been quite consistently noted that if a stone is a little hard for the work and starts to glaze, it can be made to break down and cut freely by increasing the ratio of reciprocating to rotating speed. This of course, within certain limits, applies only to stones ordinarily suited for the particular type of work and does not make it possible to employ stones a number of degrees harder on the job.

The combined rotating and traversing motion not only cleans the face of the stone, but causes it to break down more evenly, giving a more uniform grinding surface and a closer average of errors in both material and abrasive.

The Coolant Used

In the grinding of cast iron it is practically universal practice to use kerosene as a coolant during the grinding operation; this also serves as a lubricant, causing the ready displacement of all broken-down abrasive particles on the face of the stone, and giving a much freer cutting surface. The kerosene also serves to clean the surface being ground, washing it clear of free particles of both metal and abrasive.

Kerosene is also quite generally used on other metals due to its low cost and the fact that it operates quite satisfactorily, although turpentine has been found to give a freer cutting action on bronze, brass, and some alloys. Mineral seal oil can be used on most operations but is more expensive.

In this type of grinding the use of water has been entirely unsatisfactory, not so much on account of its causing tools, machines, and work to rust, but for the reason that it causes the broken-down particles of abrasive and metal to adhere to the face of the stone forming a rather gummy mass.

Stones soaked with water before using with kerosene also show this tendency, as do also stones which have been immersed in motor or cutting oils.

Oil has not been found a satisfactory lubricant and coolant in itself, although recent tests indicate that a small percentage of spindle oil in the kerosene does not interfere with its action. Much experimentation has been made along the line of developing proper coolants, but so far kerosene has proved the most satisfactory.

The Abrasive to Use

For use on cast iron, 80-, 120-, and 150-grit abrasives have found widest use for roughing operations, and 120- and 180-grit stones for finishing, depending on the surface desired.

In all cylinders finished with 180-grit stones or coarser, criss-cross scratches are plainly visible, the rotating and reciprocating motion creating diamond-shaped figures throughout the bore. These scratches are not measurable in depth, being so slight that a few passes of a close-fitting piston remove at least 50 per cent of them.

Where turned rings are used, these scratches are essential to the proper seating of the rings, as is the case with most internal-combustion engines.

By the use of the finer abrasive stones (600 grit or finer) a mirror finish can be obtained, no scratches at all being visible to the naked eye. Such finishes can only be used to advantage in engines using ground rings or in hydraulic and compressor cylinders and the like where no seating of rings is required.

In the grinding of bronze, brass, aluminum, and aluminum alloys, fine-grit stones having a small percentage of bond have proved the most practical to use, as stones which are too porous or in which the grit is too closely held will have a tendency to tear and roll up the metal. In grinding such metals a copious flow of coolant is required, and where the metal is particularly soft, the application of paraffin wax to the face of the stone prevents loading and gives an improved finish.

One of the most interesting applications of this type of grinding has been in the finishing of seamless steel tubes, tubes as long as 60 ft. being finished on a production basis. Owing to the presence of scale on the walls, abrasive stones have not proved economical for the roughing operation on such tubes, and shaving tools known to the trade as "revocipers" have been employed; these are tool steel inserts which fit the grinder heads, replacing the abrasive sticks, and are operated by the same rotating and traversing motion as the grinder.

Each insert is made up of a series of cutting teeth with spaces between them for chip clearance, and so ground as to give a continuous cutting action in both directions of the stroke cycle. The interior finish of the tube therefore has the same characteristics as that of the ground tubes, i.e., criss-cross tool marks, these requiring from $1^1/_2$ to 2 thousandths (0.0015 to 0.002 in.) grinding to clean up. In actual production a stock removal of 0.007 in. per foot per minute has been maintained on 3-in. seamless steel tubing.

The value of this type of tool is not of course in the rate with which it removes stock, but rather in its adaptability to the finishing of tubes of lengths limited only by driving mechanism.

The success of this method of finishing can be accounted for in large measure by its adoption for gang grinding—4, 6, and 8 spindles being frequently used simultaneously—for use either on motor blocks or for the multiple grinding of sleeves or bushings held in fixtures.

In the automotive industry it is common practice to leave from 0.003 to 0.005 in. after reaming to be removed by grinding. The actual finishing time varies from 30 seconds to 2 minutes per block according to the nature of the block, quality of reaming operation, power of machine, and type of abrasive used.

In grinding airplane-engine and other thin-walled cylinders, generally nine or more stones are used in the grinder to prevent "breathing" of the cylinder or distortion of the thin walls through holding.

Another element entering into the success of the method is the fact that the accuracy of the work is not dependent upon the skill of the operator.

Conclusion

The advantages of the expanding grinder or honing method of finishing cylindrical bores are:

1 Perfection of finish both as to straightness and roundness.
2 Absence of fuzz, leaving a full metal surface as nearly as possible identical with a run-in bore.
3 Uniform density of surface maintained.
4 Accuracy not dependent upon skill of operator.
5 Adaptability to gang grinding with resulting high-speed production and low cost.

The Uses of 16-Mm. Movies in Industry

By MAYNARD L. SANDELL,[1] ROCHESTER, N. Y.

Industrial motion pictures may be readily divided into two distinct classes, namely, institutional and internal. Institutional pictures include productions employed for sales promotion and advertising purposes, or for any other use involving public exhibition. Such films should be made by the professional producer of motion pictures on standard-size 35-mm. film. Internal uses include instructing employees in safety, in machine-shop practice, in plant housekeeping, and in fire prevention, as well as making records of construction and research findings, and of testing, assembling, sorting, and packing operations.

This paper deals only with the latter class, describing briefly some of the many internal uses of industrial motion pictures, and showing how members of the plant engineering staff can make such movies on amateur standard 16-mm. film with inexpensive amateur equipment.

THE craftsmanship of cinematography may be readily divided into two phases; one relates itself to the amateur, the other to the professional. This paper deals primarily with the amateur phase of motion pictures in industry.

Amateur cinematography as practiced by the engineer has its limitations, and although he is furnished with portable, handy equipment with which he can easily obtain splendid results under those general conditions that circumscribe all amateur achievements, there is a point beyond which professional service will usually be needed.

For example, making movies for advertising and selling purposes does not, for reasons outlined later, fall within the category of the amateur's ability. Such productions certainly require professional technique and will not be discussed at length here.

Time-study and motion analyses by means of amateur movies have been purposely omitted, because a satisfactory exposition of such work demands more time than is available for this entire presentation.

The Economy of 16-Mm. Film

With the introduction in 1923 of 16-mm. film coated with a special, fine-grained, reversible emulsion, a practical, successful, and economical method of making motion pictures was made available for the amateur. The prime requisite was, of course, that they be relatively inexpensive; and, in addition, that the necessary equipment involved be portable and require no more than ordinary skill and photographic ability such as an amateur can easily and quickly acquire.

All of these requirements were met in the new film. Compared with standard 35-mm. film, the cost economy effected by the new 16-mm. width was well over 80 per cent. This great saving in cost, without sacrifice of either quality or length of picture, was made possible by the various economies involved, namely:

1 The new film was only 16 mm. in width as against 35 mm. for professional film.

2 Being less in width, each individual picture was proportionately less in height, so that 400 ft. of the amateur film was equivalent in projection time to 1000 ft. of standard commercial film.

3 With standard-sized professional motion pictures the negative had to be developed and a print made from it on positive film, and the positive then developed. By means of the newly devised photographic emulsion and a special chemical process, the 16-mm. film is first developed and then, without printing, reversed from a negative to a positive—virtually one operation as against three.

4 Before the advent of 16-mm. film, amateurs using the 35-mm. width had to send their films to laboratories whose facilities were organized for orders of 100 to 200 copies, and only in such quantities was the cost materially lessened, because of the time and expense involved in preparing the first master negative. The amateur seldom wanted more than one or possibly two prints, and it was for such accommodation that 16-mm. finishing stations were equipped, although as many duplicates as desired can be made at a nominal cost.

In addition, the film base used for making the new 16-mm. film was the slow-burning type made from cellulose acetate and generally known as "safety stock." While the cellulose nitrate film commonly used in motion pictures is safe when proper projection booths and other safety appliances are provided, its introduction into the home or industrial plant would be out of the question because of the fire risk naturally involved.

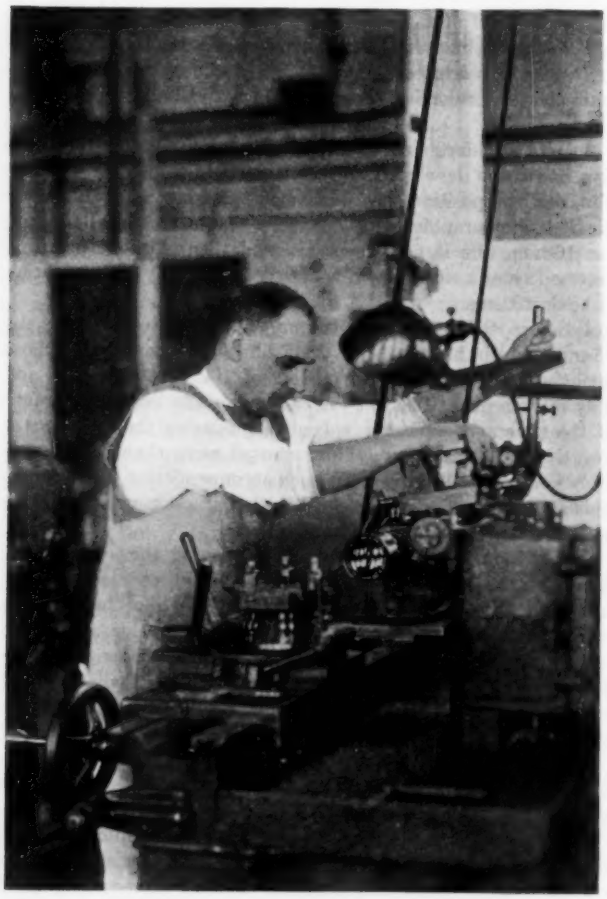
For this reason, the new film was made on the acetate base only and met the approval of the Underwriters' Laboratory standards for use where fireproof appliances were unavailable.

It was not long after its début that 16-mm. film attracted the attention of doctors, dentists, artists, and scientists, who turned to this simple and practical method of recording their technique for reference and teaching. The surgeon, for example, seeing his personal films on the screen, immediately visualizes the possibilities of 16-mm. movies applied to his professional technique.

Interesting work is being done in microcinematography with specially fitted 16-mm. equipment. The advent of this film has made the cine-photomicrography practical and economical for the research worker. The Bausch and Lomb Optical Company, of Rochester, New York, has perfected an apparatus using a synchronous motor in conjunction with the Cine-Kodak Model A, which, through a chain of gears, drives the camera at eight different speeds. The speeds range from 16 pictures a second to one picture every 4 minutes and 16 seconds. Such equipment permits focusing the microscope at any time without interfering with the photographic process. Studies involving

---

[1] Eastman Kodak Company. Mr. Sandell was graduated from Iowa State College with the degree of B.S. in Industrial Science. From 1925 to 1929 he was cinematographer in the visual instruction service at Iowa State College. In 1927 he was engaged in motion-picture work on barberry eradication for the Bureau of Plant Industry, U. S. Department of Agriculture.



Contributed by the Machine Shop Practice Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

the formation and precipitation of colloidal suspensions, crystal growth and changes occurring in crystal structure during chemical reaction, and the study of Brownian movement in rubber latex, are examples of work being done. In the paint and varnish industry it is very desirable to study the action of the surface film of paint and varnish while drying. During this process certain phenomena occur which have a definite bearing on the quality and appearance of the dry surface. Many cine-photomicrographs have been made, and the information obtained has proved of value.

Uses of Industrial 16-Mm. Film Increasing

The adaptation of 16-mm. film to industry followed very shortly its adoption in other fields. The transition from its uses in pure science to the applied science of industry was,

Instructing Employees in Machine-Shop Practice Is Effectively Done by Means of 16-Mm. Movies

figuratively speaking, overnight. Experimentation by amateurs in and around industrial plants disclosed uses for the 16-mm. camera which had never been thought of previously.

An investigation of the industrial uses of photography was conducted in 1927 by Frank Seaman, Incorporated, of New York City, and the compiled data presented on December 23 of that year. In the course of this survey, 434 companies were called on in 62 separate industries. Actually, 43 cities in 12 states, representing the industrial centers of the United States, were visited. The report of this concern showed only 18 industries out of the 62 using 16-mm. movies, or about 29 per cent. In the interim of three years since the compilation of this report, the number of industries using 16-mm. film has increased to 32, or to nearly 52 per cent.

The 18 industrial users of 16-mm. in 1927 were classified as follows:

Commercial

- Automotive
- Explosives
- Food Products
- Hardware and Tools
- Textiles
- Machinery
- Publishing
- Radio
- Ship Building

Public Utilities

- Electrical Power
- Gas
- Telephone and Telegraph

Transportation

- Railroads
- Steamships

Businesses

- Financial
- Retail Stores
- Insurance

Education

- Universities

Performance Records of Machinery and Equipment Can Be Readily and Economically Made With the 16-Mm. Film Camera

By 1930 the following 14 industrial applications brought the number up to 32:

Commercial

- Airplane
- Cement
- Chemicals
- Construction
- Electrical Equipment
- Petroleum
- Iron and Steel
- Locomotive and Car Building
- Mines
- Paint
- Paper

Businesses

- Architects
- Commercial Photographers

Miscellaneous

- Dental Supplies

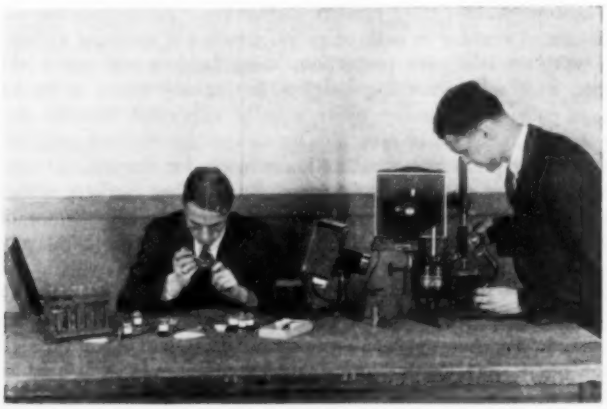
Sixteen-Millimeter Movies Used in Standard Practice and Employee Training

The compact, portable equipment for 16-mm. film permits recording the action of a machine or worker at close range without disrupting expensive manufacturing processes through distraction or interruption of the employee. For this reason, 16-mm. film lends itself admirably to work on standards of practice and process study.

Such films become an invaluable adjunct to process study when the acme of efficiency is sought. The minute details of a process cannot escape attention when a slow-motion pic-

ture is made of it. This is accomplished by a simple four-to-one attachment which gives, when projected, an action only one-fourth as rapid as the normal. Several models of the 16-mm. camera can be obtained with such high-speed attachments. In addition, the worker can study each element of a particular operation by running the machine by hand and projecting one frame at a time and studying each picture as a "still."

The Dunlop Tire and Rubber Corporation developed an efficient method for tire building. In attempting to describe this method for the benefit of the English Dunlop Company by the usual means of drawing, description, and time-study methods, it was found difficult to present the subject in such a manner that the English company could make use of it. In order to make the



Scenes Like This May Be Staged in a Plant and Prove Very Effective in Safety Education

matter entirely clear, a 100-ft. 16-mm. film was made by an amateur and sent to the English company. The display of this film cleared up all points in doubt, and enabled them to make full use of the economical method. The demonstration was so pleasing to the English company that they in turn made a film dealing with an English process that was not clear to the American company, with like beneficial results.

There are many industrial operations such as assembling, sorting, and packing, involving action of such rapidity that the eye cannot follow them. Were it not for slow-motion pictures and single-frame projection, the exact nature of the operation would never be known except to the operator; and usually the movie explains better than the operator. An example of this nature was forcibly brought out a short time ago. An examination of a very efficient worker disclosed the fact that she was doing an operation entirely with her left hand, while her less efficient co-workers enlisted the aid of their right hands for the same operation. She explained her method many times and at great length, but still her explanations were unavailing. The rest of the workers had to use both hands. A slow-motion picture revealed an action of one of her fingers which was essential to her efficiency, but of which she was unaware. The other employees quickly acquired her method, and what was once considered the acme of speed and efficiency is now an ordinary rate.

The Western Union Telegraph Company have made some very interesting films for instructing their employees. One of these, a reel called "Gumming," is proving beneficial in

Photomicrography of Motion Is Made Practical and Economical With Apparatus Such as This
(Courtesy, Bausch & Lomb Optical Co.)

When Taking the Product to the Prospective Purchaser, Requiring a Well-Planned Scenario With Special Lighting and Professional Actors, Advice From a Professional Producer Should Be Sought

teaching girls how to apply the printed tape to the telegraph blank as it comes from the machine. Another reel, "Keyboard Errors," teaches the operators how to increase their speed and efficiency and lessen the number of mistakes by avoiding certain conditions or movements which are known to cause errors. The effects upon the resulting work of long finger nails, distraction, and other factors of this nature are forcibly brought out in these films.

Employees need safety education, and there is no better method of educating them than by the use of movies. Motion

pictures taken in the plant illustrate the particular points of danger, and the inevitable results of carelessness are driven home with an impression that is lasting. It is hard for a worker to believe that he is in danger or that he is not immune to injury. Consequently, though his very life may be in jeopardy, he becomes careless and some day meets with serious mishap. A film showing how the accident happened, and perhaps a close-up of the mangled and mutilated hand, though unpleasant, will prove a stimulus to caution in the future. Many little scenarios which could be staged around the plant for safety education immediately present themselves. Films showing the danger of running in halls or alleys, grinding or chipping without goggles or other eye protection, using ladders without safety feet, smoking or carrying matches, letting oily waste or wiping rags collect, and many other equally important hazards can easily be made on 16-mm. film by an amateur cinematographer, employing plant personnel as his subjects for the sake of convenience and to bring home forcefully to other workers within the plant the points of his pictures. Here is one "ounce of prevention" which pays large dividends on a comparatively negligible investment.

To give a new employee a broad knowledge of the company for which he works, and to make him a part of it in the least possible time, there is nothing so effective as a movie trip through the plant. He learns more in fifteen minutes by this method than he would in a month through the regular channels of absorption.

Employees can be taught how best to avail themselves of their leisure time through the judicious use of movies of sporting events and competitive games shown in their recreation rooms. Such procedure kindles the spirit of fair play and friendly competition in the workers' minds, and a rising standard of morale and esprit de corps results.

Adaptation of 16-Mm. Film to the Research and Testing Laboratory

The 16-mm. camera is a faithful ally of the industrial-research laboratory. It is an excellent observer and not subject to mistakes involving the human element, or "personal errors." The camera can be equipped in the laboratory so that the operator can take a single picture at any desired interval; or the highly paid technician can set it to "watch" a certain process while he devotes his valuable time to other work. Here again the microcinematographic apparatus may be used. By removing the device connecting the camera and the microscope and putting a photographic lens in its place, the camera will take a picture at any one of the eight intervals according to the gear ratio used.

Pen recorders are not available for each new branch of research, and it would be a needless expenditure to have them made when a movie camera can be used for many phases of the work. One 100-ft. roll of film will make 4000 recordings. It is advantageous for reference purposes to photograph all new developments while under test. The small movie camera will "see" the whole procedure from a vantage point too close for safety by any other method of observation. Tests are being recorded this way on experimental high-tension transformers; explosives; automobile and airplane motors running at excessive speeds; characteristics of new alloys while under compression, tension, shearing, and torsion tests; and the crushing strength of concrete piles, beams, and culverts. An interesting application that has come to the author's attention is that of an aviator, piloting a cabin-type plane, who uses a 16-mm. camera mounted on top of the wing to "see" the action of the elevators and rudder while under stress in flight. Undoubtedly there are many other uses than those mentioned.

Building contractors and structural engineers are finding 16-mm. film a valuable asset for making permanent, authentic, visual records of their construction work. By taking a few feet at regular intervals, the entire building process is recorded from turning the first bit of soil to driving the last rivet. A construction project, taking months to do, can in this way be shown on the screen in a few minutes; and yet at any phase of the work the projector may be stopped and the scene viewed as a still picture. By dated titles for scenes of particular phases of the construction, the rate of progress between periods may be noted. Such information proves a valuable aid for computing costs based on rate of progress when undertaking future contracts.

Industrial concerns having branches and stock houses find the use of 16-mm. movies a valuable aid for disseminating knowledge or information to the other houses. Especially is this effective in the case of foreign branches. The more information an employee has concerning the product which he helps to produce and sell, the greater an asset he is to his company. Realizing this fact, several far-seeing employers have made 16-mm.-width movies among their various plants for interplant exchange and the edification of their employees.

Necessary Equipment for Making 16-Mm. Movies

Except where there is an abundance of window light, motion pictures within the factory or laboratory will require some artificial light. For this purpose, three to five portable flood lights of 500 watts each will be sufficient. The author has obtained very excellent results using "Kodalites." One of these lamps, when placed six feet from the subject, will illuminate, sufficiently brightly, an area of four square feet. For an ordinary factory close-up, more than three of these flood lights are unnecessary.

The camera should be equipped with an f.1.9 lens, which permits pictures with a minimum of artificial light, and may be either hand-cranked or spring-motor driven. An f.1.9 is a very fast lens of extremely wide aperture and has a speed equivalent to nearly 20 times that of a commonly used Kodak. A lens of lesser aperture should not be used because of the additional number of flood lights which would be required. The spring-motor-driven camera is usually held in the hands and takes, for each winding, about 15 ft. of film, which is equivalent to about 40 seconds on the screen. The hand-cranked model is used on a tripod and is capable of taking 100 ft. or a little over four minutes of projection time. Any dealer in amateur cine equipment will give what simple instructions are necessary for using lighting equipment, reflectors, backgrounds, etc. As a usual thing a few tests will solve the particular problem at hand.

The film used for making industrial 16-mm. movies is available in two emulsions, regular and panchromatic. The regular is suitable for all general purposes in and around the plant, and the cost is only about 20 per cent as much as the corresponding standard film for reasons explained earlier in the paper. Whenever the nature of the subject necessitates a correct rendition of color in monochrome, panchromatic film should be used. Regular film is mainly sensitive to violet and blue light only, very slightly sensitive to yellow and green, and practically not at all sensitive to red. Thus, when a picture is taken with ordinary film, violet and blue are the only reflected colored lights that make appreciable impressions on the film. Other colors to which the film is not sensitive make no impressions, and therefore show as black on the screen. When panchromatic film is used, correct color values are rendered in varying shades of gray, because the film is not only sensitive to violet and blue, but red, green, orange, yellow, and all other colors of light are correctly recorded. Brass fittings on a steam engine, for example, will not give the desired contrast with the darker steel parts when ordinary film is used, because of the yellowish light re-

flected by brass. Panchromatic film will increase this contrast to the normal which the eye sees because of its relative yellow sensitivity. In addition, panchromatic film, when used with Mazda lamps, requires less light than the regular film. The spectrum from a tungsten-filament light source has a predominance of red and yellow, the effect of which is lost on regular film because of its "blindness" to light of this color, as explained above. By using panchromatic film, the extra light is utilized, and good pictures can be taken where the light would be inadequate for regular film.

It is impossible within the narrow limits of this paper to explain all the uses and potentialities of 16-mm. motion pictures in industry. The very fact that the whole procedure is extremely simple and economical, requiring no special technique for making permanent, visual records, is assurance enough that its possibilities will increase as each new industrial use is found. And, in addition, the fact that duplicate prints may be made at a very nominal cost also enhances the value of 16-mm. industrial film. These "dupes" are printed from the original film and put through the regular reversal process at a cost of less than 40 per cent that of professional film. About sixty of these duplicates can be made from an original film without appreciable loss in quality.

Since only the merits of 16-mm. originals have thus far been discussed, it may be well at this point to say something regarding the use of 16-mm. movies which have been reduced from professional 35-mm. stock. These films have the advantage of the professional touch. There are, necessarily, many limitations imposed upon the use by the amateur of 16-mm. film in the factory; and when one or more of these contingencies arise, the professional cinematographer should be called in. When taking the product to the prospect requires a well-planned industrial scenario; when animated drawings may be needed to explain visually the ultra-technical details of the business or product; or when many interiors presuppose carefully regulated artificial lighting equipment, then, indeed, should professional help be sought. No amount of gaily colored sales and advertising material or cleverly phrased oratory can ever efface the stigma in the mind of the prospective customer of a poorly produced movie. For this reason it is advisable to have institutional movies made by a professional on standard film in order that the manufacturer may put his best foot forward in presenting his product to the customer, or in carrying the story of his plant or product to the public.

Again, to lower costs on duplicate prints and facilitate showing the finished picture, 16-mm. film comes to the rescue with the reduction print. These films are made by reduction printing from the original standard negative, and the salesman or demonstrator is thus enabled to carry 16-mm. prints of professional quality to show to his prospect by means of a light, compact, portable projector.

Conclusion

By way of summary, it may be said that the use of motion pictures in industry is readily divided into two distinct classes, namely, institutional and internal. The institutional use involves those productions employed for sales promotion and advertising where the film carries the story of the product or plant to the customer or public. Such films should be made by the professional producer of industrial motion pictures on standard 35-mm. film. The internal use is that made within the plant for instruction of employees in safety, shop housekeeping, and fire prevention; standard practice and employee training; layout and process engineering; recording research and testing operations; records of construction and building progress; and many other purposes in and around the plant. Uses such as these in which the film is not to be shown outside of the organization readily lend themselves to amateur technique and 16-mm. film and equipment. The convenience, simplicity, and low cost involved easily justify such applications.

Discussion

Allen H. Mogensen.[2] The principles of motion economy are so tied in with machine and tool design that it is wondered why it is not more effectively used. One manufacturer of milling machines uses the film to good advantage in order to make for more efficient operation of the machine and the tool equipment. He is also able to show the advantages gained by proper design to prospective customers with the films. Many of the present machine tools require that the operator be an acrobat in addition to his other necessary qualifications. Machine design and tool design must incorporate far more than mere ease of fabrication and low cost of production. In addition to considering fits and finishes, processing, and assembly, the designer and product engineer must also think of the man who is to use the tool or operate the machine, and it is here that a thorough knowledge of the principles of good motion practice will prove invaluable.

At the plant of the Cadillac Motor Car Company a motion-study laboratory has been established. This is used for instruction, not for theoretical solution of production problems. Groups of foremen, supervisors, time-study men, tool designers and makers, set-up men, and product engineers here learn the fundamentals of motion economy. It is here that the film has definitely proved its value, not as a means of making detailed micro-motion studies, but in teaching these principles to those who can directly and effectively lighten the work of the man in the shop.

A double die can be used in place of a single one, thus often at least doubling the productive capacity of machine and operator. The use of both hands may enable the operator to keep the machine running a greater portion of the time. Drop deliveries may not only greatly increase production, but enable a rhythm of operation more in keeping with the machine capacity. Redesign of the control mechanisms of the machine, bringing the control within the normal working area, may be a solution to what was before a serious problem in fatigue. There are many actual examples where the consideration of these simple principles

[2] Assistant Editor, *Factory and Industrial Management.*

during design or in redesign resulted in inconceivable increases in production, with consequent reduction in cost, and often solved a distressing labor problem.

One more important point. We are all concerned with the safety of the man who must use the tool or operate the machine. Often the application of these principles of motion economy may solve a problem that seemed insurmountable. Instead of slowing down production or otherwise adding to the cost of the ultimate product, thinking in these terms may give a surprisingly simple solution. We may so engage both hands in a useful portion of the cycle at the correct time as to eliminate the hazard. Thinking along this line will open up many new possibilities.

Back of all these principles of good motion practice stands the motion-picture camera, one of the most valuable production tools of today. Without detracting from its value in the field of micro-motion study, it can be stated that as a means of making a whole organization "motion-minded" the camera is supreme.

DAVID B. PORTER.[3] The writer wishes that the author had said more about the very important and far-reaching use of the 16-mm. movie in motion-study work. It would seem as though a treatment of this application would be of primary interest.

The degree of refinement and specialization to which machine design has been carried has tended to reduce the amount of machine time in proportion to the amount of manual time in the productive cycle of a unit of output. This places greater emphasis on the operator's part in the productive cycle. It therefore becomes increasingly imperative to improve his methods in order to secure the maximum of useful work with a minimum of motion and effort. Since the motions which a machine operator makes are partly predetermined for him by the machine, the designer should have a knowledge of the principles of motion and should incorporate these in his design. Also, this same knowledge should be applied to the design of jigs and fixtures so that they may be used with the greatest motion economy. The foreman, time-study man, instruction boss, and operator need to understand these principles so that all factors surrounding the operator's work may be analyzed and reduced to "the one best way."

Several companies have had considerable success in conducting classes in motion study for the purpose of teaching their people the principles of motion and of training them to think of work in terms of motion. For this they have found the motion-picture film most convenient for bringing into the laboratory or class room the material which the instructors may use in teaching. The motion-picture camera will continue to be used by the expert in resolving jobs that are important enough to warrant such detailed analysis, but such jobs must be relatively few in comparison to the countless number where time, let alone expense, would not permit of such refined treatment. It is to these jobs that a personnel trained to think in terms of motion will bring an attitude of mind and a method of analysis that will be not only most far-reaching in effecting economies, but in making the jobs more interesting to the workers. It is for such training of a selected personnel that the motion-picture equipment is indispensable and is likely to find its greatest usefulness in the motion-study field.

JOHN M. LESSELLS.[4] In recent years there has been an increased application of the motion-picture camera to research problems. For instance, there have been the applications by Drs. Prandtl and Tietjens to the study of flow of fluids around different bodies and the application by Messrs. Baud and Peterson[5] to the study of gear-tooth stresses. At the recent Congress for Applied Mechanics in Stockholm, a very interesting paper was also presented showing the action of stress on models using polarized light. All these activities show that this type of camera is valuable as a research tool, and in this respect it would be of interest to hear from the author just what is the maximum number of pictures which can be taken per second by the most modern 35-mm. equipment.

R. FAWN MITCHELL[6] AND M. W. LARUE.[6] Progressive factory managers are awake to the vital necessity of watching every operation and effecting every economy that will cut down overhead and improve the output. After all is said and done, a factory is the essence of motion, so that it is not surprising that a motion-picture camera has found such favor in assisting factory managers to solve many of their problems—mechanical, training, and research.

Pictures of intimate phases of manufacturing operations are used by salesmen to convince the prospect of the care used in making the equipment and provide a very effective selling talk. However, the principal interest in this paper will be confined to those uses of motion pictures that more directly touch upon the factory manager's peculiar problems.

A close community interest among employees is an invaluable asset to any business, and a great number of manufacturers are using motion pictures within their organization to promote this interest.

In conjunction with clubs of various kinds, activities outside of working hours, and in self-government projects, motion pictures grasp the interest and the imagination of the employee, giving him a sense of actuality of the thing before him.

For general entertainment, employees frequently enact movie plays themselves, exhibiting their screen prowess to fellow employees at regular meetings. Many subjects can be leased or rented from the many libraries of motion-picture film located in practically every town of any importance throughout the United States.

Now to consider the practical adaptation of movies to production problems in the shop, there are two natural questions that will be asked:

1 How can motion pictures be used to solve my particular problem?

2 What is the most economical method of securing results, what is the cost, etc?

The writers do not wish to create the impression that they are authorities on the subject. However, at our factory in Chicago we have, to some extent, studied the application of the motion-picture camera to various phases of factory production, and time and motion studies have engaged the attention of a number of our engineers.

Motion-study men tell us that motion study is not a speeding-up process. On the contrary, it seeks to find the one best way of doing a job, which is usually the easiest way. Time study reveals that one man makes four motions to do the job, while another uses six. Obviously, the latter should be shown how he, too, can increase output and improve the work, in order that he may increase earnings and decrease labor.

A competent engineer with a stop-watch can make time studies and motion studies and return to his office with figures which, when analyzed, can be used to definite advantage. If a motion-picture camera is added to the stop-watch he can then make a micro-motion study of the operation to be analyzed. The engineer not only has his stop-watch readings, but a visual record

[3] Assistant Professor, Industrial Engineering, New York University. Mem. A.S.M.E.

[4] Engineer, Research Department, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa. Mem. A.S.M.E.

[5] "Load and Stress Cycles in Gear Teeth," by R. V. Baud and R. E. Peterson, *Mechanical Engineering*, September, 1929, p. 653.

[6] Bell & Howell Company, Chicago, Ill.

of the operation synchronized with the time element. This can be reviewed time and time again, with the assurance that the personal element, in the use of the stop-watch, is also eliminated.

To make a micro-motion study, the operation to be analyzed is photographed, including in the field a microchronometer or stop-watch if desired. There is a type of microchronometer now on the market which operates by a synchronous motor which is ideal for the purpose. By recording photographically the movements of the operation and the movement of the clock, time may be recorded to within 0.002 of a minute.

With the recent improvements in camera design for the 16-mm. amateur film, motion-study work is made particularly easy. Among the most recent improvements in camera design of tremendous value to the analyst are the turret head and the critical focusing device. The use of lenses of varying focal length permits the placing of the camera in such a way as not to interfere with the routine performance of the operator or operation and enables the picture to be made right in the shop.

Of particular importance is the fact that such cameras are obtainable with a range of various speeds that permit photographing an operation in normal speed and then turning around and photographing the same in semi-slow motion. The speed of the camera can be adjusted to the speed of the operation so that the action can be slowed down just enough to facilitate analyzing the action without slowing it down so much that the essential sequence or rhythm of the operation as a whole is lost sight of.

For simpler operations it is possible to do away with the clock by running the film through the camera at a constant speed; thus if the film passes through the gate at 1000 frames per minute, the elapsed time between any two frames is 0.001 minute. An element of motion occupying 2 ft. of film, or 80 frames, must have taken 0.08 minute to perform. Thus the camera alone can be made to fulfil both functions. The highest class of spring-driven cameras now available can be considered accurate to within 2 per cent. This is satisfactory for quite a large number of operations.

Probably the most satisfactory method of doing this type of work is to include the clock in the picture area, as suggested previously. This permits individual analysis of each frame so that the exact time elapsed for each portion of an operation can be determined accurately. At the end of the paper will be given references to articles describing different methods of doing this work for those interested in following it up.

There are some special types of machines now in common use, such as weaving machines, folding machines, and other automatic equipment for handling complicated operations. Every one knows how easy it is for these machines to get out of order, and also every one knows how hard it is to place one's finger on the exact cause of the difficulty. Here the super-speed camera proves its value. It is possible to take slow motion pictures of extended length with professional cameras. However, there is available a compact, spring-driven camera operating at the same speed as the professional camera, namely, 128 pictures per second, giving a picture length of about 5 or 6 seconds. Ordinarily this is sufficient to analyze the usual run of such operations so that one can readily follow on the screen happenings which are too fast for the human eye to correctly analyze. The action is slowed down eight times by taking pictures at this speed. By slowing down the projector this can be slowed down still further, though naturally this is not recommended unless the circumstances render it imperative.

Satisfactory movies taken of intricate operations tie up very nicely with ordinary time and motion study. By their aid employees can be shown the importance of different phases of an assembly very quickly and very vividly. It helps materially in enabling them to appreciate the importance of their particular part of the job in the whole. If the average employee is able to appreciate just how much his fellow worker has to rely on his workmanship, it is not a hard idea to sell the employee the importance of exercising sufficient care to have the pride of workmanship necessary to turn out a good job.

An interesting example of the use of pictures for this type of work is to be found in the telephone companies. These companies train switchboard operators not only in the actual manipulation of plugs, but also in the understanding of the circuit and the complicated wire traffic which they never see.

Automobile manufacturers train dealers in correct servicing methods, how to perform the various types of service in the most approved factory manner.

Airplane companies, motor companies, and practically every type of manufacturer can use motion pictures in analyzing and for training. There is no operation, prowess, or routine of any nature but that can be taught better by movies.

The General Electric Company has developed an interesting side line to pictures originally designed for the purposes of internal instruction. These films are sent to other factories and help more than anything else to enable branch managers in different countries to correlate their productions with that at the main factory. It was soon found that there were numerous requests for permission to show these films to high schools, universities, etc. Naturally, films shown under these conditions to budding engineers, etc., had a material sales value that, if anything, was even more effective because they were not designed to act as a selling film.

In conclusion, we would like to mention a few thoughts on the possibilities of motion pictures for research work. Possibly the average factory manager is not primarily interested in pure research, but there are many things which it is desirable for them to find out for certain. For instance, in order to check the qualities of their lubricating oil, motion pictures taken through the microscope have been found very valuable. These pictures can also be taken in color as the color of the oil often acts as a guide to its other qualities, and in this manner a permanent record is kept, which is valuable for future reference. All engineers are familiar with the value of still photographs taken through the microscope showing steel structure. Motion pictures taken of similar subjects, say under strain, etc., are providing information of great value as to the action of different steels under different types of stresses. The same thought can obviously be applied to other metals, alloys, etc.

The 16-mm. amateur size film is comparatively cheap so that if the results are not satisfactory the first time, they can be shot over without inconvenience or more than the loss of a couple of dollars' worth of film. Therefore, there is every inducement for the factory manager to investigate the possibilities of this new tool. Sufficient work has been done along this line so that it is possible to state without equivocation that motion pictures provide a most effective means for a factory manager to improve his production, to train his employees, and to do research work where records, in motion, are available for comparison at a later date.

Author's Closure

Replying to Professor Porter, the author would say that, due to the variety of methods proposed for applying the motion picture to time and motion analyses, it is considered inadvisable at this time to include more than a mere mention of any specific method. The following, however, are the three most commonly used methods:

The Gilbreth system uses a microchronometer or fast-moving clock which is photographed simultaneously with the worker. The advantage of this system is that the microchronometer record is independent of film speed—the camera may be cranked at various speeds. These clocks were expensive, and required frequent winding and calibration, and in addition it is difficult to keep the instrument in the field of view, in focus, and out of the operator's way.

The second method uses a stop-watch mounted at a fixed distance from the camera with a small electric bulb and special lens. It is Joseph A. Dubray's method, and insures correct exposure and focus at all times, but it often interferes with the field of view, just as does the Gilbreth.

The third system uses a constant-speed camera wherein the actual time is integral with the film. If the speed of the camera is made constant and changed from its present standard of 960 to 1000 frames a minute, the time between succeeding frames will be 0.001 minute, and the time of a period may be obtained by counting frames. Knowing that 16-mm. film has 40 frames to the foot, a ruler becomes the measuring device for the time element.

By attaching a small synchronous motor to a hand-cranked camera, very accurate results may be obtained throughout the entire roll of 100 ft., which is equivalent to 4 minutes. The accuracy is dependent, of course, upon how closely the frequency is regulated at the power station, but ordinarily this is within one-half cycle; so the error is considerably less than plus or minus 1 per cent. Such a method would have none of the inherent disadvantages of the systems now in use.

Replying to Mr. Lessells' question, undoubtedly the ordinary motion-picture camera is limited to speeds not exceeding 256 pictures a second, and in many cases 128 is the maximum due to the strain imposed upon the delicate mechanism by driving it at such an excessive rate. This speed retards action eight times, which is sufficient for studying the way in which a turning leaves the bar on a lathe or in which a milling tool or twist drill works. Micro-motion studies seldom require rates as high as this.

C. Francis Jenkins built a special camera to take 3200 pictures a second. Heape and Grylls designed a camera for the British Admiralty with which, by photographing 10,000 pictures a second, they were able to show the action of shells penetrating hardened-steel targets.

By using a film wound on a cylinder and feeding the cylinder ahead by a spiral while rapidly turning, Baron Shiba of the Aeronautical Research Laboratory, Tokyo Imperial University, was able to make 20,000 exposures a second.

The device used a system of polished mirrors, turning synchronously with the cylinder, which made the intermittent mechanism unnecessary. Later Toyotara Suhara made 40,000 exposures a second by the same system.

These pictures were slightly smaller than the standard frame, but were enlarged and printed on standard film by a special machine.

MSP-53-15

Cemented Tungsten Carbide for Cutting Tools

By L. J. ST. CLAIR,[1] PHILADELPHIA, PA.

In this paper the author tells of the origin of cemented tungsten carbide and the most satisfactory method for making it. Because of its hardness its use for wear-resisting tools is valuable, and particular emphasis is placed on its use for cutting tools. The physical properties of cemented tungsten carbide and its economic value as a cutting medium are discussed. Design and care of the tools are essential factors in successful application. Proper support for the cemented-tungsten-carbide tip and allowance for proper clearance angles are essentials of design.

The tool set-up should be as rigid as possible, as chatter or vibration is detrimental to successful life. The critical speed at which the tool should run for a particular job should be determined, and the machine be operated below this. Grinding of the tool is important, and the author tells of proper grinding methods. Use of cemented tungsten carbide for cutting tools has resulted in increased machine speed, longer life per grind, reduced tool maintenance, less waste of material in setting up, and greater accuracy throughout a long run.

THE COMPARATIVELY recent advent of cemented tungsten carbide into the field of cutting mediums is apt to convey the impression that this material has been known only a short time. However, such is not the case, as tungsten carbide has been known for more than 40 years, but due to certain inherent physical weaknesses and the difficulty of using its extreme hardness to good advantage, little general interest in this material has developed.

The economic pressures brought to bear on Germany with the coming of the World War made it necessary to obtain or find an adequate substitute for diamonds in drawing tungsten wire for lamp filaments. As a result, Messrs. Baumhauer and Schroter, metallurgists at the Osram Lamp Works, Berlin (an affiliation of the General Electric Company), carried on certain experiments with tungsten carbide and soon discovered that the essential properties of strength and toughness must be gained if this material was to become of commercial value.

Further experimentation disclosed the fact that metallic cobalt could be utilized for this purpose. The combination of these two materials resulted in what is now spoken of as cemented tungsten carbide.

Messrs. Schroter and Baumhauer first applied this material, cemented tungsten carbide, to wire-drawing dies as a substitute for the diamonds they had found so difficult to obtain. The success of their experiments was proved by the fact that they got equal, or better, results. Their next step was the replacement of diamond tools for the machining of various Bakelite compositions, which, as all know, present certain machining difficulties in their extreme abrasive action on the edge of a cutting tool.

Their success on this second application was the signal for considerable interest in this new material, and its possibilities were quickly recognized by interested companies who secured the rights to exploit further and apply the material. The physical properties of cemented tungsten carbide are interesting and give indications as to which of its characteristics may be taken advantage of or compensated for in iis application to cutting tools for various materials.

1 Its extreme hardness is perhaps the best known quality. Measured on the Rockwell "A" scale, its hardness lies between 87 and 92. These figures are more interesting by remembering that infinite hardness on this scale is designated 100.

2 Its coefficient of expansion is only half of that of Invar steel, which has the lowest coefficient of expansion of any known metallic substance.

3 Its electrical conductivity is low.

4 Its compressive strength is greater than that of any known material.

5 Its tensile strength determined by a transverse rupture test is somewhat more than half of high-speed or tool steel, although this value depends on the cobalt content of the material, as well as the treatment which the individual compositions receive throughout their preparation and manufacture.

6 As expressed by Young's modulus of elasticity, its bending modulus is almost three times that of steel, and is the highest modulus of elasticity of any known material, coming well above tungsten.

As might be expected, the metallurgy of combining two powdered constituents to produce this metallic substance differs considerably from the metallurgy of common practice and requires a new and different technique of procedure.

Cemented tungsten carbide is made from powdered cobalt and powdered tungsten carbide. The two powders are mixed by ball-milling, and various tests have indicated that during this milling operation a coating of cobalt is formed around the extremely hard tungsten-carbide particles. It is for this reason that the grain size and milling time become such important factors in producing cemented tungsten carbide with the required properties of hardness and strength.

This new combination of powders is then pressed into shape on hydraulic presses, after which this pressed bar is fired to increase its cohesive strength to a point where the mass is workable and may be easily cut, shaped, or turned. The final step in the production of a cemented-tungsten-carbide blank is the sintering, which is simply a firing process. The blank is placed in a hydrogen atmosphere, brought to a high temperature, which is maintained for the required length of time, and then removed. It is then ready to be attached to a tool shank.

A cemented-tungsten-carbide blank is attached to a tool shank for several reasons, among which are: The economy of such a practice, as it is only necessary to obtain a cutting edge, and secondly, as has been already pointed out, the physical characteristics of this material have indicated that this is the logical way to utilize this material to its best advantage.

Due to the tendency of the cobalt to combine with oxygen,

[1] Manager, Philadelphia District, Carboloy Co. Mr. St. Clair graduated from the University of Maine in 1923, and for several years was connected with the General Electric Co., investigating and installing wage-payment and planing systems. He joined the Carboloy Company in 1929.

Contributed by the Research Committee on Cutting Metals and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

considerable experimentation had to be carried on before the present method of brazing the cemented-tungsten-carbide blank to the tool shank with copper in a hydrogen atmosphere was perfected. Tests were made of attaching the cemented-tungsten-carbide tip mechanically and by welding, but these were discarded in favor of the copper braze, which is the practice generally followed today.

The value of cemented tungsten carbide as a cutting tool is undoubtedly the most interesting phase. What will it do? That can be best answered by pointing out the advantages that have been obtained in its use, throughout the industrial world, on many different types of applications. Because of its inherent hardness, its application to gages and other tools that must of necessity be wear resisting, has proved it a decidedly valuable material in maintaining the close tolerances which are an everyday part of quantity-production life.

It is true that up to the present time the greatest emphasis has been placed on its application to cutting tools for ferrous and non-ferrous metals, and its value on applications of this type is more tangible and easily distinguished. Briefly, they are as follows: Because of its great ability to resist abrasion, longer tool life naturally follows, as cemented tungsten carbide will hold its keen cutting edge under severe conditions, much better than any other material commercially available. This longer tool life means a saving in man power and machine power through the elimination of the lost time now expended in setting up and grinding tools. This is in effect a double saving, as it converts that time into productive effort. Again, it has been found possible to run cemented-tungsten-carbide tools at much higher machine speeds than has heretofore been the practice with other tool materials. In many cases, the increase in machine speed has been limited by the machine tool itself. It is obviously an advantage to decrease the machining time per piece, because this means a lower production cost and a greater return on the capital invested in machine equipment and man power.

In addition to this, these wear-resisting qualities make it possible to obtain longer runs without any sacrifice of accuracy. The quality of finished parts is greatly increased, due to the fact that this material is not limited in its ability to machine parts of various hardnesses successfully. That is simply another way of saying that material which heretofore had to be scrapped, due to inaccuracies, no longer goes to increase the size of the industrial world's scrap heap.

Another extremely important value of cemented tungsten carbide is seen in the releasing of certain alloys which could not be commercially machined until the introduction of cemented tungsten carbide as a cutting medium.

Knowing something of the physical properties of cemented tungsten carbide and having some appreciation of its economic value as a cutting medium, the next query is: What are the factors that lead to its successful application? These are: (1) Design of a cemented-tungsten-carbide tool, (2) the machine tool, (3) care of the tool in operation, and (4) grinding.

Tool design is fundamentally a question of getting sufficient support for the cemented-tungsten-carbide tip, and at the same time allowing for the proper clearance angles. Generally speaking, the tip should be sufficiently large to withstand any strain placed on it, and the shank should be designed to have the greatest top-to-bottom dimension possible, so as adequately to support the cemented-tungsten-carbide tip. Because of the vast difference in the physical properties of cemented-tungsten-carbide, as compared to high-speed and other tool steels, the maintenance of minimum clearance angles is very important. In general practice a front angle of 6 deg. or less, depending on the diameter of the work, has been found to work to the best advantage.

As has been pointed out, one of the characteristics of cemented tungsten carbide, that tended to retard its commercial usefulness, is the fact that it will not bend or deflect without breaking. In applying a cemented-tungsten-carbide tool on any machine, this characteristic must be kept well in mind and the general condition of the machine studied critically before the tool is run. First of all, the tool set-up should be as rigid as possible. The machine should be in good mechanical condition and any looseness that might produce vibration or chatter be eliminated. This is important, as any chatter or vibration will be found particularly detrimental in the successful life of a cemented-tungsten-carbide tool.

Cemented tungsten carbide can be used on a large percentage of the machine equipment now in use provided these machines are in, or put in, the best possible mechanical condition. Any expense incurred in doing so will find justification in the good performance of cemented tungsten carbide. This necessity for rigidity in tool set-up and machine, when using cemented tungsten carbide, quickly indicated the need for improved machine design. Today, much of the machine equipment sold has been designed with a great deal of thought given to this subject, so that cemented tungsten carbide may be used more efficiently.

When the operating conditions surrounding a cemented-tungsten-carbide application are ideal, or as nearly so as it is possible to make them, there are certain other factors which must be considered, if the greatest tool efficiency is to be obtained.

First of all it is well not to attempt to run a machine at the highest speed possible, despite the fact that one of the primary advantages when using cemented tungsten carbide is increased machine speed right from the start. It is better to start at a lower machine speed and accelerate it gradually as, in this way, it will be easier to discover the critical speed at which the cemented-tungsten-carbide tool should be run on that particular application. Following such a routine will eliminate a lot of grief.

A second thing that should be well considered is the actual tool set-up. It should be as rigid as possible and the overhang of the tool kept at a minimum. Excessive overhang tends to develop chatter and vibration, two conditions which almost invariably defeat any advantages which may be expected when the tool is working under normal conditions.

Like everything else, cemented tungsten carbide will respond to attention and will repay the cost of such time and trouble in longer life between successive grinds. Experience in many plants has proved the value of not running a tool to death, but instead, stopping it while it is still in fair shape and honing it up. By so doing the time charge of each successive grind is decreased, and the initial cost of a cemented-tungsten-carbide tool is more easily proved out in the greater number of units machined during the complete life of the tool.

Failure to comply with this necessity of rigidity is one of the greatest causes for tool failure with cemented-tungsten-carbide tools. It is bromidic to point out that tool failures are the cause of much expense, both in actual dollars and wasted time.

Grinding a cemented-tungsten-carbide tool is a simple matter that enters very largely into the efficiency of tools tipped with this material. The grinding machine used must be free from vibration, and both hand grinding and machine grinding can be used with satisfactory results, though machine grinding is preferable since the proper angles can be held more accurately. When hand grinding, the following should be considered: (1) The use of rest and angle fixtures on pedestal-type grinders is strongly recommended, and the tool should be constantly in motion back and forth. This minimizes glazing and keeps the wheel true.

When grinding a cemented-tungsten-carbide tool in an auto-

matic machine, such as a surface grinder, the down feed should not exceed 0.003 in. in any case. The proper type of wheel to be used depends on the grade of the cemented tungsten carbide, the stock to be removed, and the finish required. Best wheel performance will probably be obtained at about 5000 ft. per min. surface speed.

The tools should not be forced against the wheel, but light pressures used, and the tool moved transversely across the cutting face of the wheel. The wheel should be dressed frequently to prevent glazing. A glazed wheel causes local overheating and checks the cemented tungsten carbide. It can be ground wet or dry. If a coolant is used it should be a heavy flow.

The adaptation and use of cemented tungsten carbide by many production plants, both large and small, throughout the country since its introduction as a cutting medium, has shown that there are very decided economies to be effected with this material. These include: (1) increased machine speed, (2) longer life per grind, (3) reduced tool maintenance costs, (4) less material wasted in setting-up, and (5) greater accuracy throughout a long run. The results obtained have also indicated from what sources these savings come.

Discussion

Coleman Sellers, 3d.[2] The author of this paper failed to mention one advantage of the tungsten-carbide tool which is sometimes valuable. That is the ability to cut hard cast iron and bronze. Material that for one reason or other comes from the foundry with hard spots, hard scale, or sand burnt into the surface may be machined where high-speed steel tools will fail. The importance of grinding tungsten-carbide tools for successful application should be emphasized. In the first place it is necessary to produce the correct angles with the clearance at a minimum for the particular material and work in hand. It is also important to produce a keen cutting edge free from nicks or grooves. The grinding should not be left to the individual operators. This practice is not conducive to good results and is very wasteful. One man should be trained to handle the grinding of the material and all tools brought to him.

Machine grinding is preferable for the following reasons: (1) It is faster as the tool is held more firmly, (2) it is more accurate as to angles of rake and clearance, (3) standards are established and maintained, (4) better work may be produced, (5) water may be used in sufficient quantity to speed up grinding without injury to the tool, (6) less skill is required on the part of the operator, (7) life of tool is lengthened by eliminating waste of tungsten carbide, and (8) labor costs of grinding are minimized.

Of the machines for grinding tools, those grinding on the periphery are preferable as a line contact cuts more freely. It is also less apt to glaze the wheel or overheat the tool so as to injure the tungsten carbide.

A further advantage results in the ability to place a stream of water at the line of contact where with a cup wheel with surface contact the water may only be placed around the edge of the contact, and the center will tend to overheat.

Lapping is not essential with machine-ground tools, at least on cast iron, as has been proved by a number of recent tests on both rough and finish cuts, using ground and lapped tools versus machine-ground tools.

Last spring the Sub-Committee on Tungsten Carbide of the Special Research Committee on the Art of Cutting Metals of the A.S.M.E. sent out a number of questionnaires to possible users of this new cutting material. A report on the answers received was made at the Detroit meeting in June. The writer has analyzed these in somewhat further detail in regard to grinding, and the answers are interesting in the light of being actual experiences of leading industrials in this country.

Many of the firms replying to the questionnaire had so little experience with this material that their answers were too brief to be conclusive, and in the summary given herewith the answers are not included where their experience was limited to one or two tools.

Of 38 successful shops, 13 used machine-ground tools, 16 used hand-ground tools, and 9 did not mention the method, but 3 of them had the tools ground outside. Eight shops reported failure or very doubtful success and all used hand-ground tools. Two others reporting failure did not mention the method of grinding.

The clearance angles varied anywhere from 2 to 29 deg. Six degrees was the most popular clearance angle, probably because it is the standard of many people for high-speed steel. Those who used clearance angles above 7 deg. were successful only on non-ferrous metals such as brass, monel metal, and aluminum alloys. Two reported satisfactory results with 7 deg. on cast iron. All the remaining were 6 deg. or under. Some failures could be traced directly to incorrect clearance angles. For instance one company reported failure of a cutting-off tool. It stated this tool was ground to 25 deg. clearance angle and used on cast iron.

Results on lapping did not indicate that it is essential. Nine companies reported that they lapped tools; three of them on finishing tools only. Of these nine companies, six reported success, two failure, and one doubtful success. Thirty-two companies reported they did no lapping, 26 of these were successful, six reported failure. In addition two companies reported success with and without lapping. Thirteen companies used honing after grinding, reporting success. Three of these reported on the grain and grade of stone which varied considerably. These were 180-L, 200-K, and 280-N.

There seems to be a great variation in the time required for grinding tools. The answers ranged from 3 min. to 3 hr. Four reported an average time 5 min. per tool; four reported about double the time for high-speed steel. Seven reported between 10 and 30 min. Only one reported time for grinding a milling cutter. The figure given was 4 to 5 hr. for a 10-in. milling cutter.

The variety of answers to the questions on the grinding, as outlined, indicate a lack of general knowledge of the subject. The importance of the grinding of tungsten-carbide tools has evidently been overlooked in many cases. Several shops reported they did not note what clearance angles they were using, showing they paid little attention to this feature.

It is obvious that a better understanding of the grinding of tungsten carbide would aid in its more generally successful use.

Roger D. Prosser.[3] The remarks of the author regarding the history and use of cemented tungsten carbide are very interesting and instructive. The important facts in the process of manufacturing cemented tungsten carbide should be understood by users of the material, as the great difference between the methods of manufacture of cemented tungsten carbide and high-speed steel accounts for the difference in their characteristics, and the consequent necessity of different methods of application.

The production of cemented tungsten carbide by the method briefly explained by the author is not as simple as the short discussion of the process might lead one to believe. The utmost care must be exercised throughout the manufacture, and the

[2] Supt. Engineering Dept., William Sellers and Co., Inc., Philadelphia, Pa. Mem. A.S.M.E.

refining of the tungsten, the state of pulverization, ball milling of the ingredients, temperatures and time of sintering, and other factors greatly affect the final product. Through careful regulation of the various factors involved, great improvements are constantly being made in the quality and usefulness of cemented tungsten carbide.

Measurement of the hardness of cemented tungsten carbide on a Rockwell machine does not give an accurate indication of the resistance to abrasion or cutting properties of the material. The resistance of the material to indentation, as shown by the Rockwell test, indicates partly the hardness of the tungsten carbide and partly the character of the binder.

The Rockwell test does give some indication of the relative hardness of various pieces, but at this time the only accurate method of determining the performance is by an actual cutting test. It should also be remembered that cemented tungsten carbides produced by different methods of manufacture and having the same Rockwell hardness reading have shown quite different results in performance.

Extended experimentation has been conducted to determine the best method of attaching the tips to the shanks, and the copper braze has been adopted by Krupp as standard from the time that cemented tungsten carbide was originally placed on the market about four years ago. If the braze is properly made, it is seldom that any difficulty is experienced with the tips coming away from the shank, even when taking exceedingly heavy cuts, provided that a tip sufficiently large to carry away the heat is used on a shank of suitable size to withstand the pressure. As the author stated, cemented tungsten carbide will not bend, and any bending of the shank almost inevitably results in breakage of the tungsten-carbide tip.

The paper emphasizes the desirability of maintaining a smaller clearance angle to support the tip. It might be mentioned that a reduction of the clearance angle from 6 deg. or 8 deg. down to 3 deg. or 4 deg. has in some cases resulted in doubling the length of time between grinds.

Automatic grinding in a rigid holder results in considerable pressure on the work, with consequent danger of overheating and resultant grinding cracks. It is doubtful whether a down feed of over 0.005 in. can be used with safety, especially if one of the harder grades of tungsten carbide is being ground. Light down feeds and less rigid holders should be used wherever possible.

Most of the troubles which were experienced with cemented-tungsten-carbide tools at first have been eliminated. Overenthusiastic salesmen as well as users have learned that these tools are not a cure-all. They have become accustomed to the proper method of application, and grinding practice has greatly improved. The workmen understand that the tools must be properly handled. The tools are employed not only in the most difficult places, but also are being used more and more on the production jobs where real savings can be effected. The history of high-speed steel seems to be repeating itself, and cemented tungsten carbide is finding its place in industry.

FRANK W. CURTIS.[4] Perhaps less has been accomplished with tungsten carbide as applied to milling than in any other form of metal removal where cutting tools are used. Even in Europe, where tungsten carbide was first developed, very little has been done with milling cutters. There are several milling applications in this country, of course, but these are few and far between as compared to turning and boring tools.

The present high cost of milling cutters equipped with tungsten carbide has a tendency to hinder progress. There is no question that satisfactory returns will more than offset the initial cost involved, but then again there seems to be no assurance or guarantee of satisfactory performance.

Experience with tungsten-carbide milling has shown that there is a decided advantage in having milling machines basically designed for this new metal. The machine must have ample rigidity and strength to enable metal removal at faster rates, including of course high spindle speeds suited to tungsten-carbide speeds. Next, the cutter must embody a design that affords the correct application for tungsten carbide. Here, again, it is a case of rigidity and strength with the addition of proper cutting angles.

There are two types of return that can be gained with tungsten-carbide milling cutters. One offers a small profit, the other a more generous profit. Existing machines can only be expected to offer smaller returns, whereas the newly designed machines, built for tungsten-carbide application, will enable much larger profits. There are many milling machines in use today that are not suited for tungsten carbide and prospective users should know where to draw the line.

When experiments with tungsten carbide were first started the first cutter, a 12-in. face mill with 32 blades, did not prove successful due to brazing failure of the tungsten-carbide tips. Several of the tips broke loose after very little use before any comparative results were obtained. Unfortunately, cutters having many teeth are likely to be ruined when one tip breaks, but the same is true with other cutting metals.

It was realized that every effort was being made to improve brazing and that one failure would not justify withdrawal of further tests, so an 8-in. cutter of similar design was made using 20 tungsten-carbide blades. Results were bettered considerably, and several experiments were conducted that taught the limitations of present cutter design when applied for use with tungsten carbide.

In the first place, when this cutter was stopped in the cut—that is, the spindle was stopped with the feed engaged—all the blades that were engaged in the cut invariably broke, if the cut was of medium or heavy nature. The tungsten-carbide tips seemed to fracture or break in two, but the braze did not let go. This offered another problem and led to further experiments with cutter-body design. What was evidently needed was greater support and more rigidity.

The latest cutters were made by inserting the blades almost flush with the face of the body and cutting chip clearances in the body proper. This design has been most successful and is probably the nearest approach to a foolproof cutter. Several cutters made this way have undergone severe tests and no failures have been experienced. The blades received proper support directly in back of their cutting edges, and there was no chance for them to spring under pressure of the cut, since there was practically no overhang.

As to the cutting angles, the writer is not ready at this time to announce the extent of experiments, although progress has been made and it is believed that blades set at a slight negative angle with the axis of the cutter body will serve for general-purpose work with an assurance of a satisfactory finish.

In line with experiments on tungsten carbide, a milling machine with spindle speeds up to 1000 r.p.m. has been developed and built, basically designed for high-production milling, using tungsten-carbide milling cutters. Many recent tests have been conducted on this machine and the results have shown that increased machine stiffness and strength are highly essential if tungsten carbide is to operate at its maximum efficiency.

So far most of the tests have been with cast iron and aluminum, although a cutter is being made that will be used for milling steel. On cast iron the average peripheral speed suited for general-purpose work is 275 to 300 ft. per min. The feed per tooth per

[4] Research Engineer, Kearney & Trecker Corp., Milwaukee, Wis.

revolution will vary from 0.007 to 0.012 in., with 0.010 to be preferred from a standpoint of power consumption and assurance of a free-cutting action. On aluminum it is possible to operate tungsten-carbide cutters around 1500 ft. per min. with as much feed as the machine will stand. At these higher speeds the feed per tooth per revolution will be less than specified for cast iron, although the feed per minute will be greatly increased. Hence, it is more a matter of machine power. Cuts have been taken in aluminum $^1/_{16}$ to $^1/_8$ in. deep with a 5-in. inserted-blade tungsten-carbide cutter operated at 1300 ft. per min., using 240-in. per min. feed to prove the cutting ability of tungsten carbide. Such cuts are not impractical nor impossible, although the machine must be designed primarily for high-speed work of this kind.

Malleable iron will machine similar to cast iron at about the same speeds and feeds. Bronze and copper are also machinable with tungsten carbide, although not many experiments have been conducted with these metals. With the cuts taken, regardless of the material, a very fine, smooth finish has been possible, which leads to the belief that finishing cuts can be taken with tungsten-carbide cutters, which is somewhat contrary to earlier beliefs.

Nothing has been done with solid-type cutters because it is the experience that inserted teeth have many advantages not offered in solid-type cutters. When a tip of a solid cutter breaks, the repair requires complete rebuilding and regrinding. With inserted-blade cutters, however, single teeth can be replaced without difficulty and without necessarily having to take out the remaining teeth.

It has been found that it is much better to regrind tungsten-carbide cutters before they become too dull. There are two reasons for this: First, dull cutters not only tear the metal they cut, but there is a greater chance of breaking the tungsten-carbide inserts if the edges do not cut freely. Second, there is more waste in grinding cutters that have become extremely dull, and likewise the cost of regrinding is somewhat higher.

Above all, it is essential to grind tungsten-carbide cutters with the greatest of care. Before application, the teeth of a cutter should be checked in a fixture to determine their concentricity and squareness. For face mills, it is found that the teeth should be concentric within 0.001 in. for finishing purposes and 0.002 in. for roughing cuts. The faces should be square within 0.0005 in. for finishing and 0.001 in. for roughing. These limits can be easily maintained if an amplifying indicator is used while grinding.

There is need for cutter grinding equipment suited to tungsten-carbide cutters because the present machines do not seem to offer enough stiffness to overcome deflection when the wheel passes over the tungsten-carbide tips. Many minor improvements are also needed to enable grinding with ease and at less time than is required at present.

Summing up this experience, there is no doubt that tungsten carbide has a very valuable and definite use in connection with milling, although the outstanding drawback has been the absence of machines embodying features so necessary to assure satisfactory results, which to some extent has retarded broader progress. It is believed that most failures have resulted from an attempt to follow high-speed steel and Stellite cutter design rather than to develop cutters to suit tungsten carbide. With a rigid machine and a well-built cutter, the possibilities of tungsten carbide for milling are unusually broad.

James B. Giern.[5] A cylinder-department foreman once remarked: "I would like to see the contrivance which could machine a cylinder, round, straight, and finished." Such a contrivance is here. It is the tungsten-carbide tool, provided it is used in the proper combination. Its combination is a rigid and expanding boring-bar.

Boring-bars in general may easily be said to have been somewhat "step-children" to modern production, yet they have found quite a market on account of their rather cheap upkeep and their faculty for boring round. However, a special situation has been created, by which the boring-bar will rank in the first class, by the advent of tungsten carbide. For with that as a material for cutters, the other two conditions may easily be met, and this completes the picture as to efficiency, such as is demanded.

In cast-iron boring, the boring naturally is in the two main stages of roughing and finishing. By the use of fixed centers such as bushings, preferably rotating bushings, and shallow feed, say 0.015 in. per revolution, and a total of 250 ft. per min. surface speed, or thereabouts, the roughing operation may be carried on and the result is a round hole, created under no side-thrust and no heat worth mentioning; consequently, a good preparatory operation.

That is one of the cardinal points in machining—viz., the better the preparatory operations, the better the finish. As to the finishing operation, semi-finishing may occasionally be omitted altogether by observing the foregoing. Fixed centers are important and the foregoing operations should not be depended on to create a center, as it were. Finishing is quite successful at a surface speed ranging from 250 to 300 ft. per min.

Grinding. Regarding the grinding of tungsten-carbide tools, much has been written and said concerning it. As a rule it may be stated that about half the cutting angle usually in vogue may be employed with success. The reason is very simple, for the ordinary tools soon wear off the extreme cutting edge, or perhaps crumble, the result being that it crushes its chips, rather than cuts them, whereas tungsten-carbide tools retain their keenness, so that it is unnecessary to allow for this condition. Also, this is the reason for their cool cut. Radial back-off should prove very successful and is recommended for experimentation along this line.

In the practical use of tungsten-carbide tools, not enough emphasis can be laid on the importance of rigidity. As far as possible jig-tools should be self-contained, so as to avoid any machine inaccuracy, or wear, influencing the boring.

Data and Statistics. Of statistics, there are not many. Yet these few are impressive:

Shock-absorbers: Have been bored at the rate of 2 every 22 sec.
Cast-iron pistons: Cross-bore 40,000 between grinds
Thin cast-iron carburetor parts: 120,000 on one grinding
Bronze bushings: With limits of 0.00025 in. 140,000 between grinds
Cast-iron brake drums: 17 in. diameter, 5 in. deep, 5 min. 300 pr. grind, one operation only.

Predictions are but predictions, but the possibilities point toward elimination of thousands of operations; toward unprecedented economy and the use of hitherto unheard of materials in future machine building.

C. J. Schipplock.[6] The writer wishes to call attention to the fact that much must be done before cemented tungsten carbide as a tool material can be profitably employed in a more general sense than is now possible, taking into consideration, of course, the fact that up to this time its use is confined to certain classifications of tools, and that it has not been successfully adapted to the making of threading tools and units of like character.

Taking the respective items in the order in which they are

[5] Western Tool and Manufacturing Co., Detroit, Mich.

[6] Engineer of Tests, Crane Co., Chicago, Ill.

mentioned in the paper, attention should be brought to the fact that not only can cemented tungsten carbide, when possible of correct application, be expected to equal the performance of diamond tools, but in many instances it will surpass them in economy and efficiency. One instance of this is a turning operation on brass castings that required an appreciable amount of stock to be removed in one roughing cut, with a return cut of lesser feed and depth. A first-class finish must be provided as well as a fairly high degree of accuracy; a definite taper being involved, and the cut being of intermittent nature. On this operation, with an increase in cutting speed to compensate for reduced feed in comparison with carbon tool-steel operation, to more closely suit the requirements of tungsten carbide, each tool of course being operated on a basis best suited to permit of maximum performance, comparison between carbon tool steel, diamond insert, costing $85, and a tungsten-carbide tipped tool with 2.5-gram tip summed up as follows:

Carbon tool steel—75 pieces per grind or an average life of 40 min.

Diamond insert—700 pieces per grind or approximately 6-hr. operation

Tungsten-carbide tip—Count discontinued as five weeks' operation was maintained before it was deemed necessary to grind.

It must be remembered in this instance that the machine equipment involved was specially designed to perform the particular operation and was, with slight change and expense, adapted particularly to the requirements of the tungsten-carbide tool in so far as feeds and speeds were concerned, and consequently permitted the tool to provide maximum performance. It might be further stated that in the hands of a careful operator this same tool continued to give service on the above basis from January to the middle of August, cutting red brass every working day of that period, the working limit per grind, however, being reduced to one week, when a very light dressing-up put the tool back into condition for the next week's performance.

Before going to another phase of this matter, and in order to continue along the lines of discussing each item in the respective order, mention is made by the author that other methods of attaching tips have been generally discarded in favor of the copper braze, and although he does not specifically include the use of brass brazes, in the opinion of the writer this latter material is superior to copper, as experience with several hundred of each type has resulted in loosening of an appreciable percentage where copper was depended upon and as yet the first occurrence is to be experienced where brass was used. This not only covers tools tipped under the supervision of the writer, but in the greatest number of instances where tools purchased from outside sources were involved. The only reason that can be given offhand, no particular research having been attempted as yet along these lines, is that the brass better resists softening where high frictional temperatures are developed in the tip, and must be radiated through the brazing medium.

Returning to the application and operation of tungsten-carbide tools and particularly to the running of these tools at higher speeds, it is needless to say that this is an incontrovertible requirement, as not only does the nature of the material demand operation along the lines of light feeds and consequent high speeds to compensate, but continuous production, especially under present-day machine-tool conditions makes it hazardous, so far as tool survival is concerned, to contemplate feeds greater than 0.030 in. under any circumstances, even though shank sizes up to $1^1/_2$ in. square are possible and front clearances approximating 4 deg. are accurately maintained. Feeds of 0.015 in. to 0.020 in. provide best practice with cuts in proportion to tool design and machine abilities. Exceptions to these figures, which are purposely rather definitely given, can be made, and the writer is frank to state, have been successfully practiced in both directions on experimental work but, as already mentioned, where continuous production is concerned with operators or machine hands of average ability, and machine equipment in good condition and of the character to be found in the average well-equipped shop today, if costly losses are not desirable, or as is more often the case decidedly not permissible, great care must be exercised in keeping feeds down to or somewhat below the above range.

Now if in the past it has been found possible and in fact good practice to utilize feeds of 0.063 in. and upward on ferrous materials with tensiles up to 115,000 lb. per sq. in., utilizing cutting speeds of 35 ft. per min. and upward, say with cobalt high-speed cutting tools, it is evident that spindle and table speeds of lathe and mill-tool equipment will have to be increased from three to five times to permit an even break in cubic removal within a given time where tungsten-carbide tools are used, and the above feed limitations are necessary. Further, if on top of this "even break," advantage is to be taken of the superior speed possibilities of cemented tungsten carbide, these r.p.m. requirements can be multiplied by such factors as will be required to satisfy the demand imposed.

As there apparently is no such effect possible as "burning" tungsten-carbide tools through frictional heat (except for loosening the braze), as is experienced in drawing the temper of steel-cutting tools, the only limits in speed that must be observed are the probability of softening the braze; the speed, rigidity, and horsepower capabilities of machines driving the tools; the ability of the structure being machined to resist distortion through pressure and heat generated; and the possibility of exerting sufficient chucking or clamping power to hold the work without distortion. These are no idle suppositions or mere conjecture, but will all be encountered in some phase or other when utilizing higher speeds, and more particularly where varying or intermittent cuts are concerned. The magnitude of the speeds that may be expected and regularly encountered can be judged from the advertisements of a machine-tool manufacturer, who without doubt has found extended research and experiment necessary before sponsoring spindle speeds up to 4400 r.p.m. in order that available advantages of this type tool can be realized economically.

The advent of cemented tungsten carbide as a tool material throws industry today, as far as tooling practices are concerned, into an even greater period of transition in machine-tool development than was experienced at the development and adoption of high-speed steel in place of carbon tool steels, and unless some means is discovered or invented to increase the strength and ductility of cemented tungsten carbide this transition will be confined entirely to one line of endeavor, and that will be on the part of the machine-tool builder to attempt furnishing these surface speeds, with ever-increasing difficulty in likewise furnishing proportionately increasing rigidity.

Attempts along this line of solution will also demand greater accuracy in forgings, castings, and such other types of articles as generally require machining, this accuracy having to do more particularly with the elimination of lumps, hard spots, or other causes of uneven cuts, as it is needless to state that where such high speeds are incidental to operation, and defects of the nature mentioned become even the exception, the successful prolonging of the life of a tool that has a low impact value becomes a difficulty, and at present prices, an exceedingly costly gamble in which high stakes are played for, and unless properly guarded, can be easily lost.

The present factor of cost combined with that of fragility in comparison with other tool materials will tend to delay the general use of cemented tungsten carbide for tool purposes

more than the necessity for making appreciable expenditures for new or rebuilt machine equipment to use it properly. The introduction of tantalum carbide, however, promises some relief along these lines as it has been within the experience of the writer to witness corresponding if not somewhat better performances on the part of tantalum carbide than those furnished by cemented tungsten carbide, and at prices considerably below those demanded for the latter.

All that has been said in the foregoing in connection with the machining of ferrous materials applies in a corresponding degree to non-ferrous, with the possible exception that harder grades of tool materials can be utilized with prolonged resistance to abrasive wear or, if preferred, the softer, tougher grades best utilized on high-tensile materials can be applied with a corresponding lessening of breakage.

Nothing that is set forth in the foregoing is intended to disparage the qualities of cemented tungsten carbide as a tool material nor in any way convey the impression that its use should be discouraged; on the contrary, in order that prospective users may appreciate some of the procedures that are vital to the successful culmination of its adoption, and that they do not inadvertently suffer costly losses that might at least temporarily or possible entirely change their original desire to utilize its advantages, endeavor is made to bring these important facts to attention in the belief that ultimately this will speed correct understanding of its proper place in the particular field to which it is adapted rather than delay it through improper use. One thing is certain, the manufacturers of this material are doing their best to educate, and cooperate with, purchasers of these tools but, as in every other human endeavor, a great deal must be learned through direct experience of the individual and, as stated before, due to the great cost of cemented-tungsten carbide this experience is liable to prove extremely expensive education unless, through benefiting by the experience of others, breakage and other failures are kept to the almost irreducible minimum.

The human element in the adaptation of this material is particularly vital of consideration, especially where the operators or machine hands on a piece-work basis have been trained for years in existing practices, and must first be untrained both in the grinding and use of the tool, and re-educated on a new basis. Again must it be stated that this is important where present-day machines are also concerned, for in spite of cajoling, threatening, and disciplining, when an operator feels that he is being limited by light feeds in a certain set-up, and he is using the maximum speeds available, it is generally found to be, at least until a costly tool or two has been damaged, and he learns by his own experience that it just cannot be done, a great temptation to "hook it up a notch or two" on the feed set to approximate more closely the old feed practice, and thereby help out the pay envelope at the temporary expense at least of the firm footing the cost of the tool.

To offset some of the present disadvantages under which cemented tungsten carbide is laboring, there are many other advantageous possibilities opened up through its use, not the least of which is mentioned by the author when he says that certain alloys are released for practical use which could not be commercially machined heretofore. Not only is this a fact, but the technique of cutting is also improved in many ways, one instance of which is the fact that unbelievably highly burnished and accurately finished surfaces can be made in one cutting by reducing the front clearance and maintaining the proper position of the tool in relation to center so that the front of the tool immediately under the cutting edge rubs or burnishes the cut, the highest speed possible being utilized. This procedure is limited of course to certain types of metals or materials that lend themselves by nature to such treatment (brass, for instance) and the tool likewise must be properly prepared by careful polishing or lapping. Should this be attempted with ordinary tools the temperature generated would soon destroy both cutting edge and burnishing surface.

Proper support of cutting edges by correct design and maintenance of this by correct grinding are so important as to warrant special provisions in connection with the latter. Free-hand grinding of tungsten-carbide tools without some adjustable rest, which will provide and indicate correct angles, is nothing more or less than rank extravagance, and should not under any circumstances be permitted. Wheels should also be of the cup type to eliminate "undercutting," especially where small diameters are utilized in dressing large tools, and the proper grade and grain for the particular type of grinding to be done should be made a subject of close study. A 100-H silicon-carbide wheel has been found particularly suited to all-around use on both hard and soft grades of tungsten-carbide tools by the writer. Where any appreciable number of such tools are used in a shop, grinding equipment with suitable fixtures and wheels can be provided for less than $500 per unit; and without fear of contradiction, it may be said that this cost can be saved inside of a reasonably short period of time, especially when a man trained in this work is put in charge of the tools and grinding equipment.

In this connection it must also be stated that men using tools should not attempt to get that last piece off of the tool before grinding, but determine on any given operation by close observation at first what a fair number of pieces per grind should be, and even then set a limit a good 10 per cent to 20 per cent under to allow for a safety margin, as again it is in order to remind that those last few pieces may prove expensive through crushing off the nose of a tool at the rate of $1 per gram.

As can be readily judged from these remarks, this discussion covers mainly the use of the rugged class of turning and cutting tools. The more costly types of profile and form-cutting tools, with which some experience has been gained, where the generating of accurate outlines increases the cost due to labor in the making of the tool, must be carefully approached from an engineering standpoint and equally as carefully used. Where this has been found possible of accomplishment unbelievable results as regards performances have been obtained, and to date special machinery, in which ordinary tooling materials will not survive long enough to warrant setting up, has been designed and put into successful production.

W. S. Huson.[7] There still seems to be some misapprehension as to the structure and treatment of cemented tungsten carbide. There is a feeling that it is an alloy similar to tool steel and partakes of features pertaining to steel. There is not, however, the coalescence of the elements typical of steels; it is just what its name implies—a cemented material in which cobalt is the bond, holding the grains of hard tungsten carbide together. The success obtained in cutting tools and the continuing laboratory work and investigations lead to the hope that out of it all there will come a fused alloy lacking the present brittleness, and having the good characteristics of high-speed steel, but much harder and better adapted for formed tools and the like. As to the structure and proportion of component parts there is an excellent paper by Wyman and Kelley of Schenectady, N. Y., given at the Chicago meeting of the A.I.M.E., September, 1930, which goes deeply into the laboratory side of the material and shows by micrographs how varying proportions affect the final structure.

It is in some ways unfortunate that the grinding and sharpening of cemented-tungsten-carbide tools come in for so much comment; the idea that they are very susceptible to fracture from heat or undue pressure seems to have gained a strong hold. This

[7] Technical Industrial Engineer, Brooklyn, N. Y. Mem. A.S.M.E.

is not so for, though the material is brittle and can be ruined by improper attempts at grinding, the fact remains that the temper cannot be modified by grinding when properly done. This is the same as for steel tools, except that in the tool steel care must always be taken not to draw the temper of the cutting edge. These tools lend themselves very well to dry grinding as the edge can be watched and the policy of sharpening tools before they are too dull is a good one to follow. They should be held firmly yet gently against a sharp wheel and, while a somewhat longer time is needed than for steel tools, if the same care is taken, the result will be satisfactory. Wet grinding is entirely feasible, and possibly the best sharpening is done on a grinder where the tool can be clamped, and the clearance angles preserved. However, with minor fixtures at hand, this can be done by hand sharpening dry or wet, and the plan of having one man do all the grinding of these tools has much to commend it. Good wheels of suitable grit run at proper speed in a rigidly set-up grinder and reasonable care in not trying to force grinding because the material is hard will make the work as commonplace as for any tools. The use of fine-grit wheels for giving a keener edge and honing for still smoother edges all help, but due to the peculiar structure of the material honing is not quite as effective as with steel tools.

Cemented tungsten carbide is in the process of further development. Wherever it can be applied at present within its limitations it is a profitable investment, and the outstanding hope is that as experience broadens, the peculiar hardness of the tungsten carbide will be adapted to much greater efficiency not only in edged tools, but in dies and the like, where extreme hardness is desirable.

Author's Closure

The author is thoroughly in sympathy with the discussion as brought forth by Coleman Sellers, 3d. Much of his discussion had to do with grinding tungsten-carbide tools. Proper grinding is the greatest single factor in their success.

In regards to the discussion by Roger D. Prosser, he emphasizes the desirability of maintaining smaller clearance angles to support the tip. He states that reducing the clearance angle from 6 to 8 deg. down to 3 or 4 deg. has resulted in doubling the length of life between grinds. This statement is particularly valuable in that it greatly diminishes the cost of using tungsten carbide.

With reference to the discussion of F. W. Curtis, we have a great number of milling cutters in actual production to date, and in many cases we have increased the production by 50 per cent and have increased tool life in the ratio of from 10 to 1 to 30 to 1 over high-speed steel and Stellite cutters. It is believed he emphasizes too strongly the need of new machine-tool equipment. The mentioned results are being obtained on machines 5, 10, and 15 years old. Of course these machines often have to be put in good repair.

With reference to the discussion of C. J. Shipplock, the author wishes to take exception to this discussion in regards to the feeds, in which he claims tungsten carbide is limited to actual operation. We consider a feed of 0.060 in. per revolution a medium feed for tungsten-carbide tools, providing the shank is in proportion. The majority of tungsten-carbide tools in use with shanks $1^1/_2$ inch square can readily use a feed of 0.060 in. per revolution. With shanks 2 by 2 and 2 by $2^1/_2$ and 2 by 3, it is not at all unusual to take feeds ranging from $^1/_8$ to $^1/_{16}$ and with depths of cut as high as 1 in. We have changed our ideas somewhat in regards to using the light feeds and high speeds. We prefer in most cases to use normal feed and increase the speed normally. This discussion has put undue emphasis on the subject of using fine feeds and high speeds, and in a great many cases this practice is causing much more injury to tungsten-carbide tools than by using heavier feeds and less speed. Naturally in approaching the foregoing condition we feel that thought should be given to the design of tool overhang and machine rigidity. The improved tool design has been successful in reducing such breakage as has happened in the past. The most severe applications can be successful with the proper tool design

The Lorenzen Gas Turbine and Supercharger for Gasoline and Diesel Engines

Particulars Regarding the Design and Construction of a Gas Turbine Having a Rotor With Hollow Blades Which Are Cooled by Air Circulated Through Them Under Pressure, Together With a Discussion of Present and Possible Applications

By CHRISTIAN LORENZEN,[1] BERLIN, GERMANY

THE gas turbine works upon the same principle as the internal-combustion piston engine: after precompression of the working mixture (in the gas turbine the air and fuel are compressed separately) ignition takes place, and in the expansion that follows a part of the heat is converted into mechanical work. In the piston engine, however, work is done as the expansion progresses to the end of a stroke, whereas in the turbine the expansion of the gases and the resulting work are continuous.

The hopes held out by the gas turbine are based upon the possibility it affords of complete expansion of the gases, which is impossible in the piston engine owing to the limitations of cylinder dimensions; further, the performance capacity of a piston engine is much restricted by reason of the difficulties encountered with increased dimensions.

Just as in the piston engine, with regard to the heat supply we have to distinguish between—

a Heat supply under constant volume. The combustion takes place as an explosion under increasing pressure. The Holzwarth gas turbine works according to this method

b Heat supply under constant pressure. The combustion takes place without an increase in pressure, as the gases can expand accordingly. The Lorenzen turbine is an example of this method.

Method *a* as compared with method *b* has two drawbacks: First, it is necessary to employ regulating or timing devices in the hot combustion chamber. Second, there is a considerably higher shock and eddy loss at the regulating valves and at the entrance edge of the turbine blades owing to the great variation of velocity in the gases. On the other hand, the thermodynamic efficiency of the explosion turbine is superior to that of the constant-pressure turbine.

In the piston engine and in general also in the gas turbine the working gases are generated inside the machine itself—in the combustion chamber in the case of the gas turbine. The turbine, however, can also work in combination with a piston engine, utilizing the energy in the exhaust gases of the latter. In recent years various turbines have been operated according to this method, notable among them being the Lorenzen exhaust-gas turbine described later in this paper.

Compared with a steam turbine, which generally has many stages, the gas turbine has but one or two working stages, owing to difficulties encountered in the materials from which it is constructed. It then operates on the constant-pressure principle, similar to the original De Laval turbine, and it is obvious that for this reason the gas turbine is at a disadvantage compared with the steam turbine. However, this difficulty will probably be overcome in time, but in comparing the two types of turbine it may be said that the exhaust from the gas turbine does not carry away as much waste heat as does that of the steam turbine, in which latter the loss in one pound of steam is 990 B.t.u.

That it has taken such a long time to develop a reliable gas turbine in spite of the many years' experience which we have had in building steam turbines, is to be ascribed to various reasons. Principally, however, as we shall see in a later portion of this paper, it is owing to the enormous stresses, both mechanical and thermal, to which the material is subjected, and to the low efficiency of the turbo-compressor—the only type of compressor that can be considered in connection with a gas turbine.

The vital question in building a gas turbine is to prevent the blades from attaining a red heat, principally at their enter-

[1] Engineer and Managing Director, Lorenzen G.m.b.H., Berlin. Mr. Lorenzen was active in early automobile developments in Germany, and went to England in 1905 for the exploitation of German designs there. When aviation started he began building airplane propellers in England. Before the World War he returned to Germany and engaged in airplane-propeller manufacture there. He participated in the earliest supercharger and adjustable-pitch aircraft-propeller developments. About the time of the Armistice he proposed a combination of adjustable-pitch propeller and exhaust-gas supercharger with automatic controls so that an airplane engine would always be charged at one atmosphere absolute pressure and its propeller pitch always adjusted to the air density where the plane was flying. The Treaty of Versailles forbade Germany to build airplanes, and so Mr. Lorenzen turned to equipping other engines with superchargers and to the development of the gas turbine. Recently he has resumed work with aircraft power plants.

Presented at the National Oil and Gas Power Meeting of the A.S.M.E. Oil and Gas Power Division, State College, Pa., June 12–14, 1930.

ing edges. Before expansion takes place the gases have a temperature of from 1000 to 1200 deg. cent. (1832–2192 deg. fahr.) and a pressure of a few atmospheres in a stationary container. To build the latter sufficiently strong to resist the pressures and temperatures involved is not a matter of great difficulty. After expansion the temperature of the gases drops about 150 to 350 deg. cent. (270–630 deg. fahr.) according to the pressure ratio employed. With a temperature drop of 150 deg. cent. a velocity of 600 meters (1968 ft.) per sec. is obtained, and with one of 350 deg. cent. (662 deg. fahr.) a velocity of about 850 meters (2790 ft.) per sec. The jet of gases now passes through and impels the blades of the fast-running turbine rotor. The peripheral speed of a single-stage rotor should, if possible, be half of the jet velocity. Fortunately, the efficiency curve of a turbine is reasonably flat near its maximum, so that with the highest possible peripheral speed a fairly good efficiency is obtainable. The centrifugal force encountered at such speeds is high even for normal temperatures, and were the turbine blades to be heated to the same temperature as the jet of gases the tensile strength of the blade material would scarcely be able to resist it.

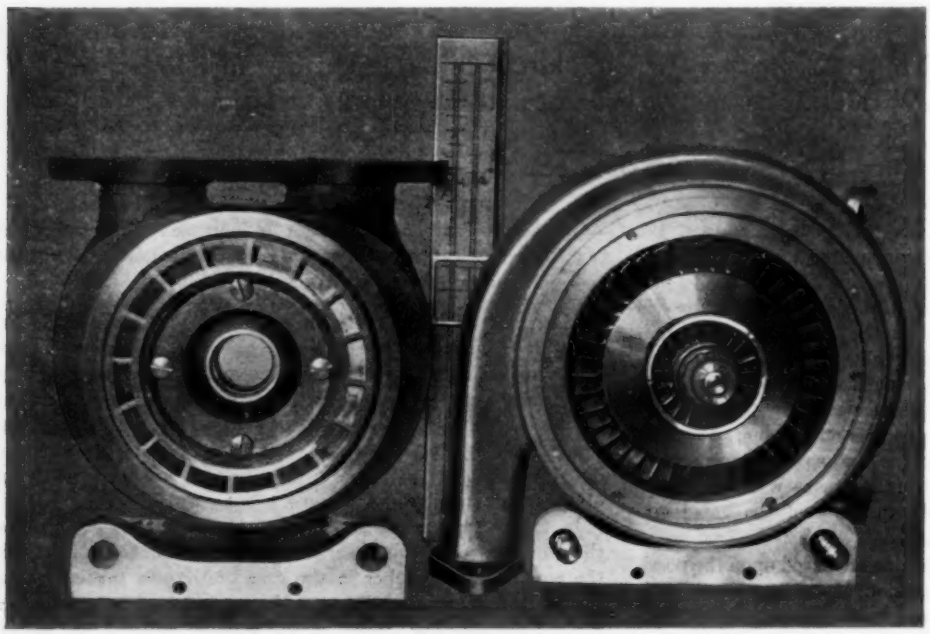

FIG. 1 SHOWING INTERIOR OF THE LORENZEN TURBINE

Water injection has been used effectively to reduce temperatures, but it has the disadvantage that most of the heat is used up in generating steam, leaving but a small amount available for work. Cooling by means of water jackets has the same disadvantage, as may be seen from the working area of the *p-v* diagram. To lower the temperature by further expansion means the application of an exhauster to create a vacuum beyond the turbine, which could only be done at the cost of efficiency. A better way, and the one which has been followed in building the Lorenzen turbine, is to overcome the difficulty by suitable construction.

THE ROTOR OF THE LORENZEN TURBINE

The construction of the rotor of the Lorenzen turbine is the same in a pure or "live" gas turbine—i.e., a turbine with its own combustion chamber and producing its own gas—as in an exhaust-gas turbine driven by the waste gases from a piston engine. Its special characteristics are as follows: [see Figs. 1 and 2]:

1 It is a single-stage impulse turbine acted upon in the axial direction by the working gases
2 The turbine rotor acts at the same time as a compressor wheel
3 The turbine blades are hollow, with very thin walls, and form the continuation of the compressor wheel in such a way that
4 The compressed air serves at the same time to cool the hollow blades internally by flowing in a radial direction from the inner to the outer ends.

The hollow blade which specially characterizes this turbine is the result of long years of search for a good and reliable material and the most suitable shape and form in which to dispose it. The tensile strength is about 100 kg. per sq. mm. (142,000 lb. per sq. in.) and the thickness of the wall about 0.25 mm. or 0.01 in.

That this method of cooling the turbine blades is effective may clearly be seen from the following considerations. The gases flow between the blades with a velocity of about 350 to 450 meters (1150–1475 ft.) per sec. and at a temperature of perhaps 700 deg. cent. (1292 deg. fahr.). Using accepted formulas for calculation, this gives a heat transfer of 750 kg-cal. per sq. m. per hr. per deg. cent. (154 B.t.u. per sq. ft. per hr. per deg. fahr.). To prevent the blades from becoming red hot it is also necessary that the air flowing inside the hollow blade shall have sufficient velocity so that it will carry away the heat as fast as it comes through the blade walls from the gas side. This can be effected by converting the static pressure created in the compressor wheel into velocity. For example, if the peripheral speed of the blades is about 320 meters (1050 ft.) per sec., then an air velocity of 250 meters (820 ft.) per sec. is obtainable which will cause a heat transfer of 572 kg-cal. per sq. m. per hr. per deg. cent. (117 B.t.u. per sq. ft. per hr. per deg. fahr.), and the heat flow through the wall, according to the formula

$$K = \frac{1}{\frac{1}{\alpha_G} + \frac{1}{\alpha_L}}$$

will be 324 kg-cal. per sq. m. per hr. per deg. cent. (66 B.t.u. per sq. ft. per hr. per deg. fahr.). The temperature of the hollow-blade wall will be

$$t_W = t_G - \frac{K}{\alpha_G}(t_G - t_L) = 428 \text{ deg. cent. (802 deg. fahr.)}$$

This temperature is allowable provided suitable material is used, particularly as at the most stressed part of the blade, namely, the root, the wall temperature is considerably lower owing to the reduced heating and to the better cooling obtained with the still cool air at the beginning of expansion.

The Lorenzen Turbine as an Exhaust-Gas-Turbine Supercharger

In an exhaust-gas turbine the impelling gases come from a piston engine and flow to the turbine nozzles. The cooling air leaving the hollow turbine blades is collected in a diffuser or volute chamber surrounding the rotor, where its velocity is converted into pressure, and it can then be used as compressed air for scavenging or supercharging the engine. The gain by this compressed air through utilization of the exhaust gases which otherwise would be wasted increases the economy and makes it possible either to increase the output of the engine or to obtain the same output with smaller cylinders.

The kinetic energy remaining in the exhaust gases leaving the piston engine may easily be determined from the p-v diagram by planimetering the hatched area $ABDEFA$ in Fig. 4, assuming the expansion line AB to be an adiabatic. A is the point at which the exhaust valve opens, and EF indicates the back pressure.

For a Diesel engine with a cylinder bore D of 500 mm. (19.68 in.) and a stroke S of 700 mm. (27.56 in.) running at 155 r.p.m. the indicated horsepower N_i (see Fig. 5) will be 188 hp., the brake horsepower N_e, 150 hp., and the theoretical energy in

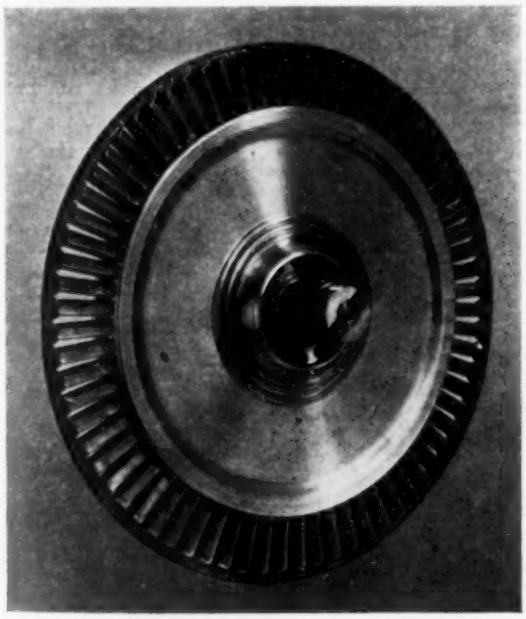

Fig. 2 Rotor of Lorenzen Turbine

the exhaust gases sufficient to generate 32.2 hp. Using this energy to drive the turbine supercharger, the working diagram of the engine will be that shown at II, and the performance of the exhaust gases will be accordingly increased. Diagram II*a* corresponds to a supercharge of $0.9 \times 1.25 = 1.125$ atmos. (16 lb. per sq. in.). In the factor 0.9 the losses of flow from the turbine to the cylinders have been taken into consideration, whereas diagram II*b* corresponds to an overloading of $1.50 \times 0.9 = 1.35$ atmos. (19.2 lb. per sq. in.). The theoretical performance of the exhaust gases gives for II*a*, 54.8 hp. and for II*b*, 77.1 hp. The energy required for the compression, if assumed to be adiabatic, is 4.9 hp. in the case of II*a*, and for II*b*, 10.9 hp., so that the performance capacity of the exhaust gases for II*a* is 11.2 times and for II*b* 7.0 times the energy required for supercharging the engine.

To obtain good performance of exhaust-gas turbine superchargers in connection with multi-cylinder Diesel engines, it is proposed to attach a small turbine to each cylinder, or in smaller-sized Diesel engines one turbine to two cylinders. In the second case the inlet casing of the turbine will be divided into two halves by a wall. This will expose the nozzles to the gases of one cylinder only. The gas jet of high velocity imparts a considerable amount of energy to the turbine rotor, causing a reverse action as soon as the pressure in the cylinders is released. The turbine wheel passing the nozzles rapidly keeps up this flow and ejects the remaining gases from the cylinder which it is scavenging. If several turbines are employed, then the compressed air from the various exhaust-gas superchargers

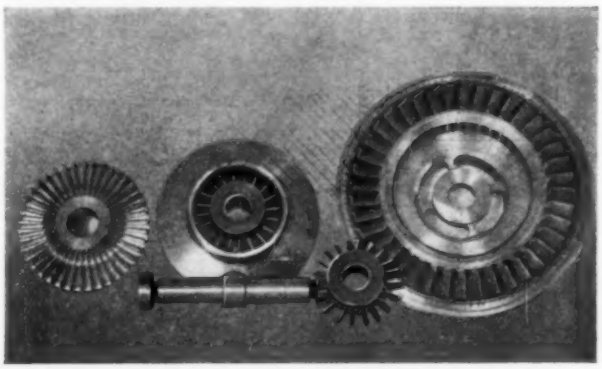

Fig. 3 Component Parts of the Rotor of a Small Exhaust-Gas Turbine

should be led into one container. This increases the reliability of scavenging to a considerable degree, because one turbine getting out of order will not stop the delivery of air: the other turbines will simply deliver more air with a little less pressure.

One great advantage of the turbine supercharger lies in the fact that it can be attached to any existing engine without making any constructional alterations, whereas a mechanically driven supercharger requires a driving shaft with the necessary gears, clutch, etc. In applying the turbine supercharger it is only necessary to alter the run of the piping.

In practice it has been found that the application of a turbine supercharger makes the operation of an engine very flexible. The reason is that with increasing performance of the engine the output of the turbine also increases automatically, although the engine may keep on running at the same speed. This of course is impossible with a mechanically driven compressor unless a speed changer is employed.

One of these turbines was built to run at 30,000 r.p.m. During the tests it was often brought up to 40,000 r.p.m., and at the conclusion of the trials it was run up to the bursting point. At 48,000 r.p.m. measurements could still be made. When it burst it was running at about 50,000 r.p.m., this very nearly agreeing with the theoretical calculations made previously.

In this and also in later tests with larger turbines, temperatures up to 835 deg. cent. (1535 deg. fahr.) were measured ahead of the turbine and 875 deg. cent. (1607 deg. fahr.) back of it. The increase in temperature was due to incomplete combustion in the engine, and through the escape of cooling air this caused after-burning in the turbine. By taking the turbine to pieces after such tests it was found possible to determine by the color of the rotor disks and the roots of the blades that there had been a temperature of about 280 to 300 deg. cent. (536–572 deg. fahr.).

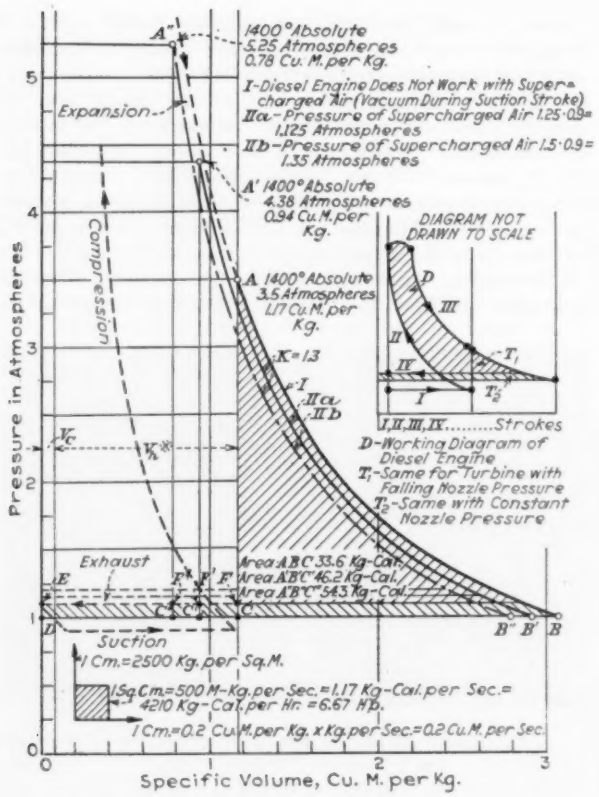

FIG. 4 *p-v* DIAGRAM OF TURBINE UTILIZING EXHAUST FROM A DIESEL ENGINE

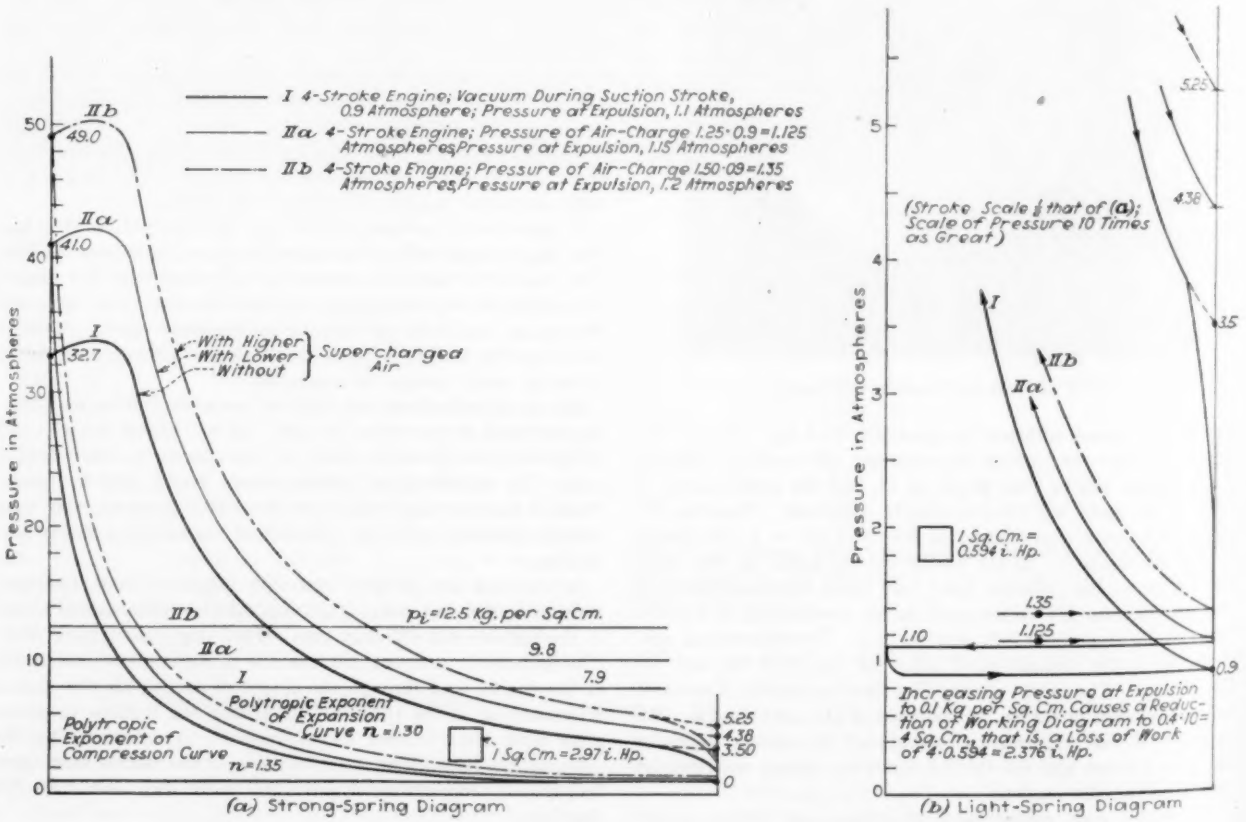
THE LORENZEN TURBINE AS A PURE GAS TURBINE

The excellent results obtained with the Lorenzen rotor in exhaust-gas turbines led to its employment in a pure or "live" gas-turbine plant on a much larger scale. It was decided to build a machine according to the constant-pressure principle ("constant pressure" meaning a continuous generation of the working fluid), although the Lorenzen rotor can also be used in the explosion type of turbine. This was done to avoid the difficulties encountered by timing and regulating devices inside a hot combustion chamber. The arrangements employed are shown in Figs. 6 and 7, namely,

(*a*) Turbine and compressor combined into one rotor (Fig. 6), and

(*b*) Turbine and compressor with separate rotors (Fig. 7).



The first arrangement is only applicable for low pressures which can be obtained in one stage, whereas the second must be employed when higher pressures and larger quantities of working fluid are required.

In the first arrangement (Fig. 6) the air enters the rotor

at *a*, flows through the compressor and the hollow blades, its high velocity then being converted into pressure in a volute chamber or diffuser surrounding the rotor. This compressed air is then led into a heat exchanger of special construction (Fig. 8) which has been in use for about two years in the Berlin municipal gas works and operates exceptionally well because of the continuous internal rotation of the air and gases flowing. After flowing through the heat exchanger the air is led into the combustion chamber, where sufficient fuel is added to obtain the desired temperature. As the combustion chamber is open toward the turbine nozzles, the same constant pressure exists inside it as in the compressor—less, of course, the loss in the heat exchanger. The gases now expand in the nozzles of the turbine and impel the hollow blades of the turbine rotor, after which they pass into the heat exchanger where they give up their remaining heat to the compressed air.

The second arrangement (Fig. 7) differs from the first, a special compressor being employed. The cooling air may then

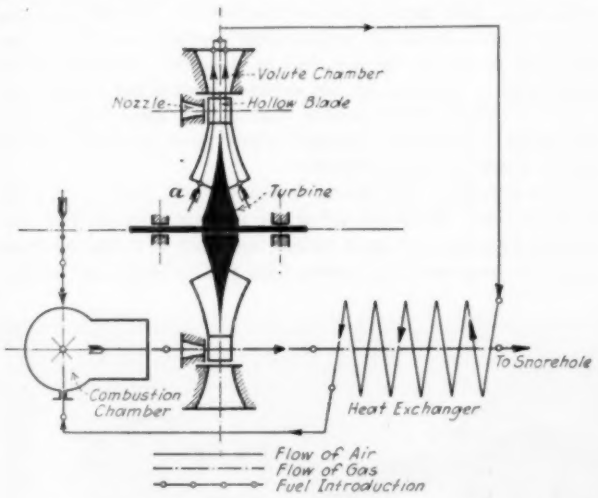

FIG. 6 COMBINED TURBINE AND COMPRESSOR ROTOR

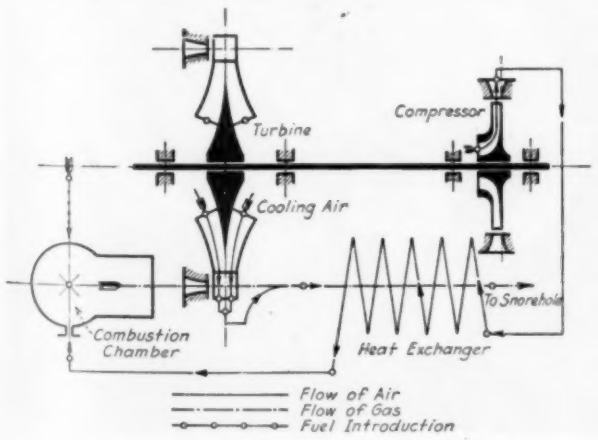

FIG. 7 TURBINE AND COMPRESSOR ROTORS SEPARATE

be used for heating purposes or led under a boiler or the like. The highest efficiency is obtained when the cooling air is applied as described in the first arrangement in a special combustion chamber with lower pressure and its own sectional portion of nozzles.

That it is necessary to utilize the heat remaining in the exhaust when a high efficiency is to be obtained, can easily be seen from the entropy diagram in Fig. 9, which has been drawn to scale for a special example. In this drawing *ABCDA* represents the quantity of heat added through fuel supply, and *AEFGHKA* the turbine performance after deducting the work required for the compressor and the cooling air. The heat re-

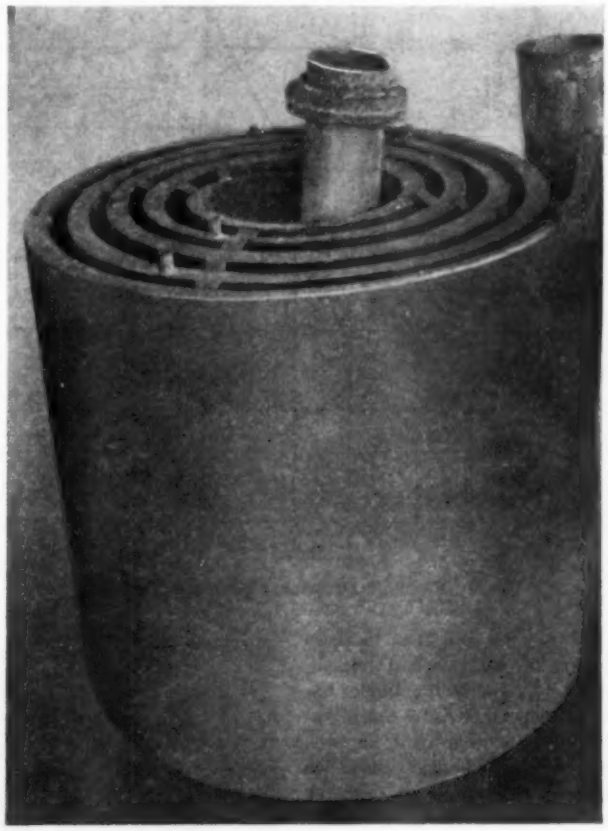

FIG. 8 SPECIALLY DESIGNED HEAT EXCHANGER

maining in the exhaust is shown by the area *LMNOL*. The relation of the area *AEFGHKA* to *ABCDA* gives the thermal efficiency when the heat remaining in the exhaust is not utilized. In order to regain the greatest possible amount of heat from the exhaust for use in the turbine plant, a heat exchanger may be considered. How far this is feasible depends only on the size and the efficiency of the heat exchanger. If, for example, we allow a difference of 100 deg. cent. (180 deg. fahr.) between gas and air and the turbo-compressed air comes from the compressor at 125 deg. cent., we can then easily raise its temperature to 600 deg. cent. (1112 deg. fahr.) in the heat exchanger. In the combustion chamber it is desired to bring this temperature up to 1000 deg. cent. (1832 deg. fahr.), so it is necessary to add fuel according to the area *APQDA*, making the thermal efficiency the ratio of the area *AEFGHKA* to *APQDA*, or $\eta_{th} = \sim 29$ per cent for the example in question.

The curves of Fig. 11 show the relationship between amount of fuel, size of heat exchanger, and thermal efficiency at various pressures and temperatures at the nozzles in a gas-turbine plant of 7500 kw., assuming that the gases impelling the hollow blades have a temperature of 750 deg. cent. (1382 deg. fahr.) and a constant peripheral speed of 320 meters (1050 ft.) per sec. The isothermal efficiency of the turbo-compressor is $\eta_{is} = 72$ per cent, as the loss of pressure in the heat exchanger is assumed to be 0.15 atmos. (2.13 lb. per sq. in.). The plant then shows an

efficiency of about $\eta_{th\,max} = \sim 31$ per cent when the working fluid is at a pressure of $p = 3.5$ atmos. (45.8 lb. per sq. in.). The effect of a rise in temperature is very great—for example, an increase of 100 deg. cent. increases the total efficiency about 5 per cent.

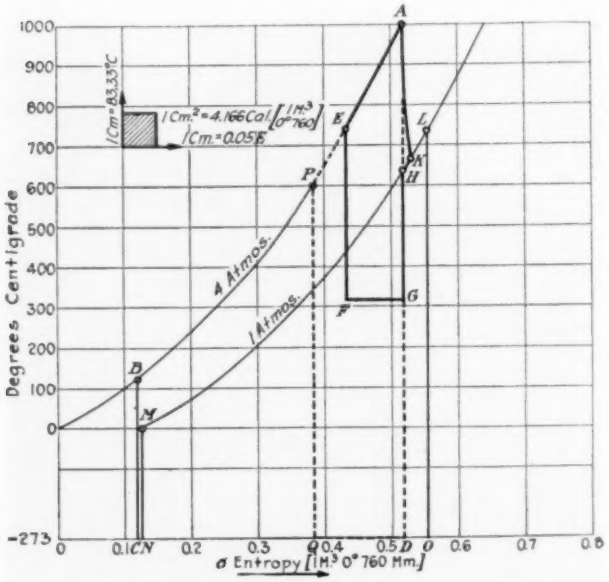

FIG. 9 ENTROPY DIAGRAM FOR A SPECIAL CASE

It may be said that in these curves the utilization of the cooling air by the hollow blades has not been taken into consideration; on the other hand, the area of the heat exchanger, which has been calculated as an ordinary straight-run exchanger, will be considerably reduced by using the spiral form shown in Fig. 8.

Fig. 10 shows a pure (or "live") gas turbine in the course of assembly. At the center is the rotor, its diameter being 990 mm. (38 in.); behind it at the right the inlet casing and the nozzles, both entirely built out from the special Krupp steel NCT3; and at the left the outlet casing, which is welded up from V2A Krupp steel. In addition both casings are enclosed in a sheet jacket, the space between casing and jacket (3 to 4 in. wide) being filled with firebrick ground to about pea size and put under pressure through a pipe connecting with the compressor. This arrangement protects the outer jacket from the combustion heat and the inner casing from pressure.

Fig. 12 shows the entire plant. Regulating devices are necessary only for the intake to the compressor and for the fuel supply, and these are of the same types as those used with other compressors or steam boilers.

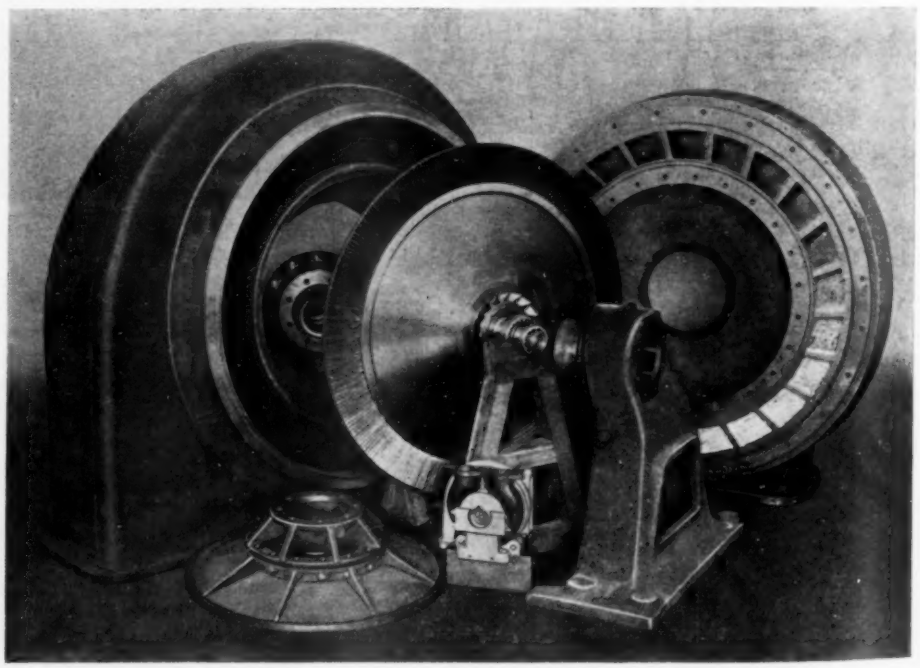

FIG. 10 ASSEMBLY OF PURE GAS TURBINE WITH 38-IN. ROTOR

FUTURE POSSIBILITIES

Another method of utilizing the heat in the exhaust and one which shows the highest efficiency is the following: When the compressed air is not preheated by the exhaust, its temperature must be raised from 125 deg. cent. up to about 1000 deg. cent. (257 to 1832 deg. fahr.) by the fuel supply. Owing to the limitation of the temperature to about 1000 deg. cent. (1832 deg. fahr.) the combustion takes place with about three times as much air as is necessary and the exhaust from the turbine with a temperature of about 700 deg. cent. (1292 deg. fahr.) contains sufficient oxygen to bring its temperature up to 1400 to 1500 deg. cent. (2552–2732 deg. fahr.) by adding fuel. This is high enough to be used under a steam boiler or in melting metals in foundries or the like. If the heat remaining in the exhaust is fully utilized in this way, then the turbine plant will show an efficiency of more than 85 per cent.

The combination of a gas turbine with a steam-turbine plant may be of special interest in municipal electric plants or in ship propulsion, and particularly in battleships, because the gas-turbine plant is ready at any moment to start, and would have sufficient power to set the ship in motion. A steam-turbine plant able to utilize fully the exhaust from a gas turbine will have an output about double that of the gas-turbine plant. The space required for the gas-turbine plant in such a combination would be inconsiderable.

In gas works, coke plants, foundries, etc., there is a great waste of heat. With the aid of the Lorenzen turbine this heat can also be saved to a great extent, inasmuch as it may be transferred to compressed air coming from the turbine, and then employed therein to do mechanical work. The temperature of this waste heat largely ranges from 400 to 600 deg. cent., 750–1100 deg. fahr.). A constant-pressure-turbine plant, however, first begins to work when the temperature of the working fluid exceeds 500 deg. cent. (932 deg. fahr.), and at first glance it would seem that little could be done. But remembering that

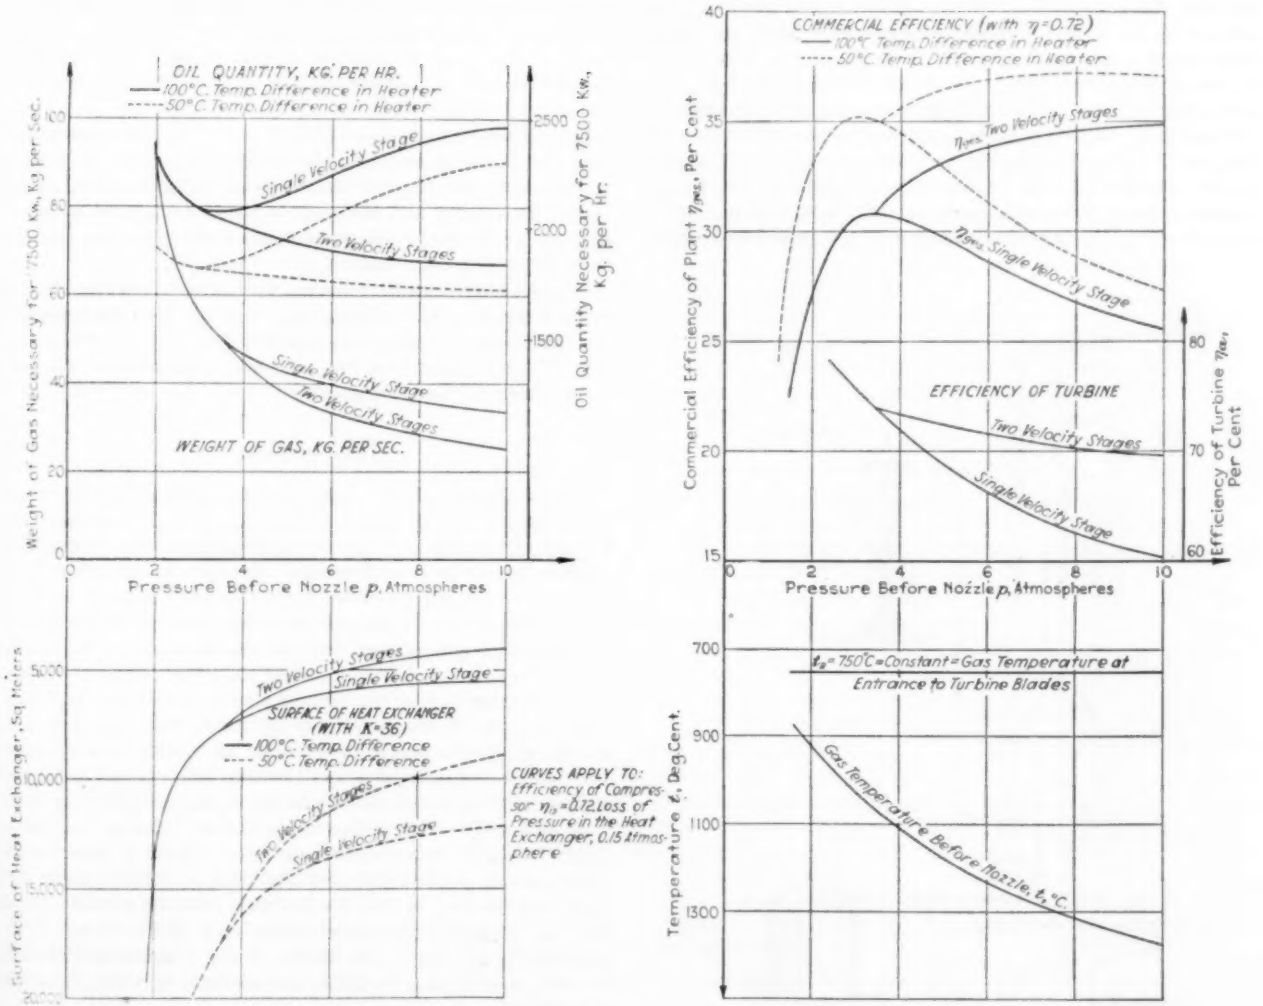

FIG. 11 EFFICIENCY, FUEL REQUIREMENTS, HEAT-EXCHANGER SURFACE, ETC., OF A 7500-KW. GAS-TURBINE PLANT FOR VARIOUS PRESSURES AND TEMPERATURES AT THE NOZZLES

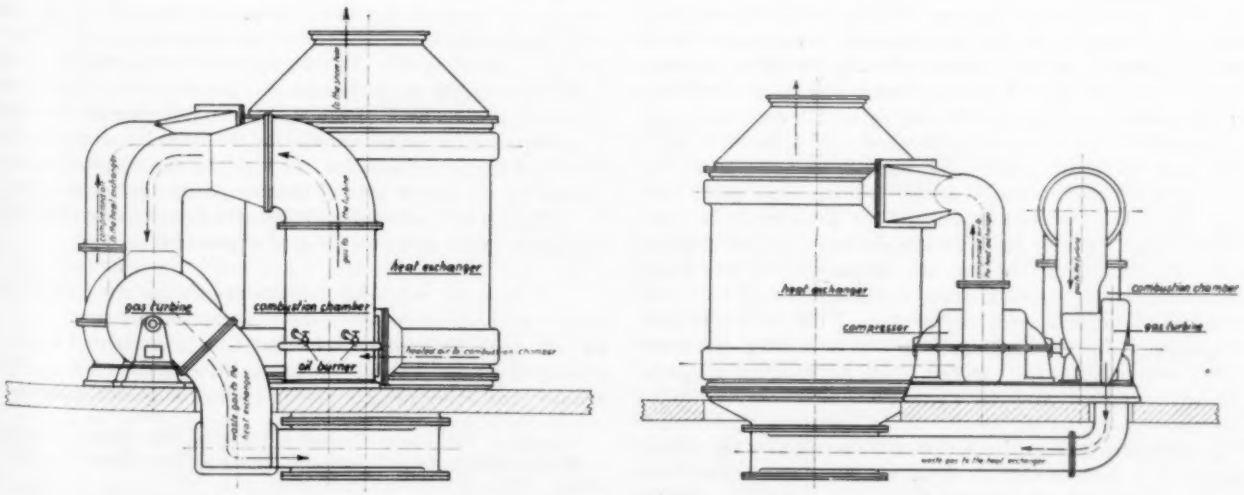

FIG. 12 ARRANGEMENT OF PLANT IN WHICH TURBINE OF FIG. 10 IS INSTALLED

the heat from the exhaust of the turbine is still available, the method shown in Fig. 13 can be employed. Most gas ovens make use of a recuperator in which the secondary air is preheated to about 600 to 800 deg. cent. (1112–1472 deg. fahr.). This preheating is done by the waste gases coming from the retorts. When leaving the retorts these gases are at about 900 to 1000 deg. cent. (1652–1832 deg. fahr.) and are cooled down to 400 to 600 deg. cent. (752–1112 deg. fahr.) in passing through the recuperator. If now these gases are led into a heat exchanger through which compressed air is driven in the opposite direction,

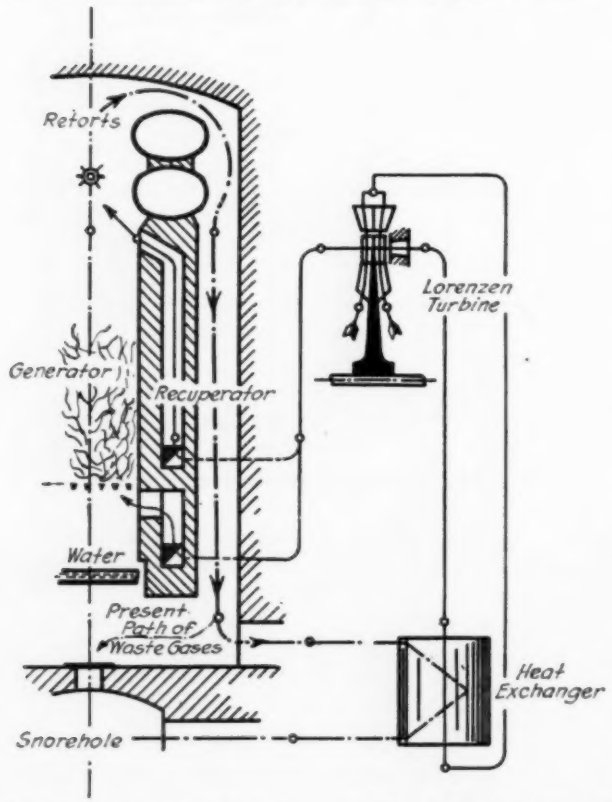

FIG. 13 ARRANGEMENT FOR UTILIZING WASTE GASES FROM GAS PLANTS

then the temperature of the latter will be raised to 300 to 500 deg. cent. (572–932 deg. fahr.) on their way to the nozzles of the turbine. Owing to the low pressure and low temperature of the air, the drop in temperature will only be slight; however, the exhaust air with its remaining heat is now led to the intake of the secondary air, say, at 300 deg. cent. (572 deg. fahr.), and as it is already partly heated it therefore cannot absorb so much heat from the waste gases. The result is that the latter will now enter the heat exchanger at 600–700 deg. cent. (1112–1292 deg. fahr.) and the compressed air will accordingly be more highly heated and the exhaust air will also have a higher temperature. By circulating the heat the temperature of the waste gases when leaving the recuperator is gradually raised to a point at which mechanical work can be done. This is the method of operating when the turbine is added to existing gas ovens which have recuperators. In new ovens the recuperator can be omitted altogether, and the waste gases after leaving the retort chamber can be led directly to the special heat exchanger. The waste gases having more than double the weight of the secondary air, it is obvious that an equal weight of compressed fresh air may be heated; the other half can then be led as primary air into the gas generator, or may be used under a boiler to generate steam. In a battery of ovens consuming 35 tons of fuel per day, the energy developed is in the first case about 200 hp., beside which there is a saving of fuel; and in the second case when a steam plant is installed, it is about 500 hp. continuously.

From these few examples, which of course could be considerably added to, it will be seen that the Lorenzen turbine is applicable over a range extending from the motor car, flying machine, Diesel engine, locomotive, and ships, up to the largest power stations, and can be operated as an exhaust-gas turbine, a pure gas turbine, or as a hot-air turbine.

In conclusion the author desires to express his sincere thanks to Prof. Fr. Schäff, of Nuremberg, who has been his scientific assistant during the whole development for about fourteen years, and to his son, Max Lorenzen, who has constructed all the turbines shown in the photographs.

Discussion

JAMES A. MOYER.[2] Dr. Lorenzen has presented some very interesting data in regard to a unique design of gas turbine. He has left the beaten path by not attempting to obtain the best possible results from a theoretical standpoint; meaning that, instead of adopting the usual high-efficiency explosion system, he has been content to experiment with the more unusual constant-pressure combustion. By this method he has, however, gained the advantages of eliminating the impact and eddy losses at the entrance edge of the turbine blades which result from the great variation in the velocity of the gasses when the explosion system of combustion is used. It is interesting to note that Dr. Lorenzen has applied with considerable success and in a unique way the idea of velocity stages in his gas-turbine designs. Unquestionably the ingenious blade system which he has introduced marks an important step in the progress of gas-turbine development. Deterioration of the turbine blades due to the high temperature involved has probably been the greatest drawback to successful accomplishments with gas turbines. This method should make the blades of gas turbines sufficiently durable to withstand the high temperatures to which they are exposed.

In order to be ideally successful, however, a gas turbine must combine the high thermal efficiency of the internal-combustion engine with the mechanical simplicity of the modern steam turbine. The designers of gas turbines have been proverbially between "the two horns of dilemma." When they have tried to utilize the velocity of the gases due to a single-stage expansion, the blades and nozzles have been found to deteriorate very much too rapidly for any practical service. On the other hand, when designers have cooled the gasses of combustion by the injection of water or excess air, or even by the method of water-jacketing to make the temperature of the gases suitable for the materials available for blade and nozzle construction, the high thermal efficiency as expressed by the simple laws of thermodynamics is unattainable. By taking a middle course in this case, Dr. Lorenzen has probably brought us much nearer to the goal of practical success.

A. L. BERGER[3] AND OPIE CHENOWETH.[3] The Air Corps has carried on the development of the turbo centrifugal supercharger aircraft since 1917 and has in that time accumulated a vast amount of service experience. From this experience it was soon learned that superchargers having high compression ratios re-

[2] Director, University Extension Division, The Commonwealth of Massachusetts, Department of Education, State House, Boston, Mass. Mem. A.S.M.E.

[3] War Department, Air Corps, Matériel Division, Wright Field, Dayton, Ohio.

quired intercoolers to reduce the temperature of the air entering the carburetor to a figure that would permit satisfactory engine performance. It was also learned that much better turbine bucket life could be obtained by not only removing the housing surrounding the turbine wheel, but by permitting the propeller slipstream to blow over the wheel, thereby cooling the buckets. In view of these experiences, it does not seem reasonable for aircraft to have to remove the heat imparted to the turbine buckets by the air being compressed and then to cool this air by intercooling. This would require a much larger intercooler which would, in turn, increase the resistance of the airplane.

(*a*) When used as a supercharger for aircraft, what would be the estimated weight of a unit suitable for 2 to 1 supercharger compression ratio for a 600 horsepower, four-stroke cycle engine operating at 3000 r.p.m.?

(*b*) When used as a supercharger for an engine of this type, what efficiency could be expected from the unit as a whole and from the turbine?

(*c*) Since the air compressed is used for cooling the turbine blades, what would be the estimated size of an intercooler necessary to reduce the air temperature to 60 or 80 deg. for the engine referred to in question (*a*)?

(*d*) When operating with an exhaust-gas pressure of about 5 lb. per sq. in. at the nozzle box, would there not be a leak of exhaust gas into the air being compressed to such an extent that the output of the engine would be reduced by this exhaust contamination?

CHARLES E. LUCKE.[4] The commercial possibilities of the gas turbine will depend upon two factors, neither of which is mentioned in the paper. It may be assumed that the efficiency of the gas turbine cannot be as high as the efficiency of the internal-combustion piston engine. It is possible that a gas turbine may be built with an efficiency somewhere between that of the internal-combustion piston engine and that of a steam engine or turbine of the same size. This is the first factor—the efficiency obtainable in different sizes of machines so that engineers may compare these values with those now known for steam and internal-combustion piston engines.

The second factor is concerned with cost. If a gas turbine with what might be called an intermediate efficiency can be built, then its commercial place will depend upon its cost; and if this is also intermediate, then there is a possibility of its finding some place, and its possibility is greater if the gas-turbine plant's complete cost should happen to be less than steam of the same size, which, however, is very doubtful.

It does not appear to be really worth while to spend time analyzing machines for which there is no economic need, and therefore for which there is no market, even if it can be built. With reference to the gas turbine, this possible market, which is a measure of the effort justified in developing the machine, will depend jointly on its cost and on its efficiency. The author has entirely ignored both of these questions, and therefore his paper is one of purely academic interest.

LEE SCHNEITTER.[5] What is the method of starting the live gas internal-combustion turbine?

W. G. LUNDQUIST.[6] The writer is not sufficiently familiar with the subject of gas turbines in general to discuss Dr. Lorenzen's turbine as such, but in connection with its use as a turbo-compressor for supercharging aircraft engines he would like to present a few items which occur to him.

The exhaust-driven supercharger admittedly has many advantages not obtained with a gear-driven supercharger, particularly for high-altitude work. However, the salient feature of Dr. Lorenzen's turbo-compressor—namely, the cooling of the turbine blades by the air which is being compressed—would, the writer fears, be detrimental in this case, since the added heat taken from the turbine blades would increase the trouble caused by detonation unless this heat were removed by proper intercoolers, which would complicate the particular installation considerably. Even with gear-driven superchargers rotating at comparatively moderate rates (23,000 to 25,000 r.p.m.) the temperature rise through the supercharger is proving to be a problem, and any additional heat such as introduced by the Lorenzen turbine would be most unwelcome, particularly when supercharging for increased power at sea level or low altitudes. If the turbine were to be used in connection with a separate supercharger impeller, then the installation would resemble the customary turbo-supercharger set up, and the only advantage to be claimed would be improved cooling of the turbine blades. It would be interesting to have a comparison of blade temperatures of such a turbine installation compared to the blade temperatures of a turbo-supercharger installation in which a conventional turbine wheel were operated in the open and directly in the slipstream of the propeller. For comparatively large amounts of supercharging, where it is necessary to employ some method of cooling the air after it comes from the supercharger regardless of the type of drive, the writer believes that the Lorenzen turbo-supercharger could be used advantageously, as it could also be used for supercharging Diesel engines where detonation is not a problem.

It may be true that it is easier to attach and operate successfully a turbo-supercharger to an already built engine that it is to attach and operate a gear-drive supercharger (radial engines excepted), but a comparison of a turbo-supercharger installation with a properly designed gear-driver supercharger will convince any one that the gear-driven compressor offers a cleaner and more compact design than will probably even be attained with a turbo-compressor. Furthermore, a properly designed gear-driven supercharger is more rugged and dependable, since it has no temperamental turbine wheel to cause trouble. Gear-driven superchargers operating at 30,000 r.p.m. and over are not usual.

The writer would appreciate an explanation of the statement in the paper which says that "a steam-turbine plant able to utilize fully the exhaust from a gas turbine will have an output about double that of the gas-turbine plant." A previous statement says that the gas-turbine exhaust does not carry away as much heat as does the exhaust of a steam turbine.

HAROLD CAMINEZ.[7] Exhaust-gas turbines for supercharger drives have been used with limited success in this country. As pointed out by Dr. Lorenzen, the high temperatures and high speeds under which these turbines operate present many difficult mechanical problems. Dr. Lorenzen's method of cooling the supercharger turbine blades may probably solve some of the difficulties experienced with aircraft exhaust-gas turbines.

As pointed out by Dr. Lorenzen, a very high peripheral speed is necessary to obtain good efficiency in a single-stage gas turbine. With a given peripheral speed, the centrifugal effect on the impeller blades is inversely proportional to the diameter, so that the blades on the smaller diameter rotors will be more highly stressed. It is probable that with proper turbine-blade cooling no difficulty would be experienced from this in a stationary machine, but in a supercharger installed in an airplane, which

[4] Professor of Mechanical Engineering, Columbia University, New York, N. Y. Mem. A.S.M.E.

[5] Plant Betterment Engineer, Electric Bond and Share Company, New York, N. Y. Assoc-Mem. A.S.M.E.

[6] Engineering Department, Wright Aeronautical Corporation, Paterson, N. J. Jun. A.S.M.E.

[7] Allison Engineering Company, Indianapolis, Ind.

is subjected to vibration and rapid maneuvers, rotors that are satisfactory for stationary work do give trouble.

The bearings for the rotors are also a source of trouble in an airplane supercharger turbine. In normal oprations these bearings have practically no load, but due to the effect of vibration and maneuvering in aircraft, the gyroscopic action of the high-speed turbine rotor puts a severe load on the rotor bearings.

With Otto-cycle-engine operation, the cooling air from the Lorenzen hollow turbine blades could probably not be employed to advantage unless the air was run through an air cooler before being fed to the engine cylinders. It would be necessary to study whether the weight-head resistance and complications caused by this additional air cooler would make the use of this air from the turbine advisable. However, in a compression-ignition or Diesel-cycle engine, the use of this hot compressed air from the supercharger turbine blades should be desirable, as it would permit the use of lower compression ratios in the engine.

The writer believes that the problems connected with the Lorenzen gas turbine for aircraft supercharger drives are possible of solution and that such a machine would be highly desirable for aircraft Diesel engines, particularly when fitted to engines used in aircraft that are not subjected to violent maneuvers.

CHARLES A. MORSS.[8] Dr. Lorenzen's gas turbine, when used as an exhaust-gas-driven turbo-supercharger for internal-combustion engines appears to be subject to some of the same criticisms which have been directed at other previous designs of this equipment. These criticisms are, mainly, as follows:

(1) Heating of air used for supercharging the piston engine.

(2) The great difficulty of properly supporting in bearings and maintaining free from vibration a wheel traveling at approximately 30,000 r.p.m., and of maintaining proper clearance between the wheel and its casing.

(3) Danger of destruction of the turbine from the use of unclean air for supercharging.

(4) An increase of exhaust back pressure of the piston engine.

(5) A variable velocity of the exhaust gases impinging upon a turbine wheel of constant peripheral speed.

The first three of these criticisms are applicable to Dr. Lorenzen's turbine to a greater degree than to other designs of exhaust-gas turbo-superchargers in which the turbine and supercharging wheels are separate. For example, heating of the air used for supercharging the piston engine is inherent in Dr. Lorenzen's turbine to a marked degree, since the air is used for directly cooling the turbine blades. This characteristic is of course at variance with the requirements of the piston engine, which should receive intake air at the lowest possible temperature in order to get good volumetric efficiency.

Similarly, the need for close and positively maintained clearances between the turbine wheel and its casing is particularly important in Dr. Lorenzen's turbine because he makes use of a labyrinth packing seal between the turbine chamber and the supercharger diffuser.

Finally, the danger of destruction of the turbine due to dirt particles and other foreign matter in the intake air, which is the danger of all high-speed centrifugal superchargers for internal-combustion engines, is particularly great in Dr. Lorenzen's turbine because the air passes at its highest speed through turbine blades of very thin wall section and of temperature approaching red heat.

The last two criticisms mentioned—namely, an increased back pressure on the piston engine and a variable velocity of the exhaust gases—result in lower efficiency, the former of the piston engine and the latter of the turbine. However, these last two objections can be obviated, in whole or in part, by converting the pressure energy of the exhaust gases into velocity energy and storing this velocity energy in what might be called a velocity-energy receiver, thereby imparting a constant velocity to the exhaust gases.

The writer would like to point out, in conclusion on Dr. Lorenzen's exhaust-gas turbine, that in its application as a turbo-supercharger for modern aeronautical gasoline engines it comes into direct competition with mechanically driven centrifugal superchargers, which in their present development are capable of giving almost complete reliability at speeds of 20,000 to 30,000 r.p.m., with a considerable advantage in weight and complexity over the exhaust-gas turbine. The other side of the picture is of course that its application to aeronautical gasoline engines is far from being the only one, or even the most important one, of its possible uses.

F. GLENN SHOEMAKER.[9] About what percentage of the air that passes through the turbine leaks past the rotating elements?

EDGAR J. KATES.[10] The running clearances between the rotor and casing being apparently quite small and the operating temperatures quite high, is there not some danger of distortion and binding when a cold turbine is being started? If so, what precautions must be taken to avoid trouble?

W. M. KAUFFMAN.[11] The analogy of the development of the prime mover described to a similar phase of pioneer development of the steam turbine during a steam-engine age elicits considerable interest in those advantages of the Lorenzen turbine which have justified this enormous work. The advantage of the principle of rotating elements is appreciated. It appears also that a wider range of fuels may be utilized and various thermal cycles employed.

From the standpoint of fuel, we find patent proposals for the use of gas, hot air, exhaust gas, oil, and powdered fuel. This opens at once a field of application for a successful turbine in which these fuels may be used directly. The savings effected over a similar steam-turbine unit with gas- or oil-fired boilers are evident. Plants utilizing gas from coke ovens, gas producers, and blast furnaces would represent possible applications.

However, if one considers the gas turbine relative to the gas engine or Diesel engine in a similar manner as in the steam-turbine analogy, he will find the problems more difficult of solution and the advantages over the piston engine appreciably smaller. It is handicapped in the degree of compression of the working charge. In the piston engine both compression and expansion take place with high mechanical efficiency. This efficiency is approximately 20 per cent better than in the turbo-compressor. A decided advantage in the case of the piston engine lies in the amount of negative work necessary to bring the compressed-air charge into the working cylinder. At present, the temperature necessary in a gas turbine to secure efficiencies exceeding those of the reciprocating engine are such as to be destructive of the available materials.

As regards the field of competition, the basis of merit is not so pronounced. With regard to utilization of a larger range of fuels, a distinct advantage is found.

The writer would ask the question, What types of fuel have been used in the Lorenzen turbine, and what would be the relative advantages or disadvantages of burning oil and powdered fuel,

as against gaseous fuel, such as coke oven or producer gas?

J. P. Stewart.[12] In this paper there seemed to be some suggestion that the gas turbine might be used to power aircraft. Is it not true that the accessories, such as the combustion chamber and heat interchanger, must be so large as to preclude its possibility, not only for aircraft, but for any mobile vehicle?

When using the turbine as a prime mover, what is the ratio of cooling air to the actual combustion air required by the turbine? Is the former all of the air that the turbine requires, or is additional cold air bled into the combustion chamber?

E. C Magdeburger.[13] It appears that the heat exchanger which apparently contributes so materially to the overall efficiency of the gas-turbine installation, as described by the author, would be a very bulky thing and would bear in size about the same relation to the gas turbine as the steam boiler does to the steam turbine. Will the author please elaborate on the volumetric space occupied by a gas turbine and the corresponding heat exchanger in any installation which he has built so far or purposes to build. The writer also would like to know how large a gas turbine has been actually built and operated according to the designs of the author.

Oliver Field Allen.[14] The purification and increase of the charge in four-cycle engines by having the openings of the exhaust and admission valves overlap while creating a slight suction in the exhaust line was accomplished experimentally some 30 years ago, and various schemes for supplying excess air to two-cycle engines were tried 15 years ago. Supercharging in the modern sense was initiated during the World War to facilitate high-altitude flying by maintaining sea-level atmospheric pressure in the engine cylinders. This development brought forth both exhaust-gas turbine and high-speed, gear-driven turbo-blowers now used as standard equipment on many types of airplanes in America and Europe.

About five years ago the application of exhaust-gas turbine-driven blowers for supercharging land and marine oil engines for sea-level operation was started. Correction for low atmospheric pressure in high-altitude power-plant installations and provision for peak-load operation by supercharging began to be seriously studied, and installations have been succesfully made using electric-motor-driven turbo-blowers and belt-driven positive-pressure blowers, as well as exhaust-gas turbine outfits.

Until quite recently, except for air service, some type of supercharger has been added to existing engine models designed for operation without supercharging. It is only within the last year or so that land and marine engines have begun to be designed to be used regularly as supercharged machines, with the supercharger considered as an essential part, as it is in aircraft motors.

Both the advantages and the limitations of supercharging are better understood now, and Dr. Lorenzen's exhaust-gas turbo-blower comes at a time when the industry is prepared to utilize it.

The gas turbine is a development long dreamed of, and this paper is especially valuable in telling of concrete accomplishments, while giving much to think about as to further developments.

AUTHOR'S CLOSURE

The numerous inquiries made by discussers from the scientific as well as the industrial standpoint indicate the great interest taken in the Lorenzen gas turbine. As several of the questions are propounded more than once by different individuals, the author will deal with all of them in general without referring to specific discussors.

All of the questions propounded may be divided into two classes:

1 Those on the exhaust-gas turbine as a supercharger, and
2 Those on the live-gas turbine as a prime mover.

With regard to the former, many years of practical test results are at the author's disposal to back up the following statement referring thereto. But while the live-gas turbine described in the paper has been built, lack of means has thus far prevented carrying out thorough and complete tests.

The Exhaust-Gas Turbine as a Supercharger

Nearly all the inquiries of this class express fear of excessive heat when using the cooling air from the turbine to supercharge the piston engine. To be quite candid, the same fear was shared by the author as well as by the officials of the German research department for aviation during the preliminary *stationary* test. However, in order to get actual test results it was decided to build a turbine small enough to be suitable for a 40-hp. engine and then fit it into a motor car. The temperature of the cooling air measured during the stationary test ranging from 100 to 125 deg. cent. (= 212 to 260 deg. fahr.), it was thought advisable to employ an intercooler. The tests were started in January, 1928, when it was very cold, and the cooling effect was so great that a bypass was introduced in order to regulate the temperature by uncooled air. It was soon found that the engine ran its best when no intercooling took place. The intercooler was left in the car as it was thought it would be needed in summer time, but even then it was found that there was no need for the intercooling. The arrangement was such that by simply turning a three-way valve the air could either be cooled or led to the engine at the temperature with which it left the supercharger, and hardly any difference could be noticed in the actual running of the car. The reason for this result the author ascribes to the following facts. Owing to the great velocity of the car, from 80 to 100 ft. per sec., and the comparatively large difference in temperature, a considerable portion of the heat is carried away through the casing of the diffuser and the piping leading to the carburetor, both exposed to the outside air, and another portion is used to evaporate the fuel at the jet in the carburetor. This produces a combustion gas instead of an air and gasoline mixture, therefore the explosion is more rapid and better use is made of the fuel in the engine. The latter had a ratio of compression of 1:5.35. The foregoing results are fortified by tests made in Europe and covering more than $2^1/_2$ years, during which a motor car was run more than 50,000 miles. Further tests in America during the hot months of June and July of this year gave a similar result. The engine withstood well the increased temperature of the charge without "knocking," as all combustion engines run better on a hot gas, provided the charge is under pressure to assure that the required weight will be injected. The cooling effect just mentioned could not of course bring down the temperature of the fresh charge in a rapidly moving car or airplane to that of the surrounding atmosphere. However, there is no need for this in the Lorenzen supercharger, as compared with a gear-driven compressor, or when turbine and compressor are two special machines and the former is running without housing and is exposed to the propeller slipstream for cooling purposes. In the latter two cases a considerable proportion of the engine's power is required to drive the supercharger. For example: to compress the air for a 600-hp. engine at a 2:1 ratio, about 100 hp. is needed with the turbo-compressors available today. If, therefore, the output of the engine is to be kept constant, then the latter must

[12] Vacuum Oil Company.
[13] Aide on Diesel Engines, U. S. Navy Department, Washington, D. C.
[14] New York, N. Y. Mem. A.S.M.E.

receive a charge sufficient for an output of about 700 hp., thus overloading the engine. For a gear-driven compressor the energy required is taken from the motor shaft; in a direct-acting turbine and special compressor the pressure in the nozzle box must be increased, which causes back pressure on the engine. It is obvious that a turbine running in a closed casing, being acted upon by all of the motive fluid and having only the ventilation work of one machine to overcome, will run at a higher speed with a given pressure at the nozzles, than when the conditions mentioned by Mr. Berger exist. Owing to the favorable running conditions the pressure in the nozzle box in the Lorenzen supercharger for aviation is considerably less than 5 lb. per sq. in. at sea level, and from 1600 ft. upward is below atmospheric pressure.

With regard to the inquiry about leakage of exhaust gases into the cooling air, it can be stated that there is none, several analyses with Orsat apparatus showing no traces whatever. On the contrary, there is a small leakage of fresh air into the exhaust, which amounts to about 25 per cent of the air drawn in by the compressor. These measurements, however, were made several years ago, since which time improvements have been made by labyrinth sealing, and it will be less today, but no further measurements have been made to enable the author to give exact data.

As regards the life of the bucket, it can be said that after two and a half years of daily use such as that to which a motor car is subjected, there is no sign of wear whatsoever. The hollow blades become black-brown in color, and their surface covered with a thin coating of soot from the exhaust.[15]

The efficiency of the supercharging unit as a whole is about 25 per cent, and the efficiency of a turbine of so small a size, about 65 per cent.

The size of intercoolers in aircraft will not have to be increased as compared with that of other superchargers. In fact, the author is of the opinion that they may be omitted altogether (see test results obtained with motor car).

According to theoretical calculations the temperature of the buckets is thought to be 450 deg. cent. (842 deg. fahr.), but in many actual test runs where the casing of the turbine was at a red heat, when later examined the rotor and the labyrinth packing seal at the top of the blades distinctly showed the well-known blue color which metal exhibits at a temperature of about 300 deg. cent. (572 deg. fahr.).

The required high circumferential speed can safely be obtained owing to the extreme lightness of the blades. In small turbines their weight is about one-sixth of an ounce, and the centrifugal stress when running at full speed is about 1200 to 1400 lb.

No trouble whatsoever due to rapid maneuvers has been experienced during the tests in the car, which often has been run over bad and winding roads. During the two and a half years' tests there have been three cases of a ball bearing's being smashed because of a broken ball. The gyroscopic action in a supercharger suitable for a 600-hp. aviation engine is, at the highest speed of the rotor, 750 cm.-kg. (65,000 in-lb.) at an angular velocity of the airplane as such of 0.5 deg. per sec., and this sets up a thrust of 56 kg. (125 lb.) in the roller bearing which it will easily stand for so short a period.

To avoid distortion through different degrees of expansion of the rotor and casing, the labyrinth joint is located in the diffuser, which has practically the same temperature as the rotor with its buckets; whereas the nozzle box and the outlet housing being fixed in their central portion, can expand radially without interfering with the rotor.

The total weight of a supercharger suitable for a 600-hp. engine is 35 kg. (77 lb.).

[15] Such a "jacket" reduces the heat transmission considerably, and is properly chargeable to the original cooling of the blades.

The Live-Gas Turbine as a Prime Mover

Although no actual test results are available as regards the live-gas turbine, the author does not think he is far from the facts in the following statements. The live-gas turbine has been developed from the exhaust-gas turbine and is of exactly the same construction, only it works under more favorable conditions, inasmuch as there is no pressure container, the working pressure being set up by the air compressor driven by the turbine itself. Therefore the impelling gases are of uniform velocity. There are no regulating, stop or timing devices in the hot zone. The combustion chamber is an enlarged passage of cylindrical shape with fireproof lining in order to insure ignition, and once ignition takes place, combustion is continuous. The output of the turbine is easily regulated by varying the fuel supply and air intake in the compressor, which latter can both be made to work in conjunction so as to assure a constant temperature, although for overloading purposes a special fuel supply is provided for.

With regard to the efficiency curves given in the paper, it should be pointed out that these only refer to a self-contained pure-gas-turbine installation. But there is nothing to prevent—on the contrary, much to warrant—building the Lorenzen turbine in conjunction with a steam-turbine plant or with smelting works or the like where heat is required, because we then obtain an efficiency in the turbine plant of 86 to 90 per cent, certainly a result never imagined. However, this will readily be understood from the following example which refers to a single-stage constant-pressure turbine, and the efficiency will be increased with higher pressure and a multiplicity of velocity stages in the gas turbine's further developments.

Example. The temperature in the Lorenzen gas turbine is limited by the heat resistance of the turbine casing only, and not by the rotor or bucket as has previously been the case. To get a performance of 3500 hp. out of the turbine illustrated in the paper, the working fluid must conform to the following:

Weight	24.4 kg. per sec. (53.7 lb. per sec.)
Pressure	3.1 atmos. (44.1 lb. per sq. in.)
Temperature	1000 deg. cent. (1832 deg. fahr.)
Weight of fuel	0.605 kg. per sec. with 9500 kg-cal. including radiation and combustion losses, or 20,200,000 kg-cal. per hr. or 80,100,000 B.t.u. per hr.

The performance of the turbine is then $75 \times 300 \times 3600/427 =$ 2,200,000 cal. per hr. or 8,734,000 B.t.u. per hr. The exhaust (at 700 deg. cent.) leaves with $178 \times 24.4 \times 3600 =$ 15,650,000 cal. per hr. or 62,140,500 B.t.u. per hr. available for steam plant, or for both together, 70,874,500 B.t.u. per hr. The efficiency is then $= \frac{70,874,500}{80,100,000} = 0.88$ or 88 per cent.

This extraordinary high efficiency is due solely to the fact that the entire exhaust from the turbine can be utilized outside the turbine, owing to its content of oxygen, a special characteristic of the constant-pressure gas turbine only. Of course the output of the turbine working in conjunction with other prime movers is limited by the amount of exhaust which can be used outside the turbine. For the combustion in the turbine plant 25 lb. of air are used, and the exhaust therefore still contains 53.7 — (25 + 0.60) = about 27 lb. unconsumed air. This is sufficient for the further combustion of 0.669 kg. (1.47 lb.) oil under the boiler, which brings up the temperature to about 1500 deg. cent. (2730 deg. fahr.)—a temperature amply high for steam boilers—as compared with a maximum temperature of about 1700 deg. cent. (3100 deg. fahr.) when no work is taken out of the gases.

A comparison with other motors based on the relation of the net output to the heat value of the fuel supplied to the combustion chamber or boiler, gives the following efficiencies:

	Per cent
Lorenzen gas turbine making use of the exhaust	88
Diesel engine making no use of the exhaust	33
Lorenzen gas turbine self-contained (single-stage expansion only)	31
Modern steam-turbine plant	23
Motor-car engine	21

The cost of the Lorenzen gas-turbine plant depends largely upon its application. If it is installed to work in conjunction with other plants or works as described above, then its cost and its space requirements will be considerably less than for any other motor actuated by heat.

The turbine itself is smaller than a steam turbine with the same output. Most of the space is taken up by the air compressor and the combustion chamber, as may be seen from Fig. 12 of the paper, which is drawn to scale. Further, it will be seen that the bulkiest part is the heat exchanger, which, however, is employed only when a "self-contained" gas-turbine plant is in question; otherwise the steam boiler or smelting furnace takes over the function of the heat exchanger, which of course reduces the cost of the plant considerably. In a "self-contained" plant the size of the heat exchanger again depends upon the efficiency required. The scale drawing shows an exchanger giving a total efficiency of 31 per cent. To obtain an efficiency of 35 per cent the size of the exchanger would have to be nearly double, but even then the space required and the weight would be less than in the case of a steam-turbine plant with the same output.

Starting has to be done by auxiliary means of one sort or other. If the turbine is to be used to drive a dynamo then it will be advantageous to build the latter to work as motor-generator so that the turbine can be started electrically. If, however, the turbine is used to drive a ship propeller or the like, the turbine must be disconnected from the driving shaft and air blown into the combustion chamber directly or through the compressor by a blower similar to those used for forced draft under steam boilers. The single-stage-turbine rotor, being free, will start to rotate at a very low pressure after fuel has been added and the temperature of the air raised.

The ratio of cooling air to working fluid is about 1:10. If working in "conjunction" this air is led into the exhaust gases, the heat carried away remaining in the process; if working as a "self-contained" unit the cooling air may be led into a diffuser where its velocity is converted into pressure, and thence through a special combustion chamber when the pressure of the main working fluid is different—a design which has not been considered in estimating the 31 per cent tabulated above.

Whether the turbine can be used as a prime mover in aircraft depends on its further development, and upon improvements in the turbo compressor now in hand.

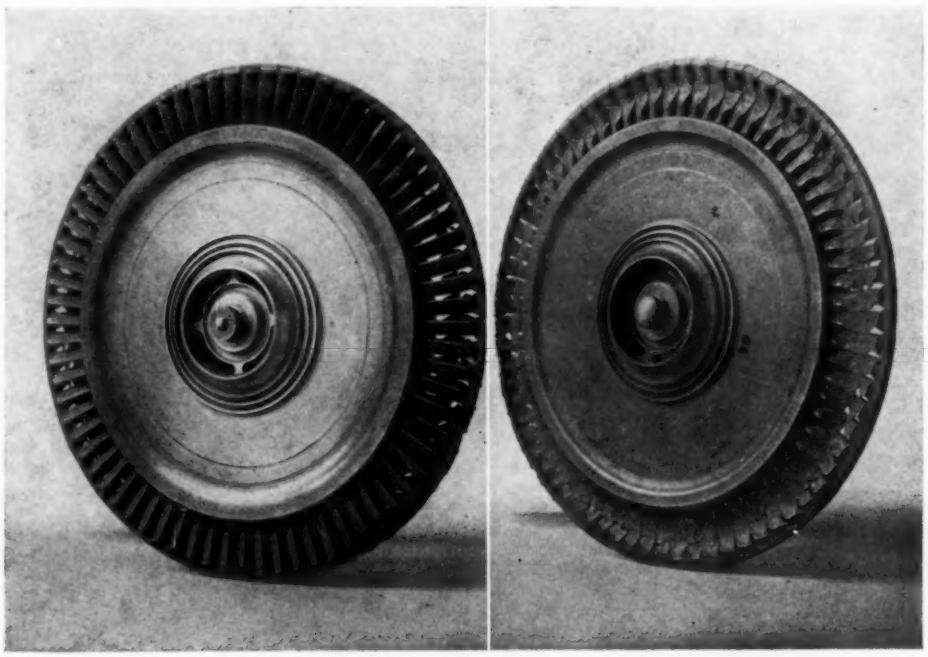

FIG. 14 SHOWING THE HOLLOW TURBINE BLADES AFTER CONCLUSION OF TESTS

The kind of fuel employed is quite immaterial, whether high-B.t.u. oil or gas from coke ovens or blast furnaces. Whether powdered fuel can be used is a matter to be determined by experience; however, the author does not think that such fuels as peat, pulverized straw, or the like in a fine grain will affect the buckets very seriously. The pulverization of peat is obtained by a simple drying process, after which it only needs to be carefully sifted.

The best proof of the reliability of the hollow turbine blades may be seen from Fig. 14. During the stationary tests on a 600–800-hp. aviation engine a connecting rod broke, which smashed the piston, a portion of it being carried by the exhaust into the turbine without being noticed by the attendant. Four months later after the engine had been repaired the tests were continued, but the turbine did not run as well as it had done before. It was therefore taken apart for examination and found in the condition as shown in the photographs. During these stationary tests a temperature from 835 to 885 deg. cent. (1535 to 1625 deg. fahr.) was measured in the turbine housing. In the left-hand illustration the outer ring of the turbine disk is somewhat darker, due to the "blue" color given it by the heat to which it was exposed.

In what has preceded, the author believes he has dealt with all the inquiries put before him, so far as these can be answered on the basis of test results and theoretical calculations. No doubt further developments will introduce difficulties which cannot be foreseen today, but the theoretical calculations with regard to the

live-gas turbine have been made with a certain reserve and great care, particularly with respect to compressor improvements, which will have a dominating effect upon the total efficiency, and in this regard the future may have some surprises in store. It certainly can be said that the working conditions for the live-gas turbine are more favorable with its constant flow and temperature of the working gases than those under which the exhaust-gas turbine works satisfactorily; and if the necessary means are made available, then the further work upon the former will be carried on in the belief that "Where there is a will, there is a way."

OGP-53-2

A Simple Method for the Calculation of Natural Frequencies of Torsional Vibration

By FREDERIC P. PORTER,[1] BELOIT, WIS.

The calculation of the torsional-vibration characteristics of the shafting of reciprocating-engine installations is generally considered a laborious undertaking. This paper presents a method for calculating the natural frequencies of the shafting that is relatively simple in its application and yet retains the accuracy of the longer methods. This simplification is obtained by the proper choice of the equivalent system for mathematical treatment and by the use of tables and charts. The accuracy of the results has been compared with that of the results of other investigators.

AT THE present time it is well known that critical speeds of torsional vibration often cause serious interferences in the operation of reciprocating-engine installations. These interferences may occur in the sinister form of the failure of shafts, the breakage of flywheel or alternator spokes, or the general failure of the engine or driven machinery; or other effects may be observed such as the excessive wear of parts, noise in the engine, and even flickering lights in electrical installations.

It is often suggested that torsional-vibration troubles may be overcome by making the shaft diameters sufficiently large. This is very true for slow-speed engines or engines with a small number of cylinders. As the shaft speeds and the number of cylinders become greater, however, this remedy leads to enormous shaft diameters.

As an alternative it is usually necessary to design the installation so as to place the larger vibrations at certain speeds where they will be the least objectionable, and then avoid them in continuous operation.

The first part of the problem from a design standpoint is the calculation of the natural frequencies of torsional vibration for the shaft arrangements. Various methods have been devised to accomplish this result. There is at least one characteristic which is common to all of these methods, namely, the reduction of the actual installation to an irregular shaft line-up which has approximately equivalent torsional-vibration characteristics.

One type of equivalent shaft arrangement is obtained by considering each cylinder, flywheel, and alternator, and other large compact parts as concentrated masses connected by elastic shafts having no mass. This equivalent arrangement will be called the "concentrated-mass system." Carried out in the proper detail this method gives reliable results. For a six-cylinder engine with flywheel and alternator this would give an equivalent system of eight concentrated masses connected by seven elastic shafts. The solution is then carried out by either an analytical or graphical procedure. For examples of the solution for this type of equivalent system, reference may be made to the published material by Holzer,[2] Geiger,[3] Wydler,[4] and others.

Another type of equivalent shaft arrangement is obtained by averaging the various masses distributed along the shafting of the installation into a number of connected uniform shafts having both mass and elasticity. This equivalent arrangement will be called the "uniform-shaft system." In the general application of this method certain of the larger masses, such as heavy flywheels, may be considered concentrated at certain points of the uniform shafts. This method was given by Prof. Frank M. Lewis,[5] who proposed a graphical procedure for the solution. An analytical solution for this type of equivalent system and for any combination with the former one was given by the author in a previous paper.[6]

While these various methods, if carried out with sufficient care, do give reliable results, their application often takes considerable time. For general application by designing engineers there is therefore an increasing need for simpler methods of calculation that are both rapid and reliable. It is the purpose of this paper to present such a method for calculating the natural frequencies of torsional vibrations in the shafting of reciprocating-engine installations.

The equivalent shaft arrangement used with the simpler method of calculation for multi-cylinder engines is a combination shaft system. For example, the inertia of the engine parts is combined to form a uniform shaft with mass by spreading the inertia at each crank over half of a cylinder distance on each side of its center line. Then if the flywheel is attached to one end of the crankshaft and is not far from the adjacent cylinder, sufficient mass is deducted from the flywheel to make the uniform shaft

---

[1] Fairbanks, Morse & Co. Mr. Porter was born in Massachusetts. After graduating from Webb Institute of Naval Architecture, he was employed by the New York Navy Yard, where he later became assistant mechanical engineer. In 1928 he went with the Fairbanks, Morse company as design calculator. Previous papers on the subject of torsional vibration by Mr. Porter are: "The Range and Severity of Torsional Vibration in Diesel Engines," Paper No. APM-50-8, 1928, also APM-50-14, 1928, and "Practical Determination of Torsional Vibration in an Engine Installation Which May Be Simplified to a Two-Mass System," Paper No. APM-51-22.

Contributed by the Oil and Gas Power Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

[6] "The Range and Severity of Torsional Vibration in Diesel Engines," Trans. A.S.M.E., Paper No. APM-50-8, 1928.

over the cylinders extend to the flywheel. The flywheel and other isolated heavy masses are considered concentrated and connected by elastic, massless shafts. In this way for a six-cylinder engine with flywheel and alternator there are three masses and two shafts as compared with eight masses and seven shafts when using the concentrated-mass system.

The accuracy of the combination equivalent arrangement has been examined and compared with the results obtained by the concentrated-mass system. These results are given in the form of curves and will be discussed later in the paper.

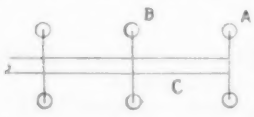

FIG. 1

A fundamental idea in the development of the method may be explained as follows: In Fig. 1, consider that A is a concentrated mass at the beginning of a shaft arrangement, that B is the next concentrated mass, and that C is a shaft without mass. Then at a given frequency, the effect of A acting upon B through the elastic shaft C can be obtained at B by adding a certain fraction of A to B. This sum can again be considered as the first mass, whose effect can be reduced to the next concentrated mass. This process of reduction is aided by tables that give the fraction of the first mass to be added to the next one. If the shaft C has both mass and elasticity, the reduction of both A and the shaft C to B is made by means of a formula, or for the case mass A equals zero, the reduction is also aided by tables.

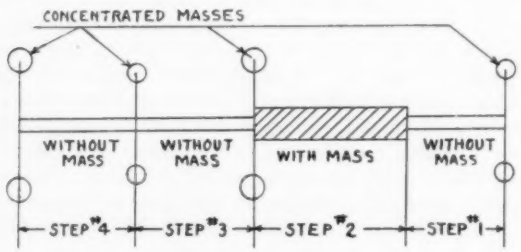

FIG. 2

The masses may be reduced from the beginning to the end, or backward from the end to the beginning, or from both ends up to some section. A natural frequency is obtained when the sum of the masses reduced from both ends up to any section added to the mass at that section is zero. At this frequency the elastic forces in the shafts and the inertia forces of the masses are in a state of equilibrium so that the system when once set into motion at this frequency will continue to vibrate indefinitely (assuming the non-existence of damping influences).

This reduction method has certain features that make a very rapid calculation for the natural frequencies when used with the combination equivalent system for multi-cylinder installations.

In using this method a certain symbolism is necessary which clearly represents the various parts of the process and shows at a glance how far the process has been carried.

The various elastic shafts used in the equivalent system with or without mass will be called "steps" of the line-up, and will be numbered in the order in which they occur. This is illustrated in Fig. 2. The step that is cross-hatched represents a step with mass, while the others without hatching lines represent steps without mass. This same convention will be used throughout the paper. Concentrated masses will be placed only between steps, but may or may not be placed at the beginning or end of steps with mass.

The letter k will mean the number of a typical step under discussion. When so used the characteristics of step No. 1 are obtained by putting $k = 1$, and of step No. 2 by putting $k = 2$, etc. The number of the end step will sometimes be denoted by the letter e.

The *length* of each step will be denoted by l (inches). If no subscript is attached it will refer to any step or length of shaft under discussion.

The rotating *inertia factor* for the various masses in the system will be denoted by J (lb-in.^{2}). This factor is similar to the mass polar moment of inertia coefficient except that it is considered in weight and length units. For this reason it will be called the "weight polar moment of inertia" of the mass, or for simplicity the "inertia factor" of the mass. The symbol J_w will represent the weight polar moment of inertia factor per unit length of a step which has mass. In this case the whole inertia of the step is $J = lJ_w$.

The *stiffness factor* of a step or certain length of shaft is denoted by C. This factor is the constant representing the proportional relationship of any twisting moment M (lb.-in.) and the resulting angular deflection θ (radians) of the shaft such that $M = C\theta$. Thus $C = \dfrac{M \text{ (lb-in.)}}{\theta \text{ (radians)}}$. For a circular shaft of constant diameter, $C = GJ_s/l$ where G(lb./in.^{2}) is the shearing modulus of elasticity and J_s (in.^{4}) is the sectional polar moment of inertia of the area of the shaft. If d is the shaft diameter in inches, $J_s = \pi d^4/32$. For steel, $G = 11{,}800{,}000$ lb. per sq. in., so that in this case

$$C = 1{,}158{,}460\,\frac{d^4}{l}\,\frac{\text{(lb-in.)}}{\text{(radians)}} \qquad [1]$$

Subscripts are used to indicate the part of the equivalent system referred to. A single subscript refers to a step. For example: in Fig. 3, l_1, C_1 are the length and stiffness factor for step No. 1; l_2, J_2, C_2 are the length and inertia and stiffness factors for step No. 2, etc. If the subscript is made up of two numbers differing by unity such as 01, 12, 23, . . . the element with the subscript occurs between the steps whose numbers are given. This is also illustrated in Fig. 3, where J_{01}, J_{23}, J_{34} . . . are the concentrated masses occurring at the beginning of the first step, between the second and third, third and fourth, etc.

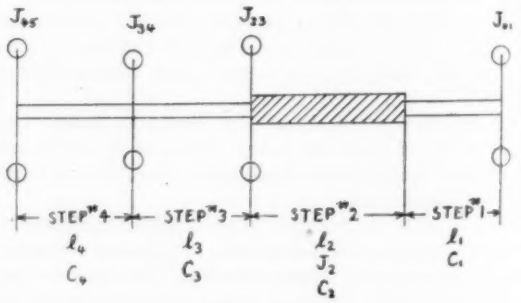

FIG. 3

In using the reduction process in making a solution, a prime mark (′) means that the effect of the masses from the beginning of the system has been reduced up to a certain section. A double prime mark (″) means that the effect of the masses from the end of the system has been reduced back to a certain section. Subscripts are then employed to indicate the section to which the reduction has been made. The subscripts 01, 12, 23 . . . mean the end of steps Nos. 1, 2, 3, etc., and 02, 03, 04 . . . mean the beginning of steps Nos. 2, 3, 4, etc. When reducing from the beginning of the system to the end of any step, such as the kth step, the reduced inertia factor is J'_{0k}. This factor does not

include the concentrated mass between this step (kth) and the next one ($k + 1$th), that is, J'_{1k} does not include $J_{k,k+1}$. The reduced factor at the beginning of the next step ($k + 1$th), however, does include $J_{k,k+1}$. Thus, inertia factors reduced from the beginning are

$$\left.\begin{aligned} J'_{01} &= J_{01} \\ J'_{02} &= J'_{11} + J_{12} \\ J'_{03} &= J'_{12} + J_{23} \\ &\cdots\cdots \\ J'_{0,k+1} &= J'_{1k} + J_{k,k+1} \end{aligned}\right\} \quad \cdots\cdots\cdots\cdots [2]$$

In reducing the effect of the masses backward from the end of the system to the beginning of any step, such as the kth step, the reduced inertia factor is J''_{0k}. This factor does not include the concentrated mass between this step (kth) and the next one (k–1th) toward the beginning of the system, that is, J''_{0k} does not include $J_{k-1,k}$. The reduced factor at the end of the next step (k–1th) toward the beginning, however, does include $J_{k-1,k}$. Thus the inertia factors reduced from the end are

$$\left.\begin{aligned} J''_{1e} &= J_{e,e+1} \\ J''_{1,e-1} &= J''_{0e} + J_{e-1,e} \\ &\cdots\cdots \\ J''_{1,k-1} &= J''_{0k} + J_{k-1,k} \end{aligned}\right\} \quad \cdots\cdots\cdots\cdots [3]$$

The factors ϕ and ψ are also used in the solution. The value of ϕ is given by

$$\phi = 360\sqrt{\frac{J}{gC}} = 18.325\sqrt{\frac{J}{C}}\ \text{(sec.} \times \text{deg.)} \cdots\cdots [4]$$

where J and C refer to a step with mass and g, the gravitational constant, is taken as 385.92 in./sec.^{2} (which is 32.16 ft./sec.^{2}).

The value of ψ is given by

$$\psi = \sqrt{\frac{J}{C}} \cdots\cdots\cdots\cdots [5]$$

where J is a reduced inertia factor. The same subscripts are used with ψ as are used with the reduced inertia factor J. The subscript for C is the same as the step number in the subscript for ψ. To complete the similarity of the symbols, prime and double-prime marks will be used with ψ to indicate that the direction of the reduction is toward the end or back toward the beginning, respectively.

Hence

$$\left.\begin{aligned} &\psi'_{01} = \sqrt{\frac{J'_{01}}{C_1}}, \quad \psi'_{02} = \sqrt{\frac{J'_{02}}{C_2}} \cdots \psi'_{0k} = \sqrt{\frac{J'_{0k}}{C_k}} \\ &\psi''_{1e} = \sqrt{\frac{J''_{1e}}{C_e}}, \cdots \psi''_{1k} = \sqrt{\frac{J''_{1k}}{C_k}} \end{aligned}\right\} \quad [6]$$

The frequency of vibration will be denoted by n in vibrations per second.

The formulas necessary for the solution of the *natural frequency* for any equivalent system are listed below.

I Reducing the Inertia Factors From the Beginning Toward the End.

a For steps without mass:

$$J'_{1k} = J'_{0k}T_0(\psi'_{0k}n) \cdots\cdots\cdots\cdots [7]$$

b For steps with mass:

1 If the first step has no concentrated mass at the beginning,

$$J'_{11} = J_1T(\phi_1 n) \cdots\cdots\cdots\cdots [8]$$

2 If the first step has a concentrated mass at the beginning or for any other step,

$$\tan\gamma'_k = \frac{\phi_k n J'_{0k}}{57.30J_k}, \quad J'_{1k} = \frac{57.30J_k}{\phi_k n}\tan(\phi_k n + \gamma'_k) \cdots [9]$$

II Reducing the Inertia Factors From the End Toward the Beginning.

a For steps without mass:

$$J''_{0k} = J''_{1k}T_0(\psi''_{1k}n) \cdots\cdots\cdots\cdots [10]$$

b For steps with mass:

1 If the last step has no concentrated mass at the end,

$$J''_{0e} = J_eT(\phi_e n) \cdots\cdots\cdots\cdots [11]$$

2 If the last step has a concentrated mass at the end or for any other step,

$$\tan(\phi_k n + \gamma''_k) = -\frac{\phi_k n J''_{1k}}{57.30J_k}, \quad J''_{0k} = -\frac{57.30J_k}{\phi_k n}\tan\gamma''_k \cdots [12]$$

III At a Natural Frequency.

$$J'_{1,k-1} + J''_{0k} + J_{k-1,k} = 0, \text{ or } J'_{1k} + J''_{0,k+1} + J_{k,k+1} = 0 \cdots [13]$$

which is the same as:

$$J'_{0k} + J''_{0k} = 0, \text{ or } J'_{1k} + J''_{1k} = 0, \text{ or } \frac{J'_{0k}}{J'_{1k}} = \frac{J''_{0k}}{J''_{1k}} \cdots [14]$$

The proofs for the above formulas are given in an appendix.

The γ-constants are defined by the equations and need no further explanation. At a natural frequency of the system the γ-constants are such that $\gamma'' - \gamma' = 0$. In this case the prime and double-prime marks are sometimes omitted on these constants.

The relative-amplitudes curve of the vibration at any section of the system follows almost immediately from the above solution. The amplitudes are represented by θ (radians) or $\theta°$ (degrees) and are given the same subscripts that are given to the reduced inertia factor at the same section. In this case, however, the amplitude at the end of any step is equal to that at the beginning of the next step, thus:

$$\theta_{11} = \theta_{02}, \quad \theta_{12} = \theta_{03}, \ldots \theta_{1k} = \theta_{0,k+1}, \ldots \theta_{1e} = \theta_{0,e+1} \cdots [15]$$

The relative amplitude at any point of a step with mass will be denoted by θ with the step number as a subscript. It will be expressed as a function of x, which is the length variable for the step with its origin at the beginning of the step.

The formulas to obtain the relative-amplitudes curve at a natural frequency, are:

1 For steps without mass:

$$\frac{\theta_{1k}}{\theta_{0k}} = \frac{J'_{0k}}{J'_{1k}} = \frac{J''_{0k}}{J''_{1k}} = \frac{1}{T_0(\psi'_{0k}n)} = T_0(\psi''_{1k}n) \cdots\cdots [16]$$

2 For steps with mass:

$$\theta°_k = \alpha_k\cos\left(\frac{\phi_k n}{l_k}x + \gamma_k\right) \cdots\cdots\cdots\cdots [17]$$

where

$$\theta°_{0k} = \alpha_k\cos\gamma_k \quad \text{and} \quad \theta°_{1k} = \alpha_k\cos(\phi_k n + \gamma_k) \cdots [18]$$

which define the α-constants.

The relative vibration twisting moments for the various sections of the system, therefore, are:

INTERPOLATION FORMULAS FOR NATURAL FREQUENCY n

$$M = C_k(\theta_{0,k+1} - \theta_{0,k}) = \frac{C_k}{57.30}(\theta^\circ_{0,k+1} - \theta^\circ_{0,k}) \ldots [19]$$

2 For steps with mass:

$$M = -\left(\frac{\pi}{180}\right)^2 C\phi n\alpha \sin\left(\frac{\phi n x}{l} + \gamma\right) \ldots\ldots [20]$$

The functions $T_0(\psi n)$ and $T(\phi n)$ are defined by the equations

$$T_0(\psi n) = \left[1 - \frac{4\pi^2}{g}(\psi n)^2\right]^{-1} = [1 - 0.10229689(\psi n)^2]^{-1}. [21]$$

$$T(\phi n) = \frac{180}{\pi \phi n} \tan \phi n \ldots\ldots\ldots\ldots\ldots [22]$$

where ϕn is an angle in degrees.

One of the time-saving devices of the reduction method is the use of the tabulated values for $T_0(\psi n)$ and $T(\phi n)$ (Tables 12–14). Two tables (12 and 13) are given for the function $T_0(\psi n)$; the first for positive and the second for negative values of the reduced inertia factor. In the latter case it will be noted that ψ is an imaginary number. The tables have been constructed to give as far as practicable a maximum error of 5 parts in 20,000 in the tabular value. To do this it was necessary to give five significant figures for numbers beginning with the numeral 1, and 4 significant figures for numbers beginning with numerals 2 to 9,

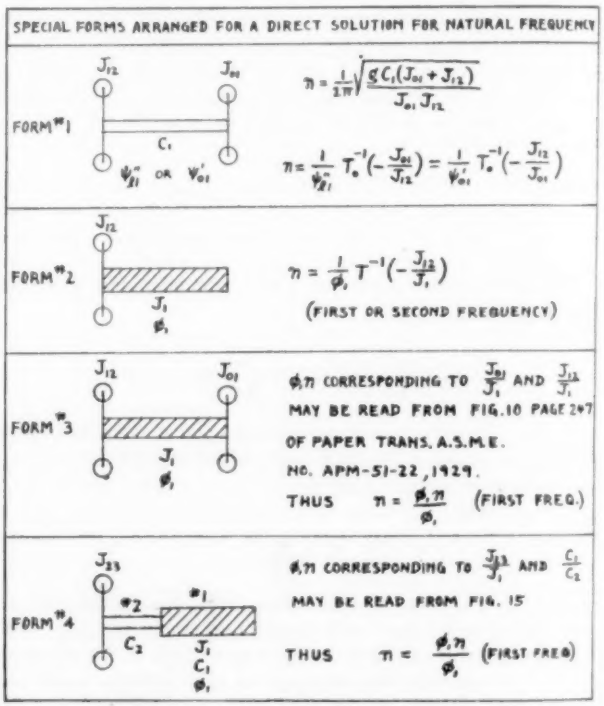

FIG. 4

inclusive. Where the tabular value ends in $\bar{5}$ or 5, the value is actually a little less or a little greater than 5, respectively. The average differences of each line are given where possible. If this average difference is inclosed in parentheses, it refers to the values after being contracted one digit. In working with the tables, $T_0^{-1}(A)$ or $T^{-1}(A)$ mean the values of ψn or ϕn, respectively, corresponding to the listed value A.

A tabular form is used in making a solution. In the general case, these forms for the various steps are illustrated in Tables 1 and 2.

Parentheses placed around letters or numbers in the tables refer to columns designated by the letter or number.

If the value of the inertia factor $J_{k,k+1}$ of a concentrated mass to give a certain natural frequency is desired, it may be obtained from Equation [13] by first solving for J'_{1k} and $J''_{0,k+1}$ by means of a tabular solution; then

$$J_{k,k+1} = -(J'_{1k} + J''_{0,k+1})$$

If the value of the stiffness factor C_k for a step without mass to give a certain natural frequency is desired, it may be obtained by solving for J'_{0k} and J''_{1k} and using either Table 3A or Table 3B.

Four special equivalent systems are given in Fig. 4 whose natural frequencies may be obtained directly from the tables for T_0 or T, or from the charts referred to.

The solution for form No. 1 is given directly by a formula. It is a little easier, however, to use the tables than the formula. Marine installations with engines amidships often approximate this form for the first natural frequency of the arrangement. This type of system was discussed in detail in a previous paper by the author.[7] The factors α and β used in this previous paper are the same as the present values $[T_0(\psi'_{01}n)]^{-1}$ and $T_0(\psi''_{12}n)$, respectively. Thus β corresponds to the tabular values for $T_0(\psi n)$ and α corresponds to the reciprocals of the tabular values.

Forms 2 to 4 may often be used to give a direct solution for certain installations. For example, a multi-cylinder engine driving a flywheel and rotor of an electric machine stiffly connected to the flywheel or made integral with it may be solved directly by one of these forms.

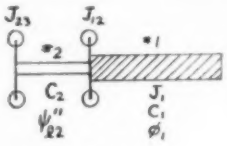

Fig. 5

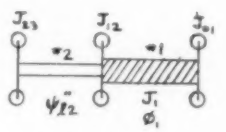

Fig. 6

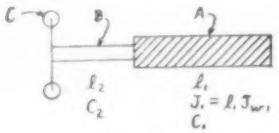

Fig. 7

In making solutions for more complicated systems, it often happens that some part of the system corresponding to either of the simpler forms, No. 1 or 2, has a larger influence in deciding one of the natural frequencies than any of the other parts. This characteristic is usually not difficult to recognize. As an example of this, consider a marine installation consisting of an engine, flywheel, propeller shafting, and propeller. It is easy to see that the first natural frequency is determined for the most part by the flywheel, propeller shafting, and propeller corresponding to form No. 1, whereas the second natural frequency will be determined for the most part by the flywheel and engine corresponding to form No. 2.

Taking advantage of the characteristic just described, the inertia factors may be reduced along from either end for an assumed frequency (n_1) until the remaining system corresponds to the form (1 or 2) having the greater influence upon the frequency.

A first approximation (n_2) for the natural frequency is thus obtained. Using this value and repeating the process a second approximation (n_3) will be obtained. If the simpler system does have the greater influence upon the frequency n_1, n_2, n_3 will form a converging series of numbers alternately on one side and then on the other of the actual frequency. In this case the frequency will be obtained with little error by using the interpolation formula No. 1 of Table 4.

It is not necessary to use the first approximation (n_2) in repeating the calculation a second time. A second assumed value (n_3) may be used which will give a second approximate value (n_4). In this case the actual frequency will be obtained by using the interpolation formula No. 2 of Table 4.

The value of the natural frequency found by the interpolation formulas of Table 4, are remarkably accurate even when the series n_1, n_2, n_3, or n_4 are slightly divergent.

Another procedure to solve for n in the general case, which may often be used with convenience is to reduce the inertia factors from each end to a step that has mass, and with several assumed values for n seek for the value that makes $\gamma'' - \gamma' = 0$. In this case a linear interpolation may be used between n and $\gamma'' - \gamma'$.

In dealing with the system shown in Fig. 5, the solution may be made by reducing from the beginning as in Table 5A or from the end as in Table 5B. If the way to proceed is not directly apparent, a reference to the curves in Fig. 15 will usually indicate the procedure for this system. For example, consider that J_{12} is removed. Then if $\phi_1 n$ in Fig. 15 is found to be less than 90 deg., Table 5A should be used for the first frequency; if $\phi_1 n$ is greater than 90 deg., Table 5B should be used; and if $\phi_1 n = 90$ deg., the first frequency is given by $90/\phi_1$ since J_{12} is at the node and has no effect on this frequency. If the first frequency is obtained rapidly from one of these tabular solutions, the second frequency will usually follow rapidly from the other.

Fig. 6 and Tables 6A and 6B show two tabular forms for another type of system. Other forms may be easily written down for any system by a reference to Tables 1 and 2. The proper procedure in making a solution, if not directly apparent, will soon become so after a few trial solutions.

Determination of Equivalent System

As previously mentioned, the equivalent-shaft system more conveniently used with the reduction method of solution is a combination of the concentrated-mass system and the uniform-shaft system. The inertias of the engine parts are averaged into a uniform shaft with mass. If the cylinders are equally spaced, the inertia at each crank is spread over the shaft for half a cylinder distance on each side of the cylinder center line. If the cylinders are not equally spaced, but occur in equal groups the inertia of each group is spread uniformly over the shafting for each group. The flywheel and other isolated heavy masses that are attached to the shaft over a relatively short length are considered as concentrated masses. Light shafts between heavy masses are considered without mass unless, as described for the engine, several equal masses connected by equal elasticities are averaged into a uniform shaft with mass.

Following this method, it will often be found (see Fig. 7) that there is a short length of shaft (B) between the uniform

[7] Trans. A.S.M.E., 1929, Paper No. APM-51-22.

shaft (A) representing the engine and the concentrated mass (C) representing the flywheel that has a much smaller inertia factor (J_w) per unit length than A. In this case the length of B is changed to have the same stiffness per unit length as A. This is done by making the length of B equal to

$$l_2 = \frac{l_1 C_1}{C_2}$$

where l_1 = length of A
C_1 = stiffness factor of A
C_2 = stiffness factor for B.

Then sufficient inertia is deducted from the flywheel (C) to make the value of J_w over B equal to its value for A. The limit to

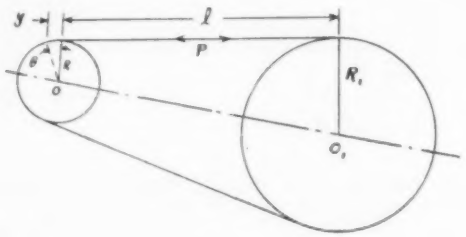

FIG. 8

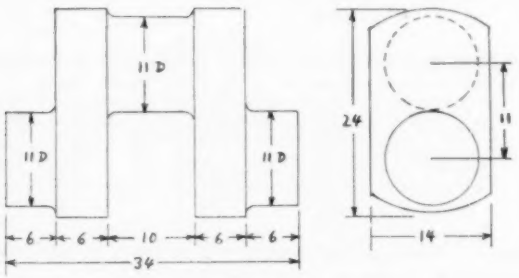

FIG. 9

which this can be carried before the accuracy is appreciably affected is illustrated by the curves in Fig. 16.

Another simplification of the equivalent system is obtained by spreading out a small concentrated mass occurring at the end of the engine opposite the flywheel so that the length of the uniform shaft representing the engine is increased by the inertia factor of the small concentrated mass divided by the value of J_w for the engine shaft. The limit to which this can be carried without appreciably affecting the accuracy is illustrated in Fig. 17.

In multi-cylinder engine installations considerable simplification is obtained by averaging the engine inertia values into a single uniform shaft instead of considering separately the inertia values at each cylinder as concentrated masses. To show that it is unnecessary to consider the engine masses by the longer concentrated-mass method to obtain accuracy, a comparison has been made of the results obtained by the two methods for the first frequency of an installation comprising an engine and flywheel. The results of the comparison are shown in Fig. 18. In an actual installation where the engine and flywheel are connected to other masses and shafts, the percentage differences in frequency will be smaller than the values given for frequencies with one node in the engine. For engines with four or more cylinders, the two methods give very little difference in frequency. For engines with two or three cylinders the frequency with one node in the engine is usually so high that noticeable critical speeds of this frequency are rarely met with in practice. Nevertheless since engines with a small number of cylinders usually have counterweights at each crank web, it seems probable that the actual installation is more like the uniform—shaft system than the system of concentrated masses. Even for the two-cylinder engine, however, the difference in this frequency from the two methods for the usual flywheel sizes will be less than two per cent. For the six-cylinder engine this difference is less than 0.5 per cent, and for a ten-cylinder engine it is less than 0.1 per cent for the usual flywheels.

In making the detailed calculations for the inertia and stiffness factors of the installation, the author has found the following working rules give reliable results.

Connecting Rod. If W is the weight of the rod and K is the distance of the center of mass of the rod from the crankpin center line divided by the connecting-rod length between the crankpin and wristpin center lines, then

Rotating part of connecting rod = $(1 - K)W$
Reciprocating part of connecting rod = KW

Reciprocating Mass. If W is the weight of the reciprocating masses and K is the radius of the crank divided by the length of the connecting rod, then

$$\left(\frac{1}{2} + \frac{K^2}{8}\right) W$$

considered as a rotating weight concentrated on the crankpin center line gives approximately the same effect as the reciprocating masses.

Geared Drives. If a mass having an inertia factor J is geared to a shaft such that the speed ratio of the mass to the shaft is h, then the inertia factor reduced to the shaft is h^2J.

Belt Drives. If a mass having an inertia factor J is belted to a shaft, it may be reduced to the shaft as follows:

In Fig. 8, let o_1 be the center of the shaft and o the center of the mass. Let R_1 be the pulley radius on the shaft and R the pulley radius attached to the mass. If a torque M acting on the mass causes a tension P on one side of the belt such that the stretch of the length l of the belt is y, then[8]

$$M = C\theta = C\frac{y}{R} = \frac{C}{R}\frac{Pl}{AE} = PR$$

where A = cross-sectional area of the belt and
E = modulus of elasticity in tension of the belt material.

Therefore

$$C = \frac{R^2AE}{l} \quad \ldots\ldots\ldots\ldots\ldots\ldots [23]$$

The modulus of elasticity for leather[9] varies between 35,500 and 71,000 lb. per sq. in.

If h is the pulley ratio R_1/R, let

$$\psi = \sqrt{\frac{h^2J}{C}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [24]$$

Hence the equivalent inertia factor at the shaft is

$$J' = h^2JT_0(\psi n) \quad \ldots\ldots\ldots\ldots\ldots\ldots [25]$$

Flexible Spokes. The effect of a heavy ring connected to a shaft by flexible spokes has been considered previously by the author.[10]

The stiffness factor for spokes with a uniform cross-section is

$$C = \frac{12NEIr}{l}\left(r + \frac{1}{3r} - 1\right) \quad \ldots\ldots\ldots\ldots [26]$$

[8] See p. 77, Holzer, loc. cit.
[9] Hütte, vol. I, 1925.
[10] Trans. A.S.M.E., 1928, Paper No. APM-50-14.

where N = number of spokes
E = modulus of elasticity in tension (lb. per sq. in.)
I = moment of inertia of the spoke section (in.^{4})
r = R/l where
R = outer radius of spokes (in.) and
l = length of spokes (in.)

If J is the inertia factor of the rim, and $\psi = \sqrt{J/C}$, then the equivalent inertia factor at the shaft is

$$J' = JT_v(\psi n) \quad [27]$$

Propeller. The inertia factor for a marine propeller is usually increased about 25 per cent to approximate the effect of the entrained water. For a rapid calculation the radius of gyration of a propeller of the usual design may be taken as 0.23 times the propeller diameter. It is of course better practice to calculate the actual inertia factor directly from a drawing of the propeller.

Crankshaft Stiffness. A crankshaft having the general proportions shown in Fig. 9 when turning in its bearings under operating conditions is about 3 per cent stiffer than a uniform shaft having the same length and the same section as the journal. For results of twisting tests on actual shafts refer to the author's previous paper (Trans. A.S.M.E., 1928, Paper No. APM-50-8, loc. cit.).

Changes in Shaft Diameter. When a shaft is composed of two uniform circular sections of different diameters such as shown in Fig. 10, the small diameter d effectively replaces D over the length λ in calculating the stiffness factor.

For D/d greater than 1.5, $\lambda = 0.1\ d$
For D/d between 1.5 and 1, λ is between 0.1 d and 0.
(Refer to Fig. 23, p. 48, Paper No. APM-50-8, loc. cit.)

Shrunk or Clamped Fits. For hubs or other members that are shrunk or clamped on a shaft, the shaft effectively enters the hub from 0.2 d to 0.5 d. The actual value of this effect will vary considerably even for installations that are supposed to be identical. For tightly shrunk-on members the factor may be taken as 0.2 d. For split hubs that are clamped on and keyed, an average value of 0.35 d may be taken.

Keyed Couplings. For keyed couplings that are merely "size and size," the shaft may be considered elastic halfway through the key length, with the limit that the increase in shaft length when considered in this manner shall not be more than one diameter of the shaft.

Flanged Couplings. In determining the elasticity of flanged couplings that are relatively short in an axial direction, the shaft may be considered to penetrate to a depth of one-half the axial length of the flange.

Short Flange. The stiffening effect of a short flange (having an axial length of less than $^1/_4\ d$) such as a thrust ring is assumed to be negligible.

Continuous Sleeve or Liner. In the case of a continuous bronze sleeve shrunk on a propeller shaft, etc., for a considerable length, the diameter of the shaft in calculating its effective stiffness in way of the sleeve is increased by the thickness of the sleeve, i.e., the radius of shaft increased by one-half the thickness of the sleeve. In considering the stiffening effect of sleeves of any length, and particularly shorter ones, two conditions should be recognized: (1) In new installations the sleeves, when carefully shrunk into place, are probably tight and do increase the stiffness of the shaft. (2) In old installations the sleeves may have worked themselves loose and do not increase the stiffness of the shaft. Thus both possibilities have to be considered.

Numerical Example. Consider a 6-cylinder, 2-cycle engine connected to a flywheel and alternator. The principal dimensions of the crankshaft are shown in Fig. 9.

Weight of piston and pin, complete, including cooling gear and oil = 1000 lb.

Weight of connecting rod, complete = 600 lb.

The center of gravity of the rod occurs at 0.38 times the center-line length of the rod from the crankpin center line. The crank-to-connecting-rod ratio = 1/5.

The formula for the inertia factor of the journals is that of a solid cylinder about its own center line; thus

$$\frac{ld^4}{36}\ [\text{lb-in.}^2] \quad [28]$$

where l is the length of the journal, d the diameter, and the weight of steel is taken as 0.2830 lb. per sq. in.

The formula for the inertia factor of the crankpin is that of a solid cylinder about an axis at a distance r from its own center line, thus

$$\frac{ld^2}{4.5}\left(\frac{d^2}{8} + r^2\right)\ [\text{lb-in.}^2] \quad [29]$$

where l is the length of the crankpin, d the diameter, and r the crank radius.

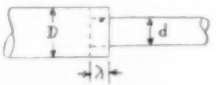

Fig. 10

A close approximation for the inertia factor for the webs of this crank may be obtained by considering each as a rectangular parallelopiped having the same width and thickness, and a height to give the same cross-sectional area. Thus the formula for the webs will be

$$\frac{bdh}{3.534}\left[\frac{b^2 + h^2}{12} + \left(\frac{r}{2}\right)^2\right]\ [\text{lb-in.}^2] \quad [30]$$

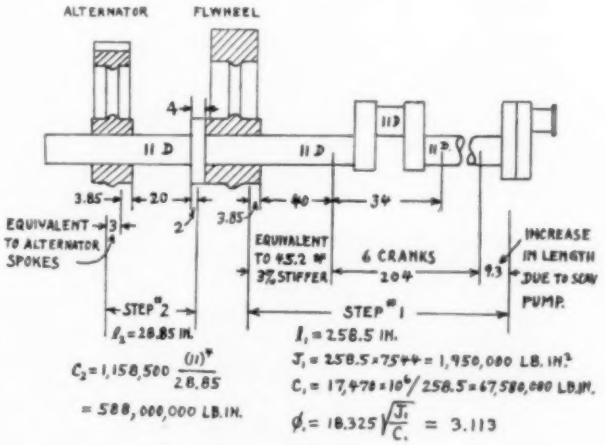

Fig. 11

where b is the breadth, d the thickness, and h the height of the equivalent rectangular section, and r is the crank radius.

Therefore the inertia factors are:

Journal: $12\ \dfrac{(11)^4}{36}$ = ... 4880 lb-in.^{2}

Pin: $10\ \dfrac{(11)^2}{4.5}\left[\dfrac{(11)^2}{8} + (11)^2\right]$ = ... 36,600

Two webs:

$$\frac{14 \times 12 \times 22.5}{3.534}\left[\frac{(14)^2 + (22.5)^2}{12} + (5.5)^2\right] = 94{,}950$$

Piston and connecting rod:

$$(11)^2[0.62 \times 600 + 0.5050(0.38 \times 600 + 1000)] = 120{,}050$$

Total inertia factor per cylinder = sum = 256,480

$$J_w = \frac{256{,}480}{34} = 7544 \text{ lb-in.}^2 \text{ per inch}$$

In engines that have counterweights and other attached rotating mass per cylinder, a careful calculation should be made for each part and added into the total.

Considering the crank 3 per cent stiffer than a uniform shaft having the same length and the same section as the journal, the value of Cl may be calculated from Equation [1]: thus

$$Cl = 1{,}158{,}500(11)^4 1.03 = 17{,}470 \times 10^6 \text{ lb-in.}^2$$

USING INTERPOLATION FORMULA "I TABLE 4 n = 36.31 V.P.S.

In the same way that the inertia factor for the crank was calculated, the total inertia factor for the scavenge pump including the shaft up to the center line of the first bearing is 70,000 lb-in.^{2} Therefore 70,000/7544 = 9.3 in. corresponds to the increase in length of the main cranks due to the scavenge pump.

The remainder of the calculations is shown in Fig 11 and the resulting equivalent system is shown in Fig. 12*a* where the alternator inertia factor is given as 5×10^6 lb-in.^{2} and the flywheel inertia is 8×10^6 lb-in.^{2} after making the deduction to make step No. 1 extend to the flywheel. For the first illustration the flywheel spokes will be assumed to be stiff.

The procedure in solving for the natural frequencies is as follows: Remove the flywheel J_{12} and obtain $C_1/C_2 = 0.1149$ and $J_{23}/J_1 = 2.564$. From the curves in Fig. 15, the value of $\phi_1 n$ is 94. Thus Table 5B will be used for the first frequency and the first assumed value of n will be 94/3.113 = 30. For the second frequency Table 5A will be used. The necessary calculations are given in Table 7.

The relative-amplitude curves for the first and second frequencies may then be obtained from Equations [16], [17], and [18]. Thus for $\theta''_{01} = 1$ deg., $\alpha_1 = 1$, and $\gamma_1 = 0$. For the first frequency,

$$\theta''_1 = \cos \frac{3.113 \times 29.67}{258.5} x = \cos 0.3573x$$

and $\theta''_{12}/\theta''_{02} = T_0(0.09221 \times 29.67) = T_0(2.736) = 4.269$

For the second frequency

$$\theta''_1 = \cos \frac{3.113 \times 44.07}{258.5} x = \cos 0.5307x$$

and $\theta''_{12}/\theta''_{02} = T_0(0.09221 \times 44.07) = T_0(4.064) = -1.4503$

These curves are shown in Fig. 12*b*.

If the flywheel were considered to have six flexible spokes with a mean elliptical section of 4 and 6$^3/_8$ in. minor and major diameters, with 74$^1/_4$ in. outside diameter and 15$^1/_4$ in. inside diameter, then in Equation [26], $N = 6$, $E = 15 \times 10^6$ lb. per sq. in. for good-grade cast iron, $I = \frac{\pi}{64} 4(6.625)^3 = 57.09$ in.^{4} $R = 37.125$ in., $l = 29.5$ in., $r = 1.2585$, so that

$$C = \frac{12 \times 6 \times 15 \times 10^6 \times 57.09 \times 1.2585}{29.5} \left(1.2585 + \frac{1}{3 \times 1.2585} - 1\right)$$

$= 1376.7 \times 10^6$

Thus $\psi = \sqrt{8/1376.7} = 0.07623$

Therefore $J_{12} = 8 \times 10^6 T_0(0.07623n)$

The frequency solution considering the flexibility of these spokes on the flywheel is given in Table 8.

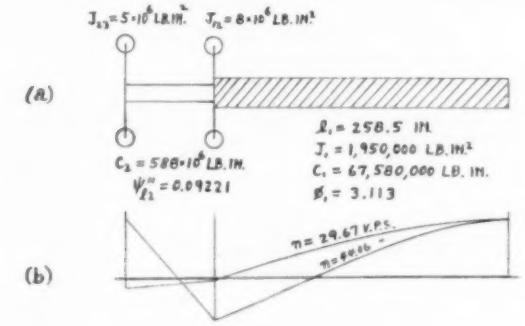

FIG. 12

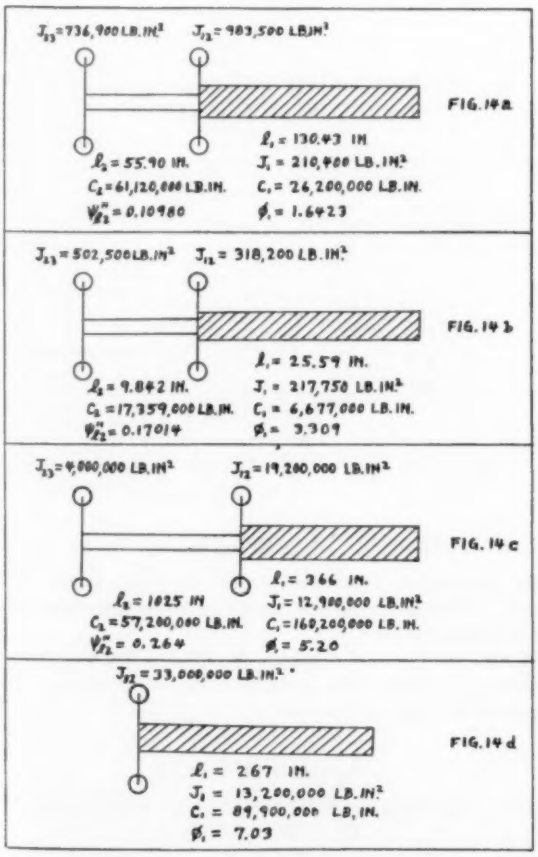

FIG. 14

Comparing the frequencies for the stiff flywheel spokes with those for the flexible ones described, it is seen that first frequency for the stiff spokes is 0.5 per cent and the second frequency is 21.4 per cent higher than the frequencies for the flexible spokes. Thus it is apparent that if the flywheel has flexible spokes it is important to consider their effect.

If a certain-sized engine with its flywheel is to be used in several different installations with various alternators and alternator shafts, curves such as shown in Fig. 13 may be drawn to give the natural frequencies of any likely combination. The curves in Fig. 13 were calculated by reducing the inertia factors to the beginning of step No. 2 for a number of frequencies by using Table 1C, and then solving for the value of the stiffness factor C_2 of the alternator shaft between the flywheel and alternator rim for the various values of the alternator inertia J_{12} by using Table 3A. Similar curves may be constructed to show the effect of different flywheels.

Appendix No. 1

SIMPLE PROOF FOR THE PRINCIPAL EQUATIONS USED IN THE SOLUTION

a Consider an irregular shaft system vibrating torsionally in simple harmonic motion. If a concentrated mass occurs at the beginning of the system having an inertia factor J_{01} and is connected to a section A (end of first step) by an elastic shaft having no mass, the twisting moment due to the inertia of the mass is

$$M = \frac{J_{01}}{g} \frac{d^2\theta_{01}}{dt^2}$$

or, since it is simple harmonic motion,

therefore, reference should be made to the original source indicated.

Fig. 14 gives four equivalent systems which have been rearranged into an equivalent system where the engine is represented by a uniform shaft with mass. The dimensions of the units have also been transformed into the inch-pound-second system. For each system references should be made as follows:

Fig. 14*a:* P. 34, Holzer, "Die Berechnung der Drehschwingungen," 1921

Fig. 14*b:* P. 20, Wydler, "Drehschwingungen in Kolbenmaschenenanlagen," 1922

Fig. 14*c:* P. 109, Purday, "Diesel Engine Design," Third Edition, 1928

Fig. 14*d:* P. 347, Purday.

Solution for Fig. 14a. Since $C_1/C_2 = 0.43$ and $J_{23}/J_1 = 3.5$, a reference to Fig. 15 shows that for the first frequency Table 5A should be used. For the second frequency Table 5B will be used. The solution is given in Table 9.

The results of this solution compared with those given by Holzer are: first frequency, the same; and second frequency, 0.84 per cent higher.

$$M = -\frac{J_{01}}{g} p^2 \theta_{01}$$

where $p = 2\pi n$.

The twisting moment in the shaft is

$$M = C_1(\theta_{11} - \theta_{01})$$

These two values of M must be equal for equilibrium, so that

$$\frac{\theta_{11}}{\theta_{01}} = 1 - \frac{J_{01}}{gC_1} p^2$$

If a concentrated mass is assumed to be placed at section A to give the same twisting moment at this section, it must have an inertia factor such that

$$M = \frac{J'_{11}}{g} \frac{d^2\theta_{11}}{dt^2} = -\frac{J'_{11}}{g} p^2\theta_{11} = C_1(\theta_{11} - \theta_{01}) = -\frac{J_{01}}{g} p^2\theta_{01}$$

Thus

$$\frac{J'_{11}}{J_{01}} = \frac{1}{1 - \frac{J_{01}}{gC_1} p^2} = \frac{\theta_{01}}{\theta_{11}}$$

b Consider the case similar to that just given except that the shaft is uniform and has mass.

For equilibrium, since the only external forces assumed to be in action are due to the inertia forces, it is necessary that the sum of all the twisting moments due to the inertia forces of the masses on one side of any section is equal to the internal resisting moment in the shaft.

The twisting moment due to the inertia of the mass at the beginning is

$$M_{01} = \frac{J_{01}}{g} \frac{d^2\theta_{01}}{dt^2} = -\frac{J_{01}}{g} p^2\theta_{01}$$

The resisting moment in the shaft at any section is

$$M_1 = C_1 l_1 \frac{d\theta_1}{dx}$$

Hence at any point in the shaft between the concentrated mass at the beginning and the section A,

$$\int_0^x -\frac{J_1}{gl_1} p^2\theta_1 dx - \frac{J_{01}}{g} p^2\theta_{01} = C_1 l_1 \frac{d\theta_1}{dx}$$

or differentiating with respect to x,

$$-\frac{J_1}{gl_1} p^2\theta_1 = C_1 l_1 \frac{d^2\theta_1}{dx^2}$$

$$\frac{d^2\theta_1}{dx^2} = -\frac{J_1 p^2}{gC_1 l_1^2} \theta_1$$

The general solution of this differential equation is

$$\theta_1 = a \cos\left(\sqrt{\frac{J_1}{gC_1}}\, p \frac{x}{l_1} + b\right)$$

where a and b are the constants of intergration and are evaluated by the end conditions. Since it is more convenient in performing numerical computations to deal with angles in degrees, the equation for θ_1 will be stated in degrees. In this way

$$\theta^\circ_1 = \alpha'_1 \cos\left(\phi_1 n \frac{x}{l_1} + \gamma'_1\right)$$

where $\phi_1 n = \dfrac{360\sqrt{J_1}}{\sqrt{gC_1}}$ n, α'_1 and γ'_1 are all angles in degrees.

Differentiating θ_1, and putting the result into M_1 gives the twisting moment in the shaft at any section. Putting $x = 0$ in M_1

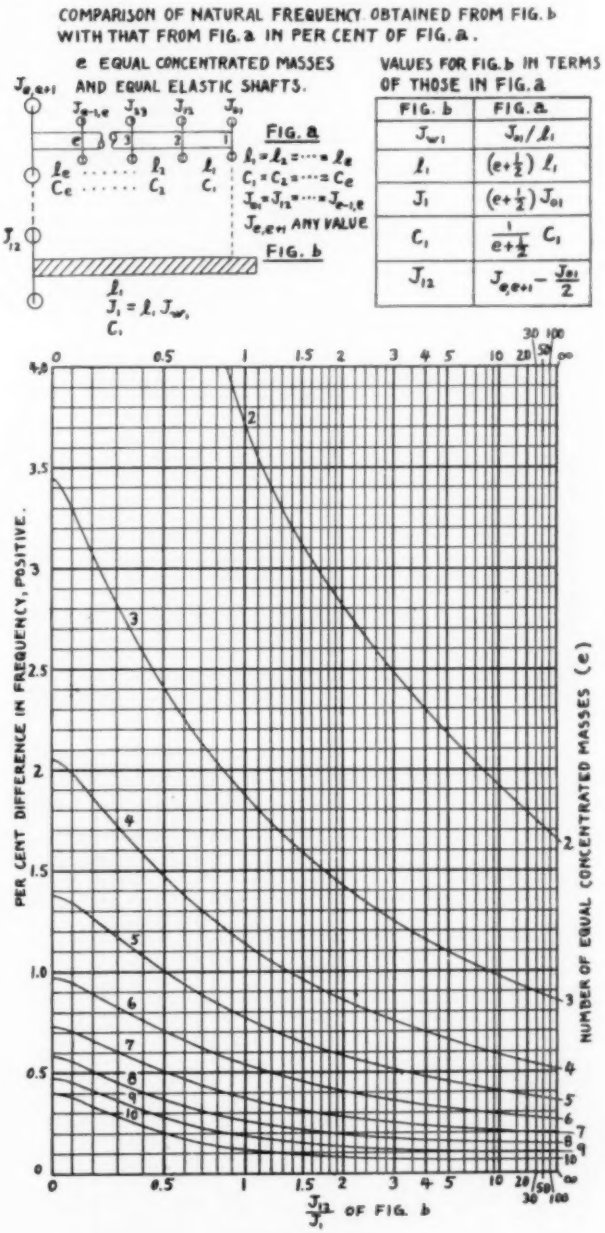

FIG. 18

gives M_{01}, which may be equated to the previous value for M_{01}. In this way it will be found that

$$\tan \gamma'_1 = \frac{\pi}{180} \phi_1 n \frac{J_{01}}{J_1}$$

If a concentrated mass is assumed to be placed at section A to give the same twisting moment at this section as stated by M_1 when $x = l_1$, it must have an inertia factor such that

$$M_{l1} = -\frac{J'_{l1}}{g} p^2\theta_{l1}$$

$\psi n/\lambda$	0	1	2	3	4	5	6	7	8	9	Ave D

For higher values of ψn, $T_e(\psi n) = \dfrac{9.775}{(\psi n)^2}$

Solving with M_1 where $x = l_1$, gives

$$\tan(\phi_1 n + \gamma'_1) = \frac{\pi}{180}\phi_1 n \frac{J'_{11}}{J_1}$$

In a similar manner the equations for reducing the masses back from the end of the vibrating system may be proved.

c In the above demonstrations a knowledge of the characteristics of simple harmonic motion has been assumed. In general simple harmonic motion is any motion such that the relation between displacement and time is of the following type:

$$y = a \cos pt$$

where a is the maximum displacement and $p = 2\pi n$. Differentiating y twice with respect to t gives

$$\frac{d^2y}{dt^2} = -ap^2 \cos pt = -p^2 y$$

Appendix No. 2

SOLUTION FOR INTERPOLATION FORMULAS OF TABLE 4

Formula No. 1.

Let h_1 and h_2 be ratios such that

$$n = n_2 + h_1 \Delta_1$$
$$= n_3 - h_2 \Delta_2$$

Then assuming that $h_1 = h_2 = h$, which is approximately true when n_1, n_2, n_3 do not diverge rapidly,

$$n_2 + h\Delta_1 = n_3 - h\Delta_2$$

Therefore
$$h = \frac{\Delta_2}{\Delta_1 + \Delta_2}$$

so that
$$n = n_2 + \frac{\Delta_1 \Delta_2}{\Delta_1 + \Delta_2}$$

Formula No. 2.

Let h_1 and h_2 be ratios such that

$$n = n_2 + h_1 \Delta_1$$
$$= n_4 - h_2 \Delta_2$$

Then assuming that $h_1 = h_2 = h$

$$n_2 + h\Delta_1 = n_4 - h\Delta_2$$

Therefore
$$h = \frac{n_4 - n_2}{\Delta_1 + \Delta_2}$$

so that
$$n = n_2 + \frac{(n_4 - n_2)\Delta_1}{\Delta_1 + \Delta_2}$$

Appendix No. 3

LIST OF THE MORE IMPORTANT SYMBOLS USED IN THE TEXT

- C = stiffness factor (lb-in./radian) of a shaft representing the proportional relationship of any twisting moment M (lb-in.) and the resulting angular deflection θ (radians) such that $M = C\theta$. Refer to Equation [1]
- e = step number for the end step
- g = gravitational constant, which is taken as 385.92 in./sec.^{2}
- G = shearing modulus of elasticity (lb. per sq. in.). For steel this is 11,800,000 lb. per sq. in.
- J = inertia factor or the weight polar moment of inertia of a mass (lb-in.^{2})
- J_s = sectional polar moment of inertia of the area of a shaft (in.^{4})
- J_w = weight polar moment of inertia per unit length of a step with mass (lb-in.^{2}/in.)
- k = number of a typical step
- l = length (in.)
- M = twisting moment (lb-in.)
- n = frequency of vibration in vibrations per second
- p = frequency constant—$2\pi n$
- t = time variable (seconds)
- $T(\phi n)$ = Defined by Equation [22]. Values of this expression corresponding to values of ϕn are listed in the tables. This function applies to a step with mass

$T_0(\psi n)$ = Defined by Equation [21]. Values of this expression corresponding to values of ψn are listed in the tables. This function applies to a step without mass

x = length variable (inches)

α = constant in degrees. This constant is defined by Equation [18]

γ = constant in degrees. This constant is defined by Equations [9] and [12]

θ = amplitude of vibration in radians

$\theta°$ = amplitude of vibration in degrees

ϕ = constant for steps having mass. Defined by Equation [4]

ψ = a constant defined by Equations [5] and [6].

Subscripts are used with the various symbols and have the following meaning. A single subscript means that the value applies to the step having the number of the subscript. If the subscript is made up of two figures, the element applies to a certain section. These sections are designated thus:

01, 12; 23 ... between the steps whose numbers are included

01, 02, 03 ... beginning of the step whose number is given

*l*1, *l*2, *l*3 ... end of the step whose number is given

A prime mark (′) means that the masses are being reduced from the beginning.

A double-prime mark (″) means that the masses are being reduced back from the end.

Discussion

MERVIN B. HOGAN.[11] The problem of torsional vibration is one of great importance in the field of internal-combustion-engine theory. This type of prime mover is now so general and found in so many applications that it is essential that engineers be familiar with the peculiarities of systems of which it is a component part. All the present-day trends in the application and design of these engines have been conducive to torsional-vibration difficulties. The tendencies are toward higher speeds and a greater number of cylinders. The higher speeds have increased the possibility of torsional vibration by raising the running speeds up into the region of critical speeds. On the other hand, it is a well-known fact that, for a given system, an increase in mass or flexibility will lower the natural frequency. As a consequence, the increase in the number of cylinders increased the mass, and the longer crankshaft, which necessarily resulted, increased the flexibility, so that the resultant effect was a lowering of the critical speeds.

[11] Power Engineering Department, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

In this and in his two preceding papers Mr. Porter has made a praiseworthy contribution to the literature of the subject in the English language. The mathematical theory of the subject has been developed to a nice degree and the practical application of the results has been pointed out. The problem here presented is that of reducing involved systems to simpler systems to which known solutions at hand can be applied.

The necessity of some such method is quite apparent. It is theoretically possible to establish relations between the natural frequencies and the physical properties of any system, expressing the former as a function of the latter. However, such equations are extremely complicated for systems of more than three masses, and the degree becomes of such order that a mathematician is required to undertake the solution. Even with a correct solution the probability of error in a numerical calculation is very high, and the labor required makes such exact solutions impractical in engineering.

The theory of the method here presented is very interesting. It seems that it would be advantageous in design work where many applications of Diesel engines to systems of approximately the same magnitude and arrangement are encountered. In such cases the routine calculation of critical speeds would be expedited. It is well to mention, though, that the time required for the actual calculation of the critical speeds is small compared to the time necessary to calculate the moments of inertia, flexibilities, and the other physical constants of the system. Consequently, the advantage in the saving of time or labor is slight.

A disadvantage of the method follows directly from the reduction method itself. To one who does not already possess an understanding of this phenomenon the reducing of the system to different forms merely introduces another complication which obscures the physical picture. Again, in order to carry out the calculations, the tables and data of the paper must be on hand. It is a disadvantage to be familiar with only one such method as there are times when these calculations must be made and the tables are not available. Sometimes it is desirable to have the relative angular displacements of the various masses, i.e., the so-called elastic curve. With this method another calculation must be made in order to determine it.

The writer is well acquainted with Holzer's method of calculation, having employed it in his work now for several years. As a consequence he naturally thinks of torsional vibration in terms of this method and compares other methods with it.

One of the best reasons for the use of Holzer's method is that it aids the engineer in getting a clear mental picture of the phenomenon. When idealized, each mass of the system is represented by a uniform circular mass, and the respective shaft flexibilities are indicated as elastic shafts without mass. It is then obvious that at a natural frequency the sum of the inertia torques of the system must be zero. As a result, after the engineer has arrived at his "concentrated mass system" he sees physically what each step of the calculation achieves. This is extremely valuable because as he gains experience his judgment enables him to prevent any numerical errors that may tend to creep in.

The actual operation of calculating numerically the natural frequencies by Holzer's method identifies it as essentially an engineering tool. The tabular method lends itself admirably to slide-rule calculation with accuracy of the results within the accuracy of the known constants. After the equivalent system has been calculated it takes but a short time to carry out the tabulated calculations for each frequency.

The disadvantage of the method is that, for each natural frequency, a cut-and-try method must be resorted to in order to determine the value. A value of the natural frequency which is very nearly correct may be obtained by considering the system

as one of three masses composed, say, of generator, flywheel, and engine. The values of the first and second natural frequencies are then obtained from the solution of the well-known biquadratic equation for a three-mass system. The numerical value as thus obtained for the lowest frequency is usually very close to the exact value, while that for the second is generally in error. Ordinarily these are the only frequencies of interest, as higher ones are sufficiently above the running speed to be of no concern.

Having made the calculation by this method, no special calculations are necessary in order to draw the relative displacement or elastic curve. This curve, for both frequencies, is readily plotted from the values of angular displacement which one of the columns of the tabulated calculations contains.

The matter of spoke flexibility is one of great importance, especially with the usual arrangement of generator, flywheel, and engine. In the case of fabricated synchronous generators where the arms are H-beams, the flexibility of the rotor is of much greater importance than that of the flywheel. This type of construction lends itself nicely to analytical treatment, however, so that its flexibility can be calculated much more accurately than can that of ordinary flywheels.

With the arrangement referred to, the node in the first critical speed ordinarily is at the flywheel. In such a case the flywheel flexibility does not influence the value of critical speed theoretically, and but slightly practically. The generator flexibility, however, is of the same order as that of the shafting between it and the flywheel. Since the frequency of this section of the system is the same as that of the whole system, the importance of the rotor flexibility is obvious. In many cases the error introduced by assuming the generator as a rigid mass is in the neighborhood of 30 to 40 per cent; that is, the critical speed as calculated will be far too high. A design approved on such a calculation usually results in trouble as the critical speed will be in the running range.

The engineer who starts to study the torsional-vibration problem finds that the theoretical field has been developed extensively. As is the case with many other problems the chief trouble comes in the practical application. Such questions as the effect of flanges, sharp changes in shaft sections, keyways, press fits, and other types of mechanical construction upon the flexibility of the system are matters which only experience can settle. Such judgment can be developed only by extensive calculations of units whose critical speeds can be observed.

From the standpoint of the Diesel engine itself, the major problem is that of the crankshaft flexibility. It is indeed an extremely rare occasion when the engine builder can supply the measured value of this characteristic. There are several well-known formulas which aim to bridge this difficulty for the engineer by enabling him to calculate the constant from the known crankshaft dimensions. Some of the most generally used are those of Geiger, Hort, Timoshenko, and Carter. These all have certain objectionable features. The first mentioned, that of Geiger, involves a constant which must be obtained experimentally. If it is possible to make such a test the formula ceases to be necessary. In any case a great deal of experimental data must be on hand in order to apply the formula to new crankshaft designs. Hort's expression is too simple to give sufficiently accurate results for most investigations. Dr. Timoshenko's work is based upon a rational analytical foundation, with the result that it is very complicated. The difficulty of such a problem is obvious as there are the effects of bearing constraint, bending, etc., which cannot be accurately considered. Carter's formula is really empirical, although derived with some rational foundation. Its advantage is that it is simple, involving only the dimensions of the crankshaft, and readily evaluated numerically. Tests have proved it to be sufficiently accurate for engineering calculations, especially in the Diesel-engine field. The writer feels that this formula is the best for this use that has yet been published.

H. WYDLER.[12] The author's work supplements the collection of methods for calculating natural frequencies of torsional vibrations by a further quite unique scheme. This should be welcomed, not so much because the calculations become shorter and simpler, but because it seems that we are presented here, again, with an accomplishment borne out of a superior command of the matter.

The beauty of the method is decidedly to be seen in the fact that it replaces the given system of many masses by a model system which is a far closer approximation to the actual mass distribution than any other simplification could produce, and, further, that it settles the calculation for this model system quickly and correctly within a few calculation steps. Fig. 18, for instance, shows that for a six-cylinder engine plant the natural frequencies of a combination-shaft system differ mostly less than $^1/_2$ per cent from that of the corresponding concentrated-mass system.

As to the simplicity of the matter it is felt that it will appeal more to men who are already familiar with the subject. Since the method necessitates the use of different charts and tables during the calculation process, it may require some practice before the calculation results obtained can be relied upon to be correct. However, the writer thinks that, for engineers who are used to other methods, it may pay them to get acquainted with Mr. Porter's work, even if it were only for checking calculation results obtained from other methods.

The writer would like to add another suggestion. The first elaborate scheme for calculating forced vibrations was presented in Holzer's book. Two articles published during this year by F. Neugebauer (*Technische Mechanik und Thermodynamik*, May, 1930, pp. 147 and 184) and M. Vollmar (*T. M. & T.*, Nov., 1930, p. 382) have also done fine pioneering work. It would be one of the most gratifying steps ahead to obtain complete theoretical control of the actual movements of elastic systems if these rather extensive calculations could be shortened. In the writer's book, on page 78 and following, he undertook to combine harmonics into two groups of forces and to follow the calculation through for the system thus simplified. He wonders if Mr. Porter could not amplify his method also in this direction. It is thought that the community of vibration specialists would appreciate this as a very welcome help in their work.

F. J. GEITTMAN.[13] The writer has been using the method outlined in the paper for the past year in the calculation of the natural frequencies of torsional vibration of Diesel installations. Some 200 installations have been calculated, of which more than 30 were tested with the Geiger torsiograph.

Every instance of a discrepancy larger than that of experimental error has been traced directly to the improper consideration of certain factors, such as the stiffness of flexible couplings, whose stiffness factors were unknown or subject to change in operation.

One of the outstanding features of the method developed by the author is its simplicity. The arithmetical operations involved are rarely more than 20 to 30 operations for a complete calculation. The possibility for error is practically eliminated by rechecking the calculation, and since there are relatively few operations, this does not require a great deal of time.

---

[12] Combustion Utilities Corporation, New York, N. Y.

[13] Design Calculation Work, Fairbanks Morse & Co., Beloit, Wis. Jun. A.S.M.E.

A few examples of the agreement between the actual and calculated frequencies that the writer has observed are given below:

Engine	Actual frequency v.p.m.	Calculated frequency, v.p.m.
8-Cylinder 16 × 20	1680	1696
5-Cylinder 14 × 17	1984	1960
6-Cylinder $8^3/_4 \times 10^1/_2$	3660	3690
3-Cylinder 14 × 17	2493	2520
4-Cylinder 14 × 17	1224	1228

When a new installation is being designed, the simplicity of the method makes it easy to determine the best design of the shafting or masses to give a desired location of the critical speeds. This calculation may be done by a direct solution, thus eliminating the cut-and-try methods which consume so much time.

Another advantage is the ease with which curves of reduced mass or extension-shaft stiffness may be calculated. In "long" installations consisting of the basic engine and flywheel with more than one power takeoff, there is frequently more than one frequency having dangerous harmonics near or in the operating range. By reducing the masses from the end to the flywheel and the masses from the beginning through the flywheel for every frequency from, say, 10 vibrations per second to 60 vibrations per second at intervals of 5 vibrations per second, and plotting both values on the same curve sheet with vibrations per second as abscissas and reduced mass as ordinates, every intersection of the curves represents a natural frequency. In this way none of the natural frequencies that will cause a dangerous vibration near or in the operating speed will be missed.

Work of this type is greatly simplified by the tables published with the paper, which are in a way comparable to the trigonometry tables, although necessarily a bit more complicated since more variables are involved. A calculation such as mentioned would be a very long and tedious job with any method not employing a simplification such as that represented by the tables.

BERNHARD H. ANDERSON.[14] The methods for calculation of natural frequencies described in this paper have undoubtedly a decided advantage over any other methods published on this subject, and the paper is indeed a valuable contribution to engineers working on torsional vibration problems.

The importance of this problem varies of course with the type and construction of the engines.

For some types of engines a torsional-vibration calculation has to be made for almost every new installation to assure a successful operation, while other types only need to be given consideration if the installations are much out of the ordinary.

For a four-cycle engine, of the trunk-piston type and of moderate speed, for instance, it is rather a simple matter to design the crankshaft so as to bring the dangerous criticals above the working range for regular marine and generating purposes. The experience of the company that the writer represents is that the additional cost caused by increasing the size of the crankshaft for this purpose is a good investment.

However, with the tendency of increasing speed for Diesel engines there is a growing need for a simple and rapid way of solving the problem of torsional vibration for commercial purpose, and whenever a tabulation of the natural frequency has to be made, the accuracy of the method applied is of prime importance. For this reason most of the short approximate methods in existence are more or less without value.

The simplification of the methods is only justified if it can be obtained without sacrificing accuracy, and after having made an investigation of the methods given in this paper the writer feels certain that this result has been accomplished by the author.

The writer has applied these methods on a number of installations and in order to investigate the reliability, the results of the calculations have been compared with the natural frequencies arrived at by the Holzer or "Concentrated Mass Method," the accuracy of which is recognized, and proved to give very reliable results for general application on Diesel installation. The installations investigated are:

(1) Six-cylinder 18 × 22 in., engine, flywheel, generator (regular generating installation).

(2) Eight-cylinder 16 × 20 in., engine and heavy flywheel (special marine engine connected to water brake on test in shop).

(3) Six-cylinder 14 × 18 in., engine, flywheel, generator (regular generating installation).

(4) Eight-cylinder 11 × 14 in., engine, combined clutch and flywheel, propeller and generator driven through forward extension shaft (special marine installation for trawler).

(5) Eight-cylinder 9 × 12 in., engine, flywheel, propeller (regular marine installation).

The results in natural-frequency v.p.s. are:

Installation	Porter method	Holzer method	Difference in per cent
1	42.634	42.572	0.145
2	38.990	38.970	0.052
3	54.910	54.870	0.073
4	25.295	25.300	0.000
5	35.600	35.600	0.000

It is interesting to note that the differences in frequencies calculated by the two methods are all smaller than the values given for "per cent error" on the charts of Figs. 16 and 18 of the paper, which they essentially should be, because any mass added to the systems shown on these charts will tend to reduce the error made by using the short method instead of the concentrated-mass method.

The slightly larger values of the frequencies calculated by the Porter method are also in accordance with the charts; that is, the errors read from the curves for the installations considered will be found to be positive.

The only conclusion to be drawn from this investigation is that the difference in natural frequency as obtained by the Porter method and the Holzer method is negligible, and so far as accuracy is concerned, either one of these two methods may be applied.

To calculate the natural frequency by the Holzer method, or by accurate methods given by other investigators (analytical or graphical), is always a laborous undertaking with a tedious procedure of "trial and error." A great saving of time by using the Porter method was very soon apparent, and the simplicity in application is distinctively emphasized by comparing the work involved in solving this problem by the different methods, and furthermore, as there are only a few arithmetical operations involved in the tabulation by the Porter method, the chances to make errors are considerably reduced.

PHILIP MALLOZZI.[15] The paper adds a very valuable method of determining the frequency of any complicated shaft arrangement when in the design stage. The writer would like to call attention to some of the relatively complicated installations found in submarines, as shown by the sketch in Fig. 19. It

[14] Diesel Division, Cooper-Bessemer Corporation, Grove City, Pa. Assoc-Mem. A.S.M.E.

[15] Assistant Mechanical Engineer, U. S. Navy Yard, Brooklyn, N. Y. Mem. A.S.M.E.

will be noted that a heavy motor armature is connected to the engine and flywheel by a length of shaft, and the propeller is connected to the motor armature by a very long shaft.

In an installation of this kind, items such as flywheel, motor armature, propeller, and their connecting shafts may be so chosen as to place the critical speeds above or below the operating range or some of the orders of vibration may be grouped at speeds where operation is not necessary.

The object of the computer is to find the items which give a change in frequency by relatively small changes in dimensions or masses. A family of curves showing the effect on shaft frequency of changes in masses and elasticities is of great assistance in picturing the effect of such changes. The author's method gives an easy and rapid means of constructing such a family of curves.

If the uniform shaft system is used, the solution becomes

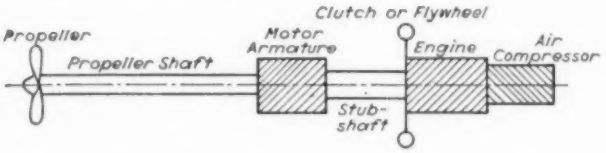

FIG. 19 TYPICAL SUBMARINE SHAFT LINE-UP

laborious because of the trigonometric equations involved. If the concentrated mass system is used, a great amount of numerical computation is required.

By using the author's method the reduction from either side of the shaft line-up is carried out more or less mechanically by the use of tables and charts or by a simple formula. This reduces the labor and chance of error.
